#### NATIVE WILD FODDER PLANTS OTHER THAN GRAMINEAE: —

*Trigonella suavissima*, sweet fenugreek; *Erodium cynorhizon*, blue Erodium; *Geranium dissectum*, cut-leaved geranium; *Lavatera plebeia*, austral holly-hock; *Daucus brachiatus*, austral carrot; *Plantago varia*, variable plantain; *Lotus corniculatus*, birdsfoot trefoil.

#### EXOTIC FODDER PLANTS NATURALISED IN VICTORIA: —

GRAMINEAE: — There are about 95 species, many of which are widely cultivated. The best are: —

*Dactylis glomerata*; *Lolium perenne*; *Poa pratensis*; *Bromus unioloides*; *Sorghum halepense*; *Phleum pratense*; *Festuca elatior*; *Alopecurus pratensis*; *Cynosurus cristatus* (drought-resistant); *Anthoxanthum odoratum*; *Trisetum pratense*; *Paspalum dilatatum*; *Eragrostis alba*; *Milium effusum* (the two last for damp soils).

*Ammophila arundinacea* and *Elymus arenarius* are very useful for fixing sand; both are refused by stock, but are excellent for thatching.

ACCLIMATISED LEGUMINEAE AND FODDER PLANTS OF OTHER FAMILIES: —

*Trifolium repens*; *T. hybridum*; *P. pratense*; *T. fragiferum*; *T. resupinatum*; *T. subterraneum*; *T. tomentosum*; *T. glomeratum*; *T. incarnatum*; *T. minus*; *T. parviflorum*; *T. procumbens*; *T. striatum*; *Medicago sativa*; *M. tribuloides*; *M. maculata*; *M. denticulata*; *M. orbicularis*; *M. scutellata*; *M. lupulina*; *Melilotus alba*; *M. parviflora*; *Poterium Sanguisorba*; *Plantago lanceolata*; *Vicia sativa*; *Anthyllis vulneraria*; *Onobrychis sativa*; *Trigonella ornithopoides*.

418 — **Bokkara or Sweet Clover (*Melilotus alba*) in New South Wales.** — BREAKWELL, E., in *The Agricultural Gazette of New South Wales*, Vol. XXVIII, Pt. 10, pp. 731-734, 1 fig. Sydney, October, 1917.

The fact that Bokkara or sweet clover (*Melilotus alba*) is one of the most widely cultivated fodder plants in the United States, lead to cultivation experiments being made with it in New South Wales, on the Glen Innes and Yanco farms. It is generally a biennial plant, but, in the two districts mentioned it flowered to a small extent during the first year, and seeded heavily during the second. The abundant flowers are very attractive to bees, which give a large yield with it.

TRIALS AT GLEN INNES. — Sweet clover, sown on September 10, 1915, in rows 2 ½ ft. apart on 1/10 acre, germinated well (75 %) and made good growth during the dry spring and the summer. The main stem was not very high, but the secondary ones were numerous and long. From the first year the spaces between the lines were completely filled, and there was a profuse yield of tender, but bitter, fodder. The winter frosts destroyed the aerial parts of the plants, but they grew again strongly in Spring. On November 20 the plants were 3 ft. high, on January 20, from 7 to 8 ft. high, and were setting seed well. The ripe plants are woody, and they should be grazed or cut for hay when still young. Horses, cattle and sheep will not eat it green.

TRIALS AT YANCO. — Comparative trials were made with American seed and seed bought in Australia. The first gave 6.4 times more green fodder than the other. Both are deep-rooters.

The advantages of sweet clover are: — it is excellent for bees; it eradicates weeds; it is a good green manure; it prepares the soil for lucerne by breaking it to a great depth with its roots and enriching it with the nodule bacteria essential to the growth of lucerne. Its disadvantage lies in the coumarin it contains, which gives it a bitter, unappetising taste. Opinion on this subject is contradictory, and it appears that animals eventually become accustomed to it and eat it willingly.

FIBRE CROPS

419 — **The Selection of Kumpta Cotton in India.** — KOTTUR, G. I., in *Department of Agriculture, Bombay, Bulletin* No. 84, pp. 1-2. Poona, 1917.

Practical advice on the choice of stock plants of the "Kumpta" variety is given. The plants should have the following qualities: — 1) well-developed stem with many internodes; 2) high ginning percentage; 3) pods with long, fine, strong staple. The plants in which the capsules open prematurely should be removed as they give only little lint of low quality.

The seed thus obtained should be sown in lines, all the seeds of one plant in one line. At the time of harvest the seed from the best line may be distributed as selected seed. These simple methods, which may be adopted by all growers, have already given appreciable results, as is seen below: —

	Yield per acre		Ginning per cent	Value per candy *
	Kapas	Clean cotton		
	lbs.	lbs.		
"Kumpta" unselected . . .	564	148	26.2	335 rupees **
"Kumpta" selected . . .	612	171	28.0	350 "

\* 1 candy = 784 lbs. — \*\* 1 silver rupee = 1s. 4d. at par.

It is seen that selected cotton is superior to unselected cotton both in yield and the quality of the product.

420 — **Ambari or Deccan Hemp, *Hibiscus Cannabinus* L., in South Africa.** — POLE-EVANS, I. B., in *The South African Journal of Industries*, Vol. I, No. 3, pp. 198-208, 6 Plates. Pretoria, November, 1917.

*Hibiscus cannabinus* L., known in the British colonies as Ambari Hemp, Deccan Hemp, Gambo Hemp and Bimlipatam Hemp, is called in South Africa "the wild stock rose" (1). Up to the present it has been practically unknown in this district as a fibre plant.

The importance of the cultivation of this plant is pointed out, and the attention of farmers and merchants in particular is drawn to it. The botanical and cultural characteristics of the plant are described, and stress laid on the value and industrial use of the fibre. The results are also given of an examination made by the Imperial Institute of samples of *Hibiscus cannabinus* fibre grown in the Transvaal, and these results show it to be of good quality.

The extraction of the fibre has been studied in the Botanical Laboratories, Pretoria, and it has been shown that there would be no difficulty in retting it under South African conditions. The length of time required for immersion in water of a temperature varying from 18 to 26° C. is from 10 to 14 days. A 10.7 to 11.9% yield of fibre of excellent quality has been obtained.

Before *Hibiscus cannabinus* can be recommended to growers for cultivation it is necessary to make a further study of the plant and its fibre, to investigate the questions of a market for it in South Africa, of the profit the grower may realise, and the best varieties to be grown, both as regards yield and the quality of the fibre. Such a study would require at least five years and careful investigation both in the field and in the laboratory. *Hibiscus cannabinus* does well in many parts of South Africa, and there appears no reason why it should not give as good results there as in India.

(1) It is the "da", or "dâh", of French West Africa. (Ed.)

OIL-YIELDING  
CROPS

421 - Contribution to the Chemical Study of the Nuts of "Sanga-sanga" or *Ricinodendron africanum*. — PIERAERTS, in the *Annales du Musée colonial de Marseille*, Year XXV, Series, 3, Vol. V, pp. 27-37. Paris, Marseilles, 1917.

The author (Keeper of the Belgian Congo Museum) has made a chemical study of the nuts of *Ricinodendron africanum* Mull. Arg. (fam. Euphorbiaceae), sent to him from Ganda-Sundi (Lower Congo). *R. africanum* is known as "sanga-sanga" in that country, "essang", "enguessang" or "issanguila" in the French Congo and Gabon, and "usa sana" in the other countries of west equatorial Africa. It is a tree some 80 to 100 feet high and 10 feet round, with very spongy wood of poor quality, not even good enough for heating. Its nuts are about the size of a hazel-nut and weigh from 1.250 to 2.400 gm; with its extremely hard, black shell it will keep a long time.

The nut has a very wrinkled surface, and is composed of: — 1) the shell (endocarp), very hard, black outside and milky white inside; 2) the kernel (really the seed), completely filling the shell in sound specimens. The unsorted nuts give 72 % of shell and 28 % of kernel. The kernel gives:

Moisture . . . . .	17.64 %
Dry matter . . . . .	82.36 %
Total mineral matter . . . . .	7.32 % of the dry matter
Total mineral matter insoluble in water . . . . .	6.70 % of the dry matter

That is, 91.53% of the total ash for the last two.

On extraction with anhydrous ether, the kernel gives 55.29 % of oil (i. e., 67.3 % of the dry matter), which corresponds to a content of 18.52 % for sorted nuts and 15.48 % for unsorted nuts. The oil extracted is limpid, pale yellow, and of a sweet flavour, leaving an earthy taste; it has no special odour. It has the following characteristics: —

Specific weight at $\frac{15^{\circ}}{15^{\circ}}$ . . . . .	0.9345
Critical temperature of solution in absolute alcohol . . . . .	90.2°
Refractive index at 19.5° . . . . .	1.5028
Polarimetric test . . . . .	$\alpha_D = + 0.04^{\circ}$
Acid index . . . . .	0.86
(calculated as oleic acid, it is 0.43 %).	
Mauméné test . . . . .	79°
Bromides insoluble in ether . . . . .	nil.
Insoluble and unsaponifiable fatty acids . . . . .	98.85 %
Glycerine . . . . .	9.77 %
Saponification index . . . . .	194.4
Elaidin test (very viscous, brownishyellow mass)	
Melting point . . . . .	32.3° to 34.5°C.
Saponification point (the melted acids remain in fusion at laboratory temperature (20°C) and only resolidify after two hours).	

The action of the air (and possibly of light as well), on "sanga-sanga" oil constitutes, as regards the drying properties, a complex chemical problem. As regards the action of iodine, the oil dissolved in chloroform, used for the polarimetric examination, was poured, while continually shaking, into an equal volume of a saturated solution of iodine in chloroform;

after a few moments the mixture set in a gelatinous mass of such a consistency that it did not flow on inverting the beaker.

The refractive index of the oil is higher than that of any other vegetable oil known, save abrasin oil. "Sanga-sanga" oil is a drying oil; it seems more drying than linseed, as it solidifies much more quickly. It might well be used for waterproofing, as a mastic for caulking ship's hulls or other objects having joints needing stopping up, and as mortar or lamp oil.

The kernel cake has an exceptionally high nitrogen content; its phosphoric acid content is also very high. This cake would be excellent as a fertiliser for nurseries, gardens, etc. If it proves to contain no toxic matter, it would provide a first class food for live stock and poultry.

422 - **Commercial Onion Growing in Indiana.** — SAYRE, C. B. (under the direction of WOODBURY, C. G.), in *Purdue University Agricultural Experiment Station, Circular No. 57*, pp. 27, 12 Fig. Lafayette, Ind., September, 1916.

HORTICULTURE

Onions are grown very extensively on the peat or muck soils of northern Indiana, the crop of 1914 amounting to 2 210 325 bushels.

Good drainage is an important factor in selecting muck soil for profitable onion growing. The soil should be well prepared before planting; many growers prefer to prepare the land in autumn. Rolling is of great value.

Potash is the element most deficient in the non-acid muck soils, and muriate of potash applied at the rate of 200 to 400 pounds per acre will give a very profitable increase in yield with normal prices. Acid phosphate at the rate of 300 to 400 pounds per acre can usually be applied profitably to the muck soil for onions. The acid muck soils are especially deficient in phosphorus, and larger amounts should be applied to them. Nitrate fertilizers can seldom be applied with profit to the muck soils. Lime cannot be applied with profit except to the acid muck soils. Manure is the best all around fertilizer for onions, but under normal conditions chemical fertilizers can be applied most economically to the muck soils. The manure should be well rotted.

The great bulk of the onions grown on the Indiana muck soils are for autumn and winter use, and for this purpose the yellow globe type is the most commonly grown, although the red globe varieties are also very popular. the white varieties are grown principally for pickling. Of the yellow type there are several varieties which are commonly grown. The Southport yellow globe is the most popular yellow variety, while the Ohio yellow globe and yellow globe Danvers are grown to a lesser extent. Of the red varieties, the Southport red globe is most popular, and the Red Wethersfield and Ohio red globe are also grown. Of the white varieties, the Southport white globe is preferred for large, mature white onions, while the white Portugal and Silver Skin are popular varieties for pickling.

Onion seed should be sown in rows 12 to 14 inches apart at the rate of 3 ½ to 4 lb. per acre as early in the spring as the ground can be worked. Frequent cultivation with wheel hoes, and two or three hand weedings are necessary. The onions are harvested about September 1. The best growers average over 500 bushels per acre, which sell at an average of 40 cents per

bushel. It costs about \$75.00 to produce an acre of onions. A large part of the Indiana crop is stored.

Onion sets and pickling onions are grown extensively in Lake county. The culture is similar to that of large onions, except that the small onions are produced by thick seeding (50 to 80 lb. per acre). Onion seed is grown successfully by some of the large growers of Indiana.

There are three insect pests, namely thrips, maggots and cutworms, which sometimes cause considerable loss to the onion growers in northern Indiana.

The onion thrips (*Thrips tabaci*) chafes off the epidermis of the leaves, principally at their base, producing yellowish, gray irregular spots on the leaves, later causing the entire leaf to dry up and die. In order to spray onion thrips successfully, high pressure (at least 100 lb.) and a fine mist-like spray which can be directed into the base of the onion leaves are necessary. A gasoline outfit or good hand pump outfit equipped with a long line of hose and extension rod is the most satisfactory type that has been used thus far. The following spray material is very efficient if it comes in actual contact with the insect:— concentrated nicotine sulphate, 5 oz.; whale oil soap, 4 lb; water, 50 gals. The spray should be applied when the thrips first appear and the onions are small and easily sprayed. It will probably have to be repeated 2 or 3 times at intervals of 10 days in order to destroy succeeding generations as they hatch.

The onion fly (*Phorbia ceparum*) lays its eggs in the sheath of the onion when the plants are very small. The eggs hatch in about 10 days and the maggots burrow into the bulbs of the onion, causing the loss of the plant. Sometimes whole fields are thus ruined. A second and sometimes a third brood appears later in the season. Field hygiene is especially important in controlling onion maggots. A new method of control devised at the Wisconsin Experiment Station, is claimed to give excellent results. This treatment, called the "poison bait spray", destroys the flies which lay the eggs. It is used as follows:— as soon as the onion seedlings appear, the first spray should be applied, and it should be repeated at intervals of 5 days or a week during the period when the flies are present. The spray consists of one ounce of sodium arsenite, 2 1/2 quarts of New Orleans molasses and 5 gals. of water. The arsenite should be dissolved in boiling water and the molasses added and thoroughly mixed. This bait must be applied, by means of a whisk broom or of a spray outfit with a coarse nozzle, in large drops along the rows so that the flies can drink it. After onions have become infested with maggots, there is nothing that will remedy the difficulty that season, but infected plants should be promptly removed and burned in order to reduce the number of insects that will appear the following season, and then the poisoned bait applied in time to destroy the flies before they can lay their eggs.

Cutworms cut off the young plants at the surface of the ground. They can be controlled by the use of poisoned bait prepared as follows:— Mix 50 lb. of wheat bran or middlings, 2 lb. of Paris green and 6 finely chopped oranges or lemons. Then add enough cheap molasses and a little water to

make a stiff dough. In the late afternoon, as cutworms feed principally at night, scatter lumps of this mixture about the size of a marble around the infested areas.

As a general rule the onion growers in northern Indiana have suffered comparatively little loss from diseases of onions. Onion mildew (*Peronospora Schleideni*) is the most serious disease and may be controlled by spraying with Bordeaux mixture.

FRUIT  
GROWING

424 - **Extension of the Limits of Cultivation of the Vine By Means of Various Hybrids** — DANIEL, L. and TEULIÉ, H., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 7, pp. 297-299. Paris, February 18, 1918.

VINE GROWING.

One of the writers, M. L. DANIEL, had shown, in 1894 (1), that, in some cases, certain qualities could be communicated to a scion or to a subject with given defects, by grafting on improving subjects. Through this information, JURIE and CASTEL obtained noteworthy improvements in their sexual hybrids both as regards quality and resistance to phylloxera. After the death of these two hybridisers, the systematic improvement of sexual hybrids of the vine was undertaken by BACO (2), who obtained in this way sexual-asexual hybrids or graft hybrids showing considerable progress on the original hybrids. Amongst these hybrids, number 24-23, improved by grafting, was noticeable for its earliness, and the authors began to grow it at Ille-et-Vilaine. After various trials and failures, the experiments made since 1914 appear successful and conclusive.

The BACO hybrids (mostly 24-23) of the authors' vineyard are planted under unfavourable conditions: the ground forms, between high buildings, a broad passage unfavourable to the concentration of heat; according to the season, the sun only reaches the plantation between 6 and 9 a. m., leaving it between 3 and 6 p. m. Nevertheless, of recent years, the grapes have been ripe at the earliest on September 26 and at the latest October 18. Still better results are hoped for when the same plants are planted on the hillside and exposed to the heat and light from sunrise to sunset.

The wine obtained is agreeable to drink, of medium quality and richly coloured.

Formerly the vine was grown all over Brittany. Since the fourteenth century, the limits of cultivation of the vine has continually receded and still recedes from north to south. With suitable plants, the former extent might be again attained, especially if cultivation were simplified, as with Baco 24-23, by the suppression of grafting, sulphuring and sulphating.

(1) DANIEL, L., Creation of New Varieties by Grafting (*Comptes rendus*, Vol. 118, 1894, p. 992). (Authors' note).

(2) BACO, Culture directe de greffage de la vigne (*Revue Bretonne de Botanique*, 192) (Authors' note).

*Analytical characteristics of the extreme harvests, 1914 and 1917.*

	1914	1917	Control vine 1914 (1).
Degrees of alcohol . . . . .	8°	8.8°	7°
Dry extract . . . . .	33.9	27.20	24.7
Dry vacuum extract . . . . .	44	32.04	30.6
Ash . . . . .	5	4.32	2.6
Sugar . . . . .	5	0.96	8.6
Total acidity, in sulphuric acid . . . . .	6.9	6.27	7.6
Fixed acidity . . . . .	6.4	5.80	6.9
Volatile acidity . . . . .	0.5	0.47	0.7
Total tartaric acidity . . . . .	4.5	4.97	2.7

From experiments cited and others in progress it seems possible that the vine might be cultivated over a larger area than the present one. Such an extension would obviously have considerable economic and social consequences.

425 - *Vinifera Grapes in the State of New York, U. S. A.* -- ANTHONY, N. D., under the direction of HEDRICK, U. P., in *New York Agricultural Experiment Station, Bulletin* No. 432, pp. 81-105. Geneva, N. Y., April, 1917.

For two hundred years vain attempts have been made to grow the European grape, *Vitis vinifera*, in eastern America. The end of these attempts was hastened by the discovery of satisfactory native sorts such as Isabella and Catawba. In the meanwhile, very different results were being secured on the Pacific coast where, in southern and central California, the *Vinifera* grapes found congenial conditions.

It has been found that there were four chief reasons for the failures to grow grapes in the east : — 1) the downy and powdery mildews, 2) black-rot, 3) phylloxera, and 4) winter injury.

Experimental culture of the European grape was undertaken at Geneva Station in 1900 when cuttings or plants of 19 varieties were received. In 1911, cuttings of more than 70 varieties were grafted upon a collection of Station seedlings ranging from 6 to 10 years old. Satisfactory results were obtained.

As a result of the work at Geneva certain recommendations can be made for New York state. One of the chief difficulties is to obtain plants of the desired kinds. Such as can be obtained are not always on resistant roots. For this reason the grower should know how to graft cuttings on phylloxera resistant roots such as *Vitis vinifera*, which can be done either in the nursery or in the vineyard.

In planting *Vinifera*s less space is required than with the native sorts ; rows 6 ft. apart and plants 6 ft. in the row give satisfactory results. In the east the vines should be supported with the regular 2-wire trellis. Because of the necessity of bending the trunk to the ground for winter protection,

(1) It seemed of interest to contrast the analysis of an ordinary wine, harvested in the department of Lot, at Bétaille, right bank of the Dordogne, and made from a mixture of Clinton, Canada, Othello in smallest part, and several other hybrids in very small amount. The 1914 analysis was made by M. FERRIER, that of 1917 by M. C. LAURENT (Author's note)

a replacing spur should be left at the base of the trunk to use in forming a new trunk when the old one becomes too stiff. The main trunk should be carried to the lower wire and 2 fruit canes and renewal spurs provided for. The young shoots that spring from these canes and spurs grow upright to the second wire, when they are pinched off and tied. This gives stockier and more mature canes for the following season. Cheap winter protection is obtained by bending the vines to the ground and covering with soil.

The chief value of the Vinifera in New York state is as a home-garden grape for the amateur, for the commercial grower supplying local markets demanding high quality, and for the plant-breeder seeking to obtain improved varieties.

Most of the Vinifera varieties have originated in regions with a longer season and a much warmer climate than that of New York and many kinds included in the tests at Geneva have been discarded because, even in the most favourable seasons, they have not reached maturity.

The varieties are classed in 4 groups: — 1) Desirable varieties for the grape regions of the State for a) the table and b) wine; 2) sorts worthy of testing in the more favourable parts of the State for a) table and b) wine; 3) kinds still on probation; 4) varieties of little or no value in the State.

After having given an historical account and discussed the work at the Geneva station, the author classifies the varieties in the following manner: —

1) *Desirable varieties for the grape regions of the State of New York.*

a) *For table use.*

Bakator  
Golden Chasselas  
Chasselas rose  
Chasselas Besson  
Fcher Szagos  
Kuristi Mici  
Lignan Blanc  
Muscat Hamburg  
Early Black Muscat  
Muscat Saint Laurent  
Grey Pinot  
Rosuki

b) *For wine*

Blue Portuguese  
Beclan  
Kadarka  
Mennier  
Black Pinot  
Pinot de Pernan  
White Pinot  
Teinturier

2) *Varieties worth testing in the more favourable parts of the State.*

a) *For table use.*

Acton  
Cinsaut  
Early Frankenthal  
Gradiska  
Irlan  
Mamelon  
Poulsard

b) *For wine.*

Berzemino (Marzemino)  
Calmette  
Grey Chauché (Chaouch)  
Franken Reesling (Sylvaner)  
Large Sauvignon  
Slankamenka.  
Syrah

3) *Varieties still on probation.*

Carignane	Oliver de Seres
Chardonnay (Chabl's)	Quagliano
Lahn Traube (Van der Laan Traube)	Savagnin Rose (Gewurztraminer or
Malaga	Red Traminer)
Mammolo Toscano	Semillon
Mantno di Pila	Servan Blanc (Servant)
Monica (Canaiolo)	Steinschiller (Rother Steinschiller)
Muscat of Alexandria	Sultanina
Black Hungarian Muscat	Vallepenas
Large Early Black Muscat	Zinfandel

4) *Varieties of little or no value in the State.*

Angelino	Pintendo
Aramon	Green Hungarian
Black Alicante (Black Saint Peter)	Grenache
Black Damascus	Malvasia
Black Morocco (Ribier)	Malvasia Rosario
Black Muscat (Jura Muscat)	Millennium
Cornichon Violet	Petio Ximines (Pedro Jimenes)
Elbl ng (Burger)	Schira Izouli
Ferrare	White Muscat (Muscat Frontignan).
Flame Tokay

## FORESTRY

428 — *The Arboretum of M. P. de Vilmorin at Pezanin (Saône-et-Loire, France), and the Results Obtained there.* — MORRET, S., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 5, pp. 175-186. Paris, February 6, 1918.

About fifteen years ago M. PHILIPPE DE VILMORIN established in Central France, in Charollais, at Dompierre-les-Ormes (Saône-et-Loire), a tree nursery for studying on a large scale under forest conditions, the acclimatation and utilisation of the forest and ornamental trees, cultivated in his experimental grounds at Verrières (Seine-et-Oise).

The estate, called "Pézamin", is at an altitude of 1276 feet. Forty-four acres of hills are at present planted, all of which slope down to a lake covering 10 acres. The soil is granitic, composed of rock more or less worn away by exposure, the finer portions of which have accumulated in the lowest parts and form the vegetable soil. The soil is very permeable, very poor in lime and clay, and subject to drought in the sloping parts more exposed to the sun. As in many mountains, moist portions are found here and there, giving very vigorous growth. By reason of the altitude the climate is cold, and there is snow for a great part of the winter.

The first plantation was made in 1903, and planting was continued regularly in autumn every year up to 1915. Since the death of M. DE VILMORIN the experiments have been continued by M<sup>me</sup> DE VILMORIN and the

author. Very interesting results have already been obtained. Over 50 000 young trees have been planted, distributed as follows :

	Trees or bushes with deciduous or persistent leaves	Conifers
General . . . . .	91	32
Species or varieties. . . .	789	206

A fairly large number of trees proved insufficiently hardy, and incapable of thriving under the harsh soil and climatic conditions ; these disappeared or only live in a weak state. Unfortunately the war has not allowed a complete list of these trees to be made yet. The winter 1916-17 caused the loss of many trees which had resisted till then, especially of several *Araucaria imbricata*, which froze completely.

As a rule deciduous trees did much less well at Pézanin than the conifers. Nearly all the Juglandaceae succumbed ; only a few *Juglans Vilmoriniana* managed to take hold in one part of the nursery. All the *Carya* died. The *Pterocarya* and *Juglans* which have survived have lost all their stem and are growing in bushes from the base. The *Catalpa*, *Paulownia*, some *Acer*, *Aesculus* and *Pavia*, *Fraxinus*, *Gleditschia*, *Tilia*, many bush Leguminaceae, and various Rosaceae, are doing fairly well, usually growing from the foot instead of forming a stem.

On the other hand, certain trees, especially common acacia, birch, hornbeam, and *Planera*, in particular, then oaks, willows, and alders, do more or less well, according to the species to which they belong and the place in which they are planted ; the depth of the soils, which varies greatly in the different parts, naturally has much influence on their vigour. All oaks do well at Pézanin, but the rapidly growing American species, especially *Quercus coccinea*, *Q. palustris*, *Q. rubra*, *Q. tinctoria*, etc., grow as rapidly as the willows when their roots find a little depth or fissures in the underground rocks ; their colours in autumn are very brilliant. Some *Quercus dentata* (*Q. Dainio*), grown in a fresh position, have developed exceedingly well after having refused to grow for several years.

Some trees that are usually weakly elsewhere, particularly at Vernières, have developed surprisingly well. This is the case with : *Dirca palustris*, the curious "leatherwood" tree, whose branches are so supple that they can be rolled up like straps ; with *Nothofagus antarctica*, which grows almost as vigorously as an elm, which it resembles by its foliage ; *Halesia tetraptera*, the "silver-bell" tree which flowers and fruits in abundance ; *Hamamelis virginica* was in flower in November 1917, at planting time ; various *Rhododendron* crosses, planted in numbers in a clearing, have taken root and are growing strongly ; on the contrary, *Azalea amœna* could not resist the great cold, whilst *Daphne Mezereum album* is growing well, being apparently well suited to the conditions there.

In general the conifers, which form the basis of the plantations, have done the best. Besides the forest trees common to the region, many spe-

cies, having found suitable surroundings there, have grown up into fine saplings. Shoots over 3 feet high are not uncommon with the Douglas fir. *Abies balsamea* has found so good a position, fresh and with a northern exposure, that some strong specimens planted in 1907 are now nearly 26 feet high.

*Abies arizonica argentea*, the famous "cork fir" now diffused in Europe for some 15 years, does splendidly; its thick and conical habit of growth, together with its fine glaucoustint, make it one of the finest conifers in the plantation. *Abies grandis* (Vancouver fir) competes in height with the silver fir and wins by its massive branching system which spreads curiously before it begins to thicken. *Abies concolor* and *A. lasiocarpa* are in perfectly suitable surroundings, and are noticeable for their fine stature and their distinctive blue colouring. *Abies Nordmanniana*, *A. cephalonica* and several other species, do very well, even *A. Pinsapo*, a southern tree; on the contrary, however, *A. cilicica* which begins vegetation early, freezes in spring, and becomes stiff and spindle-shaped.

Several Piceas succeed at Pézanin. Besides *Picea excelsa*, grown as a forest tree, the following may be noted: — *P. pungens* (*P. Parryana*) and its very ornamental glaucous forms; *P. Morinda*, whose young shoots are liable to freeze in winter; *P. orientalis*, with its small, close, dark-green foliage, it is very distinctive and grows very well; *P. sitchensis* (*P. Menziesii*), much finer than in the Paris region, too hot and dry for it during summer. On the other hand, *P. ajanensis* does not do at all; *P. Alcockiana* which it was long mistaken, freezes in spring; and *P. Omorica*, so remarkable at Verrières, remains very poor.

The Atlas cedar and its silvery form, from which such fine colour contrasts were expected, are weakly and without any ornamental effect. The slow-growing bushy foliage of the cedar of Lebanon seems to indicate that the soil is neither sufficiently deep nor sufficiently fertile for it, while the heat is insufficient.

The common larch (*Larix europaea*) is common in the district, and its wood is in great request for its straightness and its quality, superior to that of forest pines; most of the other species do equally well there, including *Larix occidentalis*, as yet still rare in plantations, and whose branches seem more developed than those of the former. But *Larix leptolepis* is much better than the related species for the surprising rapidity of its development, which rivals that of the Douglas fir, and by its fine, straight, clear bole.

Here as elsewhere, the adaptability of the various species of pine seems much more unequal than that of the firs. *Pinus sylvestris* and *Pinus Laricio* are the commonest in the region, where they are of almost equal forest value, the latter giving more wood than the first, but of less value, at any rate as a young tree. *Pinus Banksiana* and *Pinus rigida* do very well, but not so well as *P. sylvestris*; they are probably preferable to the latter for dry places. *Pinus excelsa* and *P. Strobus* do equally well in Charollais, but their white, soft wood, of low commercial value, hinders their wider growth. *Pinus densiflora* and *P. Thunbergii* which, in Japan, represent our

*P. sylvestris* and *P. Laricio*, are of no forestal interest for the region, for they branch and become bushy early, and their branches bend and break easily under snow. *Pinus ponderosa* and its varieties are weakly and its shoots are attacked by *Tortyx buoliana* as is the case in many places. Most of the other pines do not grow very well, and are only of interest in a collection.

429 — “Peh-Muh” and “Xun-Peh-Muh”, Trees in Tonkin New to Science. — BUNGO-HAYATA, in *Bulletin économique de l'Indochine*, Year XX, New Series, No 126, pp 435-440 + 1 Plate of 14 Figs. Hanoi-Haiphong, September-October, 1917.

The author's attention was drawn to a Chinese poem, the “Shu-hai-ko” (Song of Great Forests) of CHAO-OU-PEI, who pictures an immense forest composed of trees, the description of which shows them to be Coniferae, resembling the genus *Cupressus*. The author came to the conclusion that these trees were only to be found in the mountainous districts bordering on Yunnan and Tonkin, and came to Chapa (Tonkin) to study them on the spot. They belong to two species, known locally as “Peh-Muh” and “Xun-Peh-Muh”.

The conifer “Peh-Muh” is a species of new genus, *Fokienia*, formed in 1911 by Messrs. A. HENRY and THOMAS. The author calls this species *Fokienia Kawaii* Hay, and gives a description of it in Latin.

The conifer “Xun-Peh-Muh” appears to be a new species of the genus *Podocarpus* and belongs to the small section *Dacrycarpus*. The author proposes to call it *Podocarpus Kawaii* Hay, and describes it in Latin.

The forests formed by these two species are found over a considerable area in the mountain district (Chapa is at an altitude of 4 920 feet) and have never been cut (1).

## LIVE STOCK AND BREEDING.

432 — Experimental Feeding of Sheep with Two Poison Plants: Wild Indigo (*Swainsona luteola*) and Native Wild Tobacco (*Nicotiana suaveolens*) in New South Wales. — CLELAND, J. B. and MC DONALD, A. H. E., in *The Agricultural Gazette of New South Wales*, Vol. XXVIII, Pt. 10, pp. 735-739. Sydney, October, 1917.

The injurious effects on sheep caused by eating certain species of *Swainsona*, usually called Darling Pea, have long been known. The species specially concerned are *S. galegifolia* and *S. Greyana*; *S. lassertifolia* in Flinder's Island, Bass Strait, and *S. procumbens* or Broughton Pea, in South Australia are also suspected. Up to the present, analysis has not shown the presence of any poisonous substance in these plants.

(1) With regard to the wood and its possible use the author refers the reader to the *Bulletin économique de l'Indochine*, New Series, No. 98, p. 708, Sept.-Oct. 1912, “Coffin Woods in the Hà-giang District”, by BONIFACY, and No. 100, p. 106, Jan.-Feb., 1913, “Further Notes on Coffin Woods”, by BONIFACY and CH. LEMARIE, in which the authors discuss the conifers of the north of Tonkin (“peu mou”, “cha mou”, etc.), the wood of which is largely used by the Chinese for making their coffins (Ed.).

HYGIENE

*The Agricultural Gazette of New South Wales* has published papers on this subject. The most important experimental results were those contributed in 1897 by Dr. C. J. MARTIN from experiments in which six sheep were fed exclusively on *S. galegifolia*, salt and water. He observed the symptoms (nervous disorders, anaemia), attributed by herdsmen to feeding on this plant. In adult sheep definite symptoms started when the animals had eaten the plant for 3 to 4 weeks. Under the experimental conditions the sheep lived for about 3 months, but were very weak. Animals which received normal fodder after being fed on *S. galegifolia* for 4 to 6 weeks, and before the symptoms of poisoning were fully established, recovered completely. If, however, paralytic symptoms had already occurred, a return to normal food did not cure, but only prevented the animal from becoming worse.

The poison in *S. galegifolia*, if there be any, is, therefore, weak and cumulative, or possibly it may cause a "deficiency disease". If this second hypothesis be true completing the ration by foods rich in vitamins would be sufficient to prevent the disease. In the experiments described brewers' yeast was used as a supplement. The results were not conclusive, but seemed to show that the disease is not a deficiency one. The experiments were made with *S. luteola*, locally called "indigo", at the Coonamble Experiment Farm. Two sheep fed exclusively on 9 lb. per head daily of this plant became ill; two other subjects which, besides the same ration of *S. luteola*, also received  $\frac{1}{2}$  pint of brewers' yeast per day, also became ill. The experiment was started on September 1. The first symptoms occurred on October 11, a few days after the plants fed had begun to fructify. Feeding with indigo was stopped on October 27 and normal food supplied. One of the sheep fed exclusively on indigo died; the other of the same group and the two which had also received yeast, improved, and were still alive on March 20, though they had the peculiar appearance known as "crazed".

The same, or a similar, disease is known in America, where it is called "Loco disease"; it is caused especially by *Astragalus mollissimus* and *Oxytropis Lambertii*.

Native wild tobacco (*Nicotiana suaveolens*) has long been suspected to be poisonous. It undoubtedly contains active principles capable of causing serious and, perhaps, fatal results if eaten in sufficiently large quantities. An experiment was started on September 25 at the Coonamble Experiment Station to determine whether, under natural conditions, sheep can eat a sufficient quantity of it to cause ill effects. The sheep showed a strong antipathy to the tobacco, and would only accept it chopped up with wheat chaff; they ate, on the average, 1  $\frac{1}{2}$  lb. per head daily. Two animals given this ration till November 27 showed no signs of illness. The experimental amount of this plant seems, therefore, to be harmless.

433 - **Parasitic Nematodes in the Belgian Congo.** — RAILLET, A. and HENRY, A., in the *Bulletin de la Société de Pathologie exotique*, Year XI, No. 2, pp. 82-86. Paris, February 13, 1918.

A collection brought from the Belgian Congo by M. VAN SAGEGHEM and studied by him in the Parasitology Laboratory at Alfort, and another brought

together between 1907 to 1910 at the Leopoldville Laboratory by MM. BRODEN and RODHAIN, have been used by the writers to make up the following list:—

I. — Fam. STRONGYLIDÆ: A) Sub-fam. ŒSOPHAGASTOMINÆ: *Œsophagostomum* sp. (gut of a black monkey); *Œs. columbianum* (intestine of sheep and goats); *Œs. radiatum* (intestine of cattle).

B) Sub-fam. STRONGYLINÆ: *Strongylus equinus* (intestine of horse); *Ancylostoma duodenale* (man); *A. caninum* (dog).

C) Sub-fam. BUNOSTOMINÆ: *Bunostomum trigonocephalum* (intestine of goat); *B. phlebotomum* (intestine of calves); *Necator americanus* (intestine of man); *Gaigeria pachyscelis* (intestine of sheep); *Stephanurus dentatus* (body cavity of porker).

II. — Fam. TRICHOSTRONGYLIDÆ: *Haemonchus contortus* (intestine of cow, sheep, goat); *Trichostrongylus colubriformis* (intestine of sheep, goat).

III. — Fam. METASTRONGYLIDÆ: *Megastrongylus elongatus* (bronchi of pig); *Dictyocaulus* sp. (bronchi of monkey *Macacus*).

IV. — Fam. ASCARIDÆ: Sub-fam. ASCARINÆ: *Belascaris marginata* (intestine of dog).

V. — Fam. OXYURIDÆ: Sub-fam. OXYURINÆ: *Oxyuris equi* form *mastigodes* (intestine of horse).

VI. — Fam. HETERAKIDÆ: Sub-fam. HETERAKINÆ: *Ascaridia perspicillum* (intestine of fowls and pullets); Sub-fam. SUBULURINÆ: *Subulura distans* (intestine of monkey).

VII. — Fam. SPIRURIDÆ: A) Sub-fam. SPIRURINÆ: *Habronema macrostoma* (stomach of a mule imported from Teneriffe).

B) Sub-fam. GONGLYLONEMINÆ: *Gongylonema verrucosum* (mucosa of a goat's stomach).

C) Sub-fam. ARDUENNINÆ: *Streptopharagus pigmentatus* (intestine of a monkey).

VIII. — Fam. THELAZIIDÆ: *Oxyuris mansonii* (conjunctival cul-de-sac of fowls).

IX. — Fam. ACUARIIDÆ: Sub-fam. PHYSALOPTERINÆ: *Physaloptera abbreviata*? (stomach of an iguana).

X. — Fam. DRACUNCULIDÆ: *Dracunculus dahomensis* (conjunctive tissue of a python).

XI. — Fam. FILARIIDÆ: *Loa loa* (man); *Dirofilaria corynodes* (subcutaneous conjunctive tissue of monkey); *Setaria labiato-papillosa* (body and peritoneal cavities of cattle); *S. equina* (peritoneal cavity of horse).

XII. — Fam. TRICHURIDÆ: Sub-fam. TRICHURINÆ: *Trichuris ovis* (intestine of a goat).

In M. VAN SAGEGHEEN'S collection there are also: some nematodes from wild animals, still being studied, and also an *Evansia* and *Murshidia* of the African elephant; an acanthocephalus, *Gigantorhynchus hirundinaceus*, of the intestine of the pig and a trematode, *Gastrodiscus aegyptiacus*, from the intestine of the horse.

- 434 — **The Culture of the Parasite of Epizootic Lymphangitis and the Experimental Production of the Disease in the Horse, in France.** — BOQUET, A. and NÈGRE, L., in *Comptes rendus des Seances de l'Académie des Sciences*, Year CLXVI, No. 7, pp. 308-311. Paris, February 18, 1918.

Epizootic lymphangitis ("African farcy") is caused by a specific parasite discovered by RIVOLTA and placed by him in the Blastomycetes — *Cryptococcus farciniosus*. In spite of the researches of TOKISHIGE, MARCONI and SANFELICE the nature of the parasite was still doubted since, of late, certain authors considered it to be a protozoon.

The authors have shown, by their researches, the nature of RIVOLTA's cryptococcus by the growth of the parasite as mycelium in cultures which could be propagated and by the experimental production of the disease by inoculating these cultures into the horse. The experiments are fully described. Further work on vaccination and bacteriotherapy by means of heated cultures is in progress.

- 435 — **Immunisation of Goats against Malta Fever by Vaccination.** — See No. 381 of this Review.

- 436 — **Contagious Septicaemia of Swine in Morocco.** — VELU, H. (Laboratoire de Recherches du Service de l'Élevage du Maroc), in the *Bulletin de la Société de Pathologie exotique*, Year XI, No. 2, pp. 117-124. Paris, February 13, 1918.

Clinical observations have shown that, in Morocco, there exists a very contagious disease of swine, which chiefly attacks young or middle-aged subjects, and is characterised by lesions resembling those of septicaemia (pulmonary hepatisation, tumefaction and haemorrhagic infiltration of the lymphatic ganglia, congestion and haemorrhagic foci on the skin and serous membranes, but without lesions of croup or diphtheria).

An ovoid bacterium, which is probably *Pasteurella*, was found to be almost always present in the bronchial ganglia, pulmonary lesions, and the exsudates.

Experimental study has shown that: — 1) this ovoid bacterium is clearly pathogenic for the pig and, on inoculation it reproduces the disease; 2) contamination is carried out by faecal matter; 3) infection takes place through the digestive or respiratory channel.

CONCLUSIONS. — Severe epizooties of swine, with varying symptoms, and which flourish in certain piggeries of Chaouia, seem exclusively due to a *Pasteurella*, the presence of which can easily be shown in all the sick animals. The confirmation of these facts by further research would be of great importance. These simple infections could then be combatted under good conditions, by means of the usual processes of vaccination, serotherapy or bacteriotherapy.

- 437 — **Avian Blood Parasites of French Guiana.** — LEGER, MARCEL (Institut d'Hygiène de Cayenne), in the *Bulletin de la Société de Pathologie exotique*, Year XI, No. 2, pp. 124-130. Paris, February 13, 1918.

I. — **TRYPANOSOMES:** — *Trypanosoma ardeae* n. sp., parasite of *Nyctanassa violacea*; *T. ardeae* var. *major* n. var., parasite of *Ordea cerulescens*; *Trypanosoma* sp., parasite of *Butorides striata*.

II. — HAEMOPROTEUS: — six undetermined species of *Haemoproteus* parasites respectively of *Falco sparverius*, *Anas moschata*, *Tringa atricapilla*, domestic pigeon, *Columba rufina*, *Scops brasiliana*.

III. — MICROFILARIAE: — six undetermined species respectively parasites of *Nyctanassa violacea*, *Rallus longirostris*, *Crypturus cinereus*, *Planesticus phacopygus*, *Ardea coerulescens*.

IV. SPIROCHAETAE: — *Spirochaeta gallinarum*, the cause of disastrous epizooties, devastating whole roosts, and appearing, so it seems, every 4 or 5 years. Fowl spirochaetosis had not previously been identified in Guiana. The pathogenic agent was discovered in Martinique by SIMOND, AUBERT and NOC in 1909 and in Brazil by MARCHOUX and SALIMBENT in 1913.

The author observes that:— 1) according to his observations haematozoa are less common in birds in Guiana than in Tonkin, French Soudan, and even in France (Corsica and Reims region); 2) he has never found a *Leucocytozoon* during examination of more than 500 birds, belonging to 78 species of 27 families; and as the numerous haematological researches of BRIMONT in Guiana, CARINI and collaborators in Brazil, and ITURBE and GONZALES in Venezuela have also always given negative results as regards this, it seems doubtful if the genus *Leucocytozoon* is really represented in South America.

438 — **Chicken-pox in Poultry, in Canada.** — UPTON, H. E., in *Province of British Columbia, Department of Agriculture, Live Stock Branch, Poultry Division, Circular Bulletin No. 20*, pp. 5, Figs. 5. Victoria, 1917.

Chicken pox is usually accompanied by other diseases such as diphtheric croup, canker, and swollen head. As long as the affection stays on the skin of the head very little trouble is caused.

SYMPTOMS. — The disease shown itself in 2 forms: — 1) Chicken pox (*Epithelioma contagiosum*), causing nodules and ulcers on the head, especially on parts not well feathered; 2) small diphtheric patches appearing in and around the mouth, on the tongue, and at the mouth of the windpipe; if the disease is allowed to develop, the fowl will be prevented from either eating or breathing. The patches also appear on the side of the face; they may reach the eyes and cause blindness.

PREVENTIVE MEASURES. — The poultry house should be disinfected and kept clean; the poultry runs, the hands and shoes of those handling the stock, should be also disinfected and cleaned. Diseased birds should be isolated and dead birds burned. Prevent pigeons and other birds from walking on contaminated ground and thus spreading the disease. An excellent germicide to use in the drinking-water can be prepared by quickly stirring 2 oz. oil of sassafras into 2 gallons water; pour and mix slowly 2 fluid ounces sulphuric acid in this mixture; to use, add one tablespoonful of the mixture to each gallon of drinking water.

TREATMENT. — The fowls should be kept housed during the winter, and the runs covered with quicklime. Change the straw and litter in the houses, burn the dirty straw and disinfect the roosts and drop boards with carbolic acid.

The Poultry Division of the Department of Agriculture of British Columbia have carried out experiments in an endeavour to cure and prevent the disease by vaccination. The writer vaccinated about 3 000 birds ranging from five weeks to three years in age. Control birds were left in each flock; 40 % died. Some flocks were vaccinated with vaccine made from scabs only ; others with vaccine made from scabs and cheesy exudate, or from scabs and exudate mixed together then attenuated, or attenuated separately then mixed. The best results were obtained with the vaccine prepared from scabs and exudate ground together then attenuated. With 5- to 8-week old chicks (the majority showing signs of disease after severe chilling), good results were obtained by injecting  $\frac{1}{2}$  cc. of vaccine twice at an interval of 3 to 4 days. In some very bad cases, expected to die, 2 cc. were injected and complete recovery obtained. No bad effects were noticed, though 3 birds died owing to emaciation before the injection. Egg production was not affected in any way.

The scabs and exudate should be removed with a sterile pair of scissors and tincture of iodine applied to the exposed surface.

The method of preparing the vaccine is as follows: — One half gram of chicken pox scabs and exudate are ground in a sterile mortar with 100 cc. of physiological salt solution. This material is poured in a flask, stoppered, placed in a water bath, and attenuated at 55° C. for one hour. Filter into a sterile flask and wash the filter with the rest of the salt solution. It is essential that the vaccine be used as soon after preparation as possible, or it will deteriorate and give poor results.

ANATOMY  
AND  
PHYSIOLOGY :  
GENERALITIES

439 — **The Chemical Composition of the Placenta of the Cow.** — FENGER, F. (Research Laboratory in Organotherapeutics of Armour and Company, Chicago), in *The Journal of Biological Chemistry*, Vol. XXIX, No. 1, pp. 19-23. Baltimore, Md., February, 1917.

The constituents of the uterine placenta seem to remain comparatively uniform throughout gestation, while the foetal placenta varies considerably in composition at different stages of pregnancy. This is well shown by the results obtained by the author and summarized in the appended table. The results show that the maternal cotyledons contain less moisture and more protein and fats, phosphatides, etc., than their corresponding placentulas. The older uterine cotyledons contain more potassium and less sodium than the younger, but otherwise the variations in the mineral constituents are comparatively slight at the two selected stages of pregnancy. The young foetal placenta contains much more chlorine and considerably more sodium and calcium and less of the other inorganic constituents than the older foetal placenta. It is evident, therefore, that chlorine, sodium and calcium are of vital importance in early foetal life. Later, during the rapid growth periods, the amounts of these three elements diminish while the quantities of phosphorus, sulphur, potassium, iron, and magnesia increase. The 3 to 4 months old foetal placentulas, which are of a pale pink colour, contain only about  $\frac{1}{3}$  the quantity of iron that is present in the older and dark red foetal placentulas. This indicates that the amount of haemoglobin in the foetal blood is small during the earlier stages of pregnancy, but in-

creases in direct proportion to the growth of the foetus. All the samples examined by the author gave negative tests for epinephrin and iodine.

440 - **Foetal Athyrosis: A Study of the Iodine Requirement of the Pregnant Sow.** — SMITH, ENNIS, G. (Montana Experiment Station, University of Montana, Bozeman), in *The Journal of Biological Chemistry*, Vol. XXIX, No. 2, pp. 215-225, 3 Tables. Baltimore, March, 1917.

The paper describes an investigation into hairlessness and enlarged thyroid glands, found, in certain parts of Montana, among sows, sheep, cattle and mares (1).

The author obtained the following results experimentally: —

An iodine deficiency during the gestation period causes a lack of function and hyperplasia of the foetal thyroid, causing arrested development of the foetus. If more iodine were fed to the pregnant animals in many parts of the United States, their young would be more healthy and vigorous. Foetal athyrosis shows that there is a direct relation between the physiologically active constituents of the thyroid and growth of the epidermal appendages. An abundant secretion of the foetal thyroid during the later stages of the intra-uterine life is essential to the normal development of the foetus.

FEEDS  
AND FEEDING

441 - The Availability of the Energy of Food for Growth. — MOULTON, C. R., in *The Journal of Biological Chemistry*, Vol. XXXI, No. 2, pp. 389-394, 3 Tables. Baltimore, August, 1917.

Experiments on the use of food have been conducted at the University of Missouri Agricultural Experiment Station, and some data have been obtained upon the relative amount of the energy of the food which may be recovered in flesh gained. The animals used were mature beef steers, 2 or 3 years old, of the Shorthorn breed; they were as alike in weight, previous method of treatment and type as is possible. The ration consisted of 5 parts of mixed grain (8 parts of maize meal and 1 of cold-pressed linseed meal) to 2 of alfalfa hay.

The digestibility of the ration was determined by digestion trials. The cost of maintaining the animals at constant weight was determined by extended maintenance trials. After the maintenance trial steer 18 was slaughtered for analysis; the other 2 were fattened, steer 48 to prime condition, steer 121 to a condition of 40 to 50 days under prime; they were then slaughtered and analysed. Table I shows the composition of the gain of weight. In calculating the thermic equivalent of the fat and protein, the value of 5,6776 calories per gm. was used for the protein, and 9,4889 for the fat. The equivalent metabolizable energy for the ration was found by ARMSBY's method (1) to be 3,803 calories per kg. of digestible organic matter. The data are given in Table II.

The metabolizable energy that may be used for production of flesh is that amount over and above the needs for maintenance. Using the average weight of the animal while on maintenance and the maintenance cost found by trial for each, the cost of maintenance during the full feed period was calculated. The amounts of energy required for maintenance at different body weights are proportional to the body surfaces, *i. e.*, roughly to the two-thirds power of the body weights. In previous work (*J. Biol. Chem.*, 1916, XXIV, 299) the author has shown that the surface area of a thin or medium fleshed steer is more nearly proportional to the  $\frac{5}{8}$  power of the weight, while with very fat steers the  $\frac{5}{8}$  power should be used. Both the  $\frac{5}{8}$  power and the  $\frac{5}{9}$  power were used in the calculations (the latter is used in Table II) and a difference of 0.25 % of the net energy cost. (2) of

(1) See *B. June*, 1915, No. 625 (*Ed.*).

(2) Food which enters the animal body has a certain amount of total energy, called the heat of combustion. This energy is different for different feeds. Of this total energy the animal loses part by way of the faeces in the undigested food residues, part by way of the urine in incompletely oxidized bodies, and part by way of combustible bodies voided. The amount over and above these losses is called the metabolizable energy. Not all of this metabolizable energy is available for the use of the animal body in either maintenance or growth. There is a loss due to the work of digestion, mastication, and movement of the food through the digestive tract. There is also a further loss due to a stimulated metabolism upon the absorption of digestible substances from the alimentary tract. There may be a slightly greater muscular activity due to the increased food consumed. All this energy is converted into heat and lost from the body. What is left of the metabolizable energy after these second losses are accounted for is called the net, or available, energy. This may be used for production of work, or may be stored in the animal body in the form of protein, fats or other body substances.

(Author)

a pound of gain for Steer 18 and 1.5 % for Steer 48 was found. The true value would lie between that given in Table II and a value smaller by the above percentage amounts. The error could therefore be hardly more than half that shown, or about 0.75 % of the total for Steer 48. The error in the calculation of the per cent. of available energy would be about double this error. The error is so small that a more complex method of calculation is not required.

Digestible organic nutrients . . . . .	"	2 267	7 860
Metabolizable energy . . . . .	therms	3 900	13 519
Energy per lb. gain . . . . .	"	7.73	14.03
Average weight of animal . . . . .	lb.	1 041	1 384
Energy per 1000 lb. for maintenance . . . . .	therms	12.14	12.73
Total energy for maintenance . . . . .	"	1 900	8 646
Energy above maintenance . . . . .	"	2 000	4 873
Energy above maintenance per lb. of gain . . . . .	"	3.98	5.06
Energy recovered in gain . . . . .	"	1 067.6	2 558.1
Metabolizable energy recovered . . . . .	%	53.39	52.49

The results of the calculations, given in Table II, show a much higher productive energy cost of each pound of gain for the very fat steer than for the medium fat steer. Steer 48 gained about 29 % more fat than Steer 121 the productive energy increased in about the same proportion (27 %).

In the tissues gained by these animals, one recovered 53.39 % of the metabolizable energy consumed above maintenance and the other recovered 52.94 %. Thus it is seen that the energy saved was about the same in both animals. Since this proportion of the energy is recovered it may be said that this is a measure of the availability and that the metabolizable energy of the ration used was 52.94 % available, or net.

Using the data given by ARMSBY (*loc. cit.*) the author has calculated that 54.995 % of the metabolizable energy was available, which agrees very closely with ARMSBY's figure (55 %).

442—**The Feeding of Young Chicks on Grain Mixtures of High and Low Lysine Content** (1). — BUCKNER, G. D., NOLLAU, E. H. and KASTLE, J. H., in *Kentucky Agricultural Experiment Station, Bulletin* No. 197, pp. 21, Tables IV, 16 Photographs.

It has been shown by OSBORNE and MENDEL in an exhaustive series of experiments on the feeding of albino rats, that lysine is primarily responsible for the stimulation of growth. The authors undertook a series of experiments regarding this subject on feeding young chicks using grain mixtures containing a low and high lysine content respectively.

EXPERIMENT I. — Two lots of young chicks of mixed breed were chosen. At the beginning of the experiment the weight in Lot I (10 chicks) was 438 gm., or an average of 43.8 gm. per chick, and in Lot II (9 chicks) 338 gm. or an average of 43.1 gm. per chick. The experiment lasted 8 weeks (May 13 to July 6, 1915) and the two lots were fed as follows:

Lot I. — received a mash twice a day, morning and evening, consisting of equal parts by weight of finely ground wheat, wheat bran, sunflower seed and hemp seed, moistened with skim milk; and once a day at noon they were given a coarsely ground mixture of wheat, hemp seed and cracked maize.

Lot II. — received 30 gm. of a mash consisting of finely ground barley, rice, hominy and oats, 100 gm. each and 56 gm. of gluten flour, the mash being made with protein-free milk; at noon they received from 30 to 50 gm of a mixture of equal parts of barley, rice and hominy.

On hydrolysis, these various rations gave (by the VAN SLYKE method) the following figures for the lysine content: —

Lot I		Lot II	
Mash	Grain mixture	Mash	Grain mixture
3.80 %	2.23 %	0.50 %	0.79 %

RESULTS. — The chickens were weighed regularly every 6 days. At the end of the experiment 5 average chickens of Lot I weighed 2 553 gm.,

(1) See R., February 1918, No. 186 (Ed.).

while 7 in Lot II weighed 1 195 gm. The average increase in weight was thus 98 gm. for Lot I and only 15.6 gm. for Lot II. This striking difference is shown clearly by photographs, which also show the state of development and feathering. Further, the chickens of Lot I were much more active than those of Lot II.

At the end of the experiment (July 6), the chickens of Lot II were put on the rations fed to Lot I. On July 13, the chickens of Lot II gained in weight 344 gm. or an increase in 7 days of 41.2 gm. per chick (the previous average, before exchange of the rations, was 15.9 gm.).

These results show that while the chickens of Lot I grew normally, those of Lot II were stunted in their growth. This difference in nutrition is probably due to the difference in the amount of lysine received by the 2 lots and possibly to a difference in the quantity and nature of the fats in the rations. The content in fats was as follows: —

Lot I		Lot II	
Mash	Grain mixture	Mash	Grain mixture
13.08 %	8.21 %	1.8 %	1.0 %

It should be remembered that OSBORNE and MENDEL, and other investigators have shown that certain of the natural fats contain substances which stimulate animal growth (1). Such fats are found in butter, cod liver oil, yolk of egg, etc.; many grains and vegetable products probably also contain growth-promoting fats. For this reason it is not safe to explain the better growth of Lot I by the better quality of the protein in the food. It thus remains to be determined whether the difference is due to differences in the protein or fats, one or both. To throw light on this question, the following experiment was carried out.

EXPERIMENT II. — Two lots of 48 White Leghorn chicks, Lots III and IV, were given the same rations as Lots I and II, save that to the ration given to Lot IV there was added sufficient butter fat to bring up the fat content up to that of the ration fed to Lot III (the old Lot I). The total weight of Lot III (12 chicks) was 488 gm., or an average of 40.6 gm. per chick. Lot IV weighed 471 gm., or an average of 39.25 gm. per chick. After 8 weeks, each chick of Lot III weighed on an average 395.6 gm., while in Lot IV, each chick weighed an average of 118 gm. Thus Lot III showed an average gain per chick of 277.6 gm. over the chicks of Lot IV. Differences in development, health, plumage, etc., were again clearly marked, and although the chicks of Lot IV were quite healthy, their growth was obviously stunted.

At the end of the second experiment the rations were again reversed, with striking results: after 3 weeks, Lot III made a percentage gain of

(1) See R., February 1918, No. 182 (Ed.).

5.1 as against 28.9 for Lot IV. Within one week after reversing the rations, the external sexual characteristics of the chicks of Lot IV became noticeable and after the third week were very pronounced.

CONCLUSION. — It is evident that the marked differences shown by the two lots in rate of growth cannot be ascribed to the fat content of the 2 rations, but rather to differences in the amino-acid content of the rations, and particularly to differences in the lysine content.

The writers emphasise the value of feeding experiments with the chicken both from a practical and a scientific standpoint. The financial returns from a sound method of feeding chickens would be enormous. From a purely scientific standpoint the young chicken is very suitable for feeding experiments as it reaches maturity in so short a time.

443 - **The Relative Value of Certain Proteins and Protein Concentrates as Supplements to Maize Gluten.** — OSBORNE, T. B. and MENDEL, L. B. with the Cooperation of FERRY, F. L. and WAKEMAN, A. J. (Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXIX, No. 1, pp. 69-92, 8 Tables, 1 Chart. Baltimore, February, 1917.

The writers undertook to measure the comparative nutritive potencies of different proteins or protein concentrates. The experiments were made with rats. With inadequate maize gluten as the basis of the nitrogenous part of the ration, the following substances were added to the diet: — casein; lactalbumin; edestin (prepared by extracting ground hemp seed with sodium chloride, repeated solution and precipitation by dilution and cooling); cottonseed protein; cottonseed flour (43.7 % protein); milkalbumin (a commercial product containing 54.2 % protein and 23.8 % of ash); beef tissue (made by drying the residue left after thoroughly extracting fresh chopped beef with water); fish meat meal (herrings, 60.5 % protein); maize germ cake (17.5 % protein); vegetable albumin flour (a commercial product, with 74.7 % protein, presumably consisting of the residues from the manufacture of wheat starch); brewers' grains (45 % protein); distillers' grains (29.4 % protein); pea meal (26.5 % protein); peanut meal (after extraction of oil; 29.4 % protein). It was found that these food mixtures, of approximately the same nitrogen and calorific content, vary greatly in their efficiency for promoting growth, in accordance with both the character and the proportion of the protein supplement employed. The efficiency of these supplements presumably depends essentially on their relative content in lysine and tryptophane; for the addition of these amino-acids, either as such, or in the form of proteins yielding them, renders maize gluten suitable for growth.

Of the various proteins employed to supplement the inefficient maize gluten, lactalbumin is by far the most effective. Satisfactory growth is obtained with smaller quantities of this protein than of any of the others recorded. The brewers' grains, distillers' grains, and "vegetable albumin flour" were the least efficient supplements used, presumably because of their low lysine content.

It is evident that the small additions of the more efficient proteins ac-

tually *supplement* the maize gluten instead of themselves furnishing all the protein used for growth, because equivalent amounts of these proteins alone in a similar ration are incapable of inducing a comparable degree of growth.

Small amounts of a superior protein are often quite as efficient for growth as larger amounts of a less adequate protein.

444 - **The Nutritive Properties of Kafirin.** — HOGAN, A. G. (Department of Chemistry, Kansas State Agricultural Experiment Station, Manhattan), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 1, pp. 151-159, 4 Charts. Baltimore, January, 1918.

JOHNS and BREWSTER (1) have shown that most of the nitrogenous part of kafir (the north American variety of sorghum), about 67 per cent. of the total protein, is soluble in alcohol, and they called this particular protein "kafirin". This protein contains 55.19 % of carbon, 7.36 % of hydrogen, 16.44 % of nitrogen, 0.60 % of sulphur and 20.41 % of oxygen. It contains the following diamino-acids:— arginine, 1.58 %; lysine, 0.90 %; histidine, 1.00 %; and tryptophane, present.

Because kafirin forms such a large proportion of the protein of kafir, and because of its increased economic importance for growth in regions of light and insufficient rainfall, its nutritive properties were studied in detail.

A basal ration was prepared containing protein, protein-free milk, butter, starch, agar, and in which kafirin formed practically the only source of protein. This diet was given to rats and always resulted in nutritive failure. Accordingly kafirin was supplemented with other deficient proteins, gliadin (10 % of the basal ration) and gelatine (10 % of the basal ration) or both proteins together (5 % of each). The addition of gliadin, for a short time at least, barely sufficed to maintain the live weight of the animals; but the addition of gelatine enabled them to grow slowly, while the two proteins together produced more rapid growth than gelatine alone. It thus seems that there are at least two limiting factors in gliadin as a source of protein; gelatine supplies one (lysine) and gliadin the other (cystine).

In further experiments the following amino-acids were added to the basal ration: — tyrosine, cystine, tryptophane and lysine, either separately or mixed individually with lysine. It was found that the addition of tryptophane and tyrosine did not increase the rate of growth of the rats; on the contrary, however, the addition of lysine plus cystine produced marked increase of growth. The author concludes that the limiting factors in kafirin are lysine and cystine. In addition, the data obtained show that lysine is indispensable for the maintenance of young animals. OSBORNE and MENDEL (1914) were of the opinion that lysine is necessary for growth but not for maintenance, because rats receiving gliadin as the sole source of protein in their ration maintained their live weight unchanged, but failed to grow, and because it was then thought that gliadine contained no lysine. The method of VAN SLYKE showed that gliadin contained an average of 1.33 % of lysine. Kafirin contains 0.90 % of lysine, but it seems that lysine is completely wanting in zein.

## CATTLE

445 - The Influence of the Stage of Gestation on the Composition and Properties of Milk. — PALMER, L. S. and ECKLES, C. H., in the *Journal of Dairy Science*, Vol. I, No. 3, pp. 185-198. Baltimore, September, 1917.

The question of the influence which is exerted by gestation on the composition of cows' milk has received practically no attention from an experimental point of view. This paper presents data bearing on this question consisting in complete analyses of the milk and milk fat throughout the entire lactation period of ten cows which became pregnant at various stages of their lactation period, of one cow which was farrow and the complete analyses of the milk for three of the ten cows throughout a subsequent lactation when they were kept farrow.

It is well known that the percentage composition of cows' milk and the constitution of the milk fat, as shown by physical and chemical constants, undergo certain definite changes as the stage of lactation progresses. These changes are usually particularly marked at the close of lactation. Since under normal conditions, nearly all cows are bred at some stage of their lactation period, it is difficult to determine how much the fact of pregnancy or the stage of gestation contribute to these changes in the composition of the milk and milk fat.

The completeness of the data for the lactation periods of the experimental animals has made it possible to compare the composition of the milk and the milk fat at any stage of lactation with the average composition for the entire period. Inasmuch as the date of breeding of the animals occurred at different stages of lactation for each of the animals it has been possible to ascertain at what stage of lactation the composition of the milk and milk fat for each animal showed permanent changes from the average, and to note, at the same time, at what stage of gestation these changes took place. It seemed probable that there should be some uniformity among the different animals with regard to the stage of duration of the factor contributing the strongest influence upon the composition of the milk. Tabulation of the results from this standpoint revealed the fact, that permanent changes from the average composition of the fat occurred several weeks sooner, on the average, than similar changes in the percentage composition of the milk.

An examination of the data on the average composition of the milk for the entire lactation period in comparison with the composition of the seven-day composite which showed the first permanent change from the average, and the stages of lactation and gestation when this change occurred, shows a close relation existing between a change in the percentage composition of the milk and the stage of the lactation period, particularly with respect to the relative stage of lactation.

The data fail to reveal, however, that the changes in the composition of the milk bore any constant relation to the stage of gestation. Similar results are obtained on examination of similar data for the physical and chemical constants of the milk fat. Although the relations between the changes in the constitution of the milk fat and the stage of lactation is much less constant, the same result holds true with respect to the relation to the stage of

gestation. It would appear that some other factor may have been partly responsible for the changes in the composition of the milk fat.

Still more substantial evidence in regard to the influence of the stage of gestation on the composition of milk is furnished by a comparison of the composition on corresponding days of two lactation periods of the same cow, during one period of which she is pregnant and the other farrow.

An examination of the data available for three of the cows shows that the same shrinkage in milk flow and the same changes in the composition of the milk occurred at the end of the farrow lactation as took place at the end of the pregnant lactation, but at a somewhat later stage.

The conclusion drawn from the data presented in this paper is that gestation does not exert any direct effect upon the composition and properties of cows' milk, but that gestation may affect the composition indirectly by hastening the close of lactation, which is the important factor involved in the changes in the composition of milk as lactation advances. The characteristics of the milk as the end of the lactation approaches are high concentration of protein and fat, and frequently a lower concentration of lactose. The fat of cows' milk is characterized by great depression of the saponification value and Reichert-Meissl number, and great increase in iodine value and melting point. In addition, data which have not yet been published are presented on the influence which gestation exerts upon the composition of human milk, indicating that under normal conditions gestation exerts no influence on the composition of mother's milk and that the marked decrease in the percentage of all the solid constituents of the milk reported by another investigator as accompanying gestation in the case of human milk was not confirmed.

446 — **The Effect of Pepsin Whey on Calves.** — MCINNIS, I. T., in *The Agricultural Gazette of New South Wales*, Vol. XXVIII, Pt. 12, p. 850. Sydney, December 3, 1917.

Since pepsin has been used instead of rennet in the cheese factories of New South Wales, a breeder who had lost calves attributed their death to the use of pepsin whey as a food. For this reason the Department of Agriculture undertook an investigation to see whether there was any ground for this hypothesis. It was found that pepsin whey obtained from various cheese factories is often fed to calves without any ill effects, and is completely satisfactory in all respects, provided it is heated to at least 160° F. before use.

447 — **Swine Management in U. S. A.** — ROMMEL, G. M. and ASHBROOK, F. G., in *Farmers' Bulletin* 874, U. S. Department of Agriculture, pp. 1-38. Washington, D. C., September, 1917.

This bulletin deals with the various phases of swine production from a practical point of view, namely: feeding, breeding and management.

Some interesting data concerning weights of pigs at given ages are here reproduced.

Table I shows statistics based on information obtained from 12 practical breeders, asked to state the weights of their own pigs at given ages, and at the same time to name the weights which they considered pigs ought

to weigh at these ages; the aim being to establish a weight standard for swine raisers to work up to. The same table also shows the average weights of 121 pigs bred and fattened at the Bureau of Animal Industry Experimental Farm at Beltsville, Maryland: The latter weights are shown more in detail in figure 1, and it will be observed that they terminate at 8 months, when the animals were marketed.

TABLE I. — *Comparison of pig weights at various ages.*

Class	Average weights (in lbs) at			
	3 months	6 months	9 months	12 months
Breeders' pigs . . . . .	41	120	191	267
Experimental Farm pigs . . . . .	48	140	235 <sup>(1)</sup>	—
Breeders' standard . . . . .	63	176	263	347

(1) Weight at 8 months, when marketed.

FIGURE I. — *Average weekly weights of 121 hogs at Bureau of Animal Industry Experimental Farm, Beltsville, Md.*

The abscissae represent the number of weeks (1 to 34) since birth (0).

The ordinates represent the live weights in lb.

#### POULTRY

448 - **Blood Fat in Domestic Fowls in Relation to Egg Production.** — WARNER, D. E. and EDMOND, H. D., in the *Journal of Biological Chemistry*, Vol. XXXI, No. 2, pp. 281-294, 10 Tables. Baltimore, August, 1917.

The work described was carried out at the Poultry and Chemical Laboratories of the Storrs Agricultural Experiment Station, Connecticut.

The natural colour of the body fat of most hens and the fat in egg yolk is yellow. This colour is due to a pigment of the xanthophyll group together with very little of a pigment isolated in crystalline form by WILLSTÄTTER and ESCHER and proved by PALMER to be identical with plant xanthophyll.

The disappearance of this colour from the external parts of the hen's body led the authors to undertake this investigation. There is in the hen a correlation between egg laying activity and yellow pigment. BLAKESLEE and WARNER have shown that when the yellow in the ear-lobes did not exceed 20 % in a given group of hens the percentage of birds laying was high; the second percentage decreased as the first increased. They concluded that "the laying removed the yellow pigment from the body for the production of eggs more rapidly than it could be replaced by the normal metabolism". This led the authors to believe that; if the yellow pigment present in the hen's body before laying is transferred to the egg yolk, the body fat containing the yellow pigment would, in a like manner, pass in the blood from the body to the egg yolk. (It should be noted that, in this paper, by "fat" is meant the total ether extract composed chiefly of fats and cholesterol).

If this be so a hen which lays heavily should have blood much richer in fat than a hen which does not lay. The authors, therefore, studied the relationship of blood fat in fowls to:— 1) egg production; 2) the presence of food in the alimentary tract; 3) the colour of legs, etc.; 4) sex. WARNER had shown previously that the average amount of fat found in high producing and in laying hens is 1.426 %, and in low producing hens 0.886 %. The results were considered to justify further study. In October, 1916, the authors commenced their work with 12 cockerels and 82 White Leghorn hens. The hens had just completed their 1st or 3rd year of laying, and among them were birds with high, medium, and low records.

The egg producing records cover a period from November 1 to the following October 31. Blood samples were taken from October 28 to November 3, 1916. The results obtained were as follows:—

There is little or no correlation between the amount of fat in the hen's blood and its annual egg yield, but the blood of a hen laying at the time the sample is taken is much richer in fat than that of a hen which is not laying.

The average percentage of fat in the 70 hens which had just completed their first year of laying was 0.407; for the twelve 1½ year old cockerels it was 0.176. These data show that it is improbable that high producing hens can be selected merely by sampling their blood and determining its fat content unless account is taken of whether or not the hen is laying at the time of sampling, and also of the season. A 16 hour fast did not seem to decrease the fat content of the blood of fowls.

There is a close relation between the colour of the beak, legs, and vent and the percentage of fat in the blood. The birds with pale legs, beaks and ani, had a high percentage of fat in their blood and a high average egg production, and vice versa. This shows that birds which are not laying store fat in the body cells and, consequently, their beaks, legs, and ani become yellow, the natural colour for all American breeds and Leghorns.

The average percentage of fat in the blood of the 3 year old hens was much lower than that of the 1 year old birds. The percentage of fat in the blood of the male birds was more constant than that of the 1 year old hens. There seems little difference between the percentage of fat in the blood of male birds and in that of hens which are not laying.

The principal reason why the blood of laying hens is much richer in fat than those which are not laying seems to be that the fat stored in the body tissues is taken up by the blood and carried to the egg yolk.

## SERICULTURE

449 - Second Report on the Experiments carried out at Pusa to Improve the Mulberry Silk Industry (1). — DE, M. N. (Sericultural Assistant, Research Institute, Pusa), in *Agricultural Research Institute, Pusa, Bulletin* No. 74, pp. 27. Tables 12. Calcutta, 1917

CROSSING. — Multivoltine races were crossed with univoltine races to see whether a multivoltine hybrid race which will yield better cocoons than pure multivoltine races, can be established. Some success was attained; multivoltine crosses thus obtained gave better yields than the pure multivoltine races usually reared in Bengal, Assam and Mysore. It seems that it will not be possible to get all the layings multivoltine from a hybrid race; a few eggs from each laying turn univoltine but they should be destroyed. The loss of these eggs can be ignored considering the advantages gained.

It was found that, in the case of a hybrid race, if all the yellow cocoons were eliminated from each generation, it is easy to get all white cocoons; but it is difficult to get all yellow cocoons after many generations if white ones are eliminated.

The following crosses were made: — (Nistari × French) × Mysore; Nistari × (Japanese-Italian); Assam × Nistari; Assam × Chotopolu; Nistari × Chotopolu; etc.

USE OF STIMULANTS. — M. Kawahito, the Director of Aichikew Sericulture Experimental Station, Japan, has been reported to get an improvement in the cocoons of univoltine races by immersing the eggs in dilute hydrochloric acid. A similar experiment was carried out by the author with a multivoltine race, but better eggs were not obtained by treatment with dilute hydrochloric acid.

EFFECT OF FEEDING. — The yield of silk can be increased by increasing the number of feedings, but the advantage obtained is not proportionate to the extra trouble and cost required for the purpose. An experiment was undertaken to find out which variety of mulberry gives the most satisfactory result in the yield and other qualities of silk and the percentage of disease in the mother moths. The best varieties were found to be *Morus alba* var. *japonica* and *M. alba* var. *philippensis* (both for univoltine and multivoltine races) and then *M. indica*. The leaves of the variety *italica* are very big and hard and not suitable for feeding the larvae. The Bengal bush variety would probably give better results if it were allowed to grow into a big tree. All races yield more silk if fed with suitable mulberry tree leaves than when fed with bush leaves. Tree mulberry should be introduced in addition to bush.

RESISTANCE TO DISEASE. — a) *Pebrine*: In a previous report the author has shown that, in a climate like that of Pusa, univoltine races are more susceptible to pebrine than multivoltine ones. The disease appears

(1) For the summary of the first report, see B. 1915, No 1071 (Ed).

more in May to October than in September to April. The more pebrinized layings are reared with healthy layings the less the number of cocoons are obtained from a rearing. The percentage of diseased moths is more or less in proportion to the pebrinized layings reared with healthy layings. Good crops and healthy layings can be obtained from a pebrinized laying if the worms are carefully attended to and if the temperature and moisture-content of the air are suitable for the healthy growth of the larvae. Bad crops and pebrinized layings are obtained from a healthy laying if the temperature and moisture-content are high and if the worms are not properly looked after.

b) *Flacherie*. — Many moths are attacked with flacherie during the rainy season when the temperature and moisture-content are high. It was found that eggs laid by moths attacked by flacherie, can be safely kept for industrial purposes though in some cases the cocoons are a little inferior to those obtained from eggs laid by healthy moths.

HIBERNATION. — Univoltine eggs should be hibernated for about 4 or 5 months at about 35° to 45° F. The author undertook an experiment to find out whether it is possible to shorten the duration of cold storage by increasing the intensity of cold and to study the effect of intensive cold on the embryos. The results showed that the duration of cold storage can be shortened by the action of intense cold, but that the eggs hatch quite unsatisfactorily.

As regards the indigenous races the author indicates the Mysore race as being the best for yield of silk. The Nistari race should be reared in April or May, the Mysore race and hybrid races from July to October and univoltine races from October to March. Of all the univoltine races, Chinese and Japanese races thrive best in a climate like that of Pusa but their yield of silk is inferior to those of France and Italy. The cross-breds between Boropolu and foreign univoltine races should be reared in those places where imported foreign races do not thrive well.

450 - **Fresh-Water Mussels: Their Exploitation and Artificial Propagation in the Rivers of the United States.** — RAVERET-WATTEL, R., in the *Bulletin de la Société Nationale d'Acclimatation de France*, Year LXIV, No. 11, pp. 427-438, 6 Fig. Paris, November, 1917.

OTHER LIVE  
STOCK

In the inland waters of America, there are hundreds of species of fresh water mussels (family Unionidae) many of which produce pearls much used in jewelry; for this reason, they are considerably exploited in the United States. The shells are used for making mother-of-pearl buttons. The species most in demand are *Quadrula ebena*, *Lampilis anodontoides*, *L. rectus*, *L. fallaciosus*, *L. ligamentinus*, *Tringonia verrucosa*, *Plagiola securis* and *Symphynota complanata*.

For various reasons, especially over-fishing, the mussels have been greatly reduced in numbers, so much so that various measures have been proposed to remedy such a state of affairs. As these measures do not appear to suffice, the breeding of fresh water mussels is being considered.

As these molluscs pass the greater part of their larval live on fish (par-

ticularly on the gills), the latter will be of great importance in rearing the mussels.

Researches are in progress concerning the food and other needs of the fresh-water mussels, when, having left their hosts, they begin to assume adult characters.

## FARM ENGINEERING.

### AGRICULTURAL MACHINERY AND IMPLEMENTS

451 - **The Encouragement of Mechanical Cultivation in France.** — *Feuille d'Informations du Ministère de l'Agriculture*, Year XXII, No. 52, pp. 1-2. Paris, October 16, 1917.

The French Minister of Agriculture has published an order dated October 8, 1917, containing the following provisions: —

Agricultural groupings of at least 7 members, departments, boroughs, may receive State grants for the purchase of machines for mechanical cultivation, provided that they undertake to use the machines themselves and to prepare for and sow cereals with a minimum per machine of an acreage to be fixed in each case, according to the capacity of the machine and the nature of the soil. When the machines acquired by the above-mentioned groups consist of a set of at least 5 tractors and material for steam or electric ploughing, the subvention (acquisition of material and advances for the cost of cultivation) may amount to 50 % of the cost of the machines. In the contrary case, the subvention may not exceed  $\frac{1}{4}$  or  $\frac{1}{3}$  of the cost of the machines, according to whether the applicant will have recourse or not to an agricultural credit bank. In regions that have suffered through the war, the maxima may be raised respectively to  $\frac{1}{3}$  or  $\frac{1}{2}$  of the price of the machines.

Applications for subventions must be made to the Minister of agriculture through the prefect of the department. They will be accompanied with the opinion of the prefect and the following information obtained or verified by the director of agriculture: — the type and price of machine; the rules relating to the conditions under which the machine is to be used; a provisional estimate for the undertaking; a report on the geological, topographical and agrogeological conditions of the region where the machine is to work; the area to be worked; the engagement provided for; the rules of the syndicate for the agricultural associations, with the number of members and the funds available indicated, the bases of the division of common expenses and charges between them; the extract of the resolution of the general or municipal council for the departments and boroughs; and, finally, proof that the applicants have suffered from the invasion.

452 - **Mechanical Cultivation Tests at Rabat, Morocco, in 1917.** — *DESSAUBAT, R.*, in the *Journal d'Agriculture pratique*, Year LXXXII, No. 3, p. 53. Paris, February 7, 1918.

The Automobile Club of Morocco has carried out tests of mechanical cultivators at Oulja de Rabat from September 26 to 29, 1917. Five machines took part, the trials being carried out on compact soils greatly hardened by drought.

The results of these trials are given in the appended table.

Machines	H. P.	Depth of work, inches	Area ploughed per hour  sq. feet	Fuel used per acre	
				Paraffin gallons	Petrol gallons
Amanco . . . .	24	6—7	28 192	2 59	0 22
Bull . . . . .	20	6—7	23 336	2.96	1 52
Ford . . . . .	14	breaking-up stubble	—	—	3.22
Titan . . . . .	20	5—7	23 562	3.12	0 13
Moline . . . . .	12	breaking-up stubble	—	—	3 18

Notes are given below as regard the ploughs, the quality of work, the best average speed in relation to the area worked per hour and the width of work.

AMANCO: 4-furrow, automatic-lifting plough; width of work, 40 in.; very even work; average working speed, 8286 ft. per hour.

BULL: 3-furrow, automatic-lifting plough, width of work, 40 in.; good work; average working speed, 6775 ft. per hour.

FORD: 2-furrow plough, not self-lifting; width of work, 27 in.; breaks up stubble fairly well. The area worked per hour and the average speed were not determined. The FORD machine consists of the ordinary frame with a 14 HP. motor converted into a tractor.

TITAN: 3-furrow, automatic-lifting plough, width of work, 35 in.; very good work; average working speed, 7992 ft. per hour.

MOLINE: 2-furrow plough; width of work, 27 in. The area worked per hour and the average speed were not determined; the fuel-consumption indicated in the table is approximate.

The area ploughed per hour and the fuel-consumption per acre agree very well with the results obtained with the same machines in the trial at Noisy-le-Grand, France, in 1917 (1).

453 - **The Application of Electricity to Agriculture in France.** — DABAT, in *Comptes Rendus des Séances de l'Académie d'Agriculture de France*, Vol. III, No. 41, pp. 1138-1155. Paris, December 26, 1918.

The author considers the present importance of the various uses to which electricity may be put in agriculture, and suggests ways of developing the extended use of electricity on farms.

Manual labour, now of increasing scarcity, should be partly replaced by machinery. Great progress has been made by using internal combustion, gas and steam engines. Electricity, though already used in agriculture, is not employed as much as it ought. Electric motors have many advantages over internal combustion engines, which are much more generally used in

(1) See R., November 1917, No. 1051 and R. January 1918, No. 81. (Ed)

agriculture and they are cheaper. However, for mechanical ploughing the electric motor is superior to the steam engine. But in spite of its qualities, the electric motor may be less economical. If certain uses of energy could support the present sale prices, for many others (motorculture, threshing cereals) the price of 15 to 20 centimes the kw-hour should not be passed. For irrigation and drainage works, the tariff would have to be lower, according to the lift required. To lower the sale price, the height of which results from the small and discontinuous demand for farm use, farmers should unite in groups comprising enough members to represent current and number of working hours of importance. On the other hand, the State should intervene and use all possible means to obtain low tariffs for farmers. The energy being supplied at rates suiting the farmers, they should remove the obstacles formed by certain methods of farming so as to derive the greatest benefit from the use of electricity.

The foundation of hydroelectric works constitutes one of the most important factors in lowering the cost of electric energy. France has, in its watercourses, an enormous quantity of latent energy, estimated statistically at from 4 to 5 million HP. at low water and 9 to 10 million at an average level; while the total nominal HP. of steam engines in France amounts to 15 million HP. It follows that the coal beds decrease every year while the water-power remains unchanged.

The adaption of watercourses for the production of electricity only dates back some twenty years. Before the war the total water power in use amounted to 620 000 HP., of which 380 000 HP. were distributed, the rest being utilised on the spot. Since 1914, the total water power, employed or about to be employed, has increased by 400 000 HP.

The author quotes various technical, administrative or legislative measures taken by the Minister of Agriculture to develop the utilisation of "white coal".

From the technical point of view, the work of the "Services des Grandes Forces hydrauliques", often praised by both French and foreign scientists and engineers, will eliminate the necessity for private individuals of long and costly study regarding the exploitation of watercourses.

Regarding administration and legislation, the Minister of Agriculture has drawn up rules for Communes when about to transfer their water rights and he has put forward several bills attempting to remove the hindrance caused by the present legislation to the industrial use of watercourses. To obtain reduced tariffs for agricultural work, he has obtained that the principle of reduced tariffs in favour of syndicates should be inserted in the contracts. The obligation of furnishing current at low prices is also provided for in various concessions for works on rivers of the public land conceded by the Minister of Public Works. The text of a recent bill regarding *all the categories of watercourses* not only gives concessions to syndicates, but also to *agricultural groupings of any kind*. The bill contains clauses requiring industrial concession-holders to provide reserves of water and current for agriculture and accords reduced tariffs to all agricultural groupings of general interest.

The Minister of Agriculture also helps to organise coöperative societies for the generation and distribution of energy. The State, in this case, has helped financially as well as providing for the collaboration of the technical experts of the Service for agricultural improvements. The Minister has also profited from the establishment of works founded since the war to intensify the production of chemical fertilisers. To this end, some contracts require that, for a certain period of years after peace has been declared, considerable amounts of energy shall be provided for the manufacture of calcium carbide and cyanamide.

For some years, the electrical distribution societies have completely neglected to obtain the custom of farmers. But they have finally realised that if, when commercing work, they were justified in seeking more paying customers (lighting, transport, industry), it would have been better management to seek other outlets, such as agriculture, which, by means of lowered tariffs, would consume that surplus energy which is often too difficult to utilise. Accordingly the distributors have decided to do propaganda work to interest farmers in the uses of electricity in agriculture. The electrical exhibition at Marseilles (1908), the international electrocultural congress at Rheims (1912), the general agricultural competition of 1913, have greatly contributed to a more widely diffused knowledge of the application of electricity to agriculture. Some distributing societies addressed the farmers directly. For example, the Motive Power Society of Refrain, at Montbéliard, should be mentioned, as it has installed electricity in several agricultural villages, under the stipulation that if the consumers were not satisfied, the current would be withdrawn and no charges made. In every case the installation has been retained.

The author thinks that the State should encourage these societies to continue in this way, by helping to form agricultural associations for using energy in common. In this way, not only would the total energy required by farmers increase, but the hours of current consumption would be greater owing to circulation established between the associations. Whilst distributing energy among the consumers to as to reduce variations of load while increasing its duration, thus playing a similar part to the syndical associations for the distribution of irrigation water, the association would reduce the concession-holders' expenses and assist development. If new lines have to be installed to supply the agricultural consumers, the association will help to equalise the charge on the capital invested by dividing it among a large number of consumers. The association has also the advantage of buying the more expensive apparatus to be used in turn by the members.

The author shows that the State rather than distribution societies should found these associations. The distributors might hesitate on account of the time and capital required and become discouraged by the set-backs always produced by attempts to unite agriculturists. The State has more powerful means of action and it should intervene all the more, seeing that these collective organs would not only be useful for furnishing energy, but would enable all sorts of agricultural improvements to be carried out: threshing in common, co-operative dairies, distilleries, etc.

The author also points out the value of State help in showing the most economic and suitable method of utilising energy, so that all possible facilities may be obtained from the distributors and full profit from the advantages given them by law. In the case where the supplying of farms would require the extension of a distribution network, and the cost would fall on the consumers, the project might be formulated by the technical experts of the Service for agricultural improvements, who would supervise the work, while the cost would be lightened by subventions and loans from State funds. This technical and financial aid would always be given to farmers whenever the utility of forming a special service for production and distribution is recognised.

It is to be hoped that the co-operative movement, first intended for the common working of farm products, with oil works, cooperative wine-cellar, and continued by the common purchase and use of threshing machines, will extend to the generation and distribution of electric energy. Thanks to the various measures now under discussion, which will be supplemented by active propaganda, the agricultural use of electricity will be rapidly developed, to the great profit of French agriculture.

454 - **Tractors in the United States.** — I. Extract from the *American Thresherman* published in the U. S. Department of Agriculture Experiment Station Record, Vol. XXXVII, No. 4, pp. 387-288, Table. Washington, September, 1917. — II. RINGELMANN, MAX, in the *Journal d'Agriculture pratique*, Year LXXXII, Vol. XXXI, No. 2, p. 30. Paris, January 24, 1918.

I. — Tabulated data concerning the operations of 50 large tractors and 37 small tractors during 1916-17. Fifteen of the large tractors used gasoline and 44 used either kerosene or distillate.

The relation of horsepower to work is shown in the following table:—

Rating of tractors HP.	Area ploughed in 10 hours, acres.	Rating of tractors. HP.	Area ploughed in 10 hours, acres.
5-12	6.30	15-30	11.80
8-16	6.60	25-45	19.20
10-20	7.70	30-60	21.00
12-25	9.00	40-60	25.75

II. — M. RINGELMANN observes that the figures apply to lighter soils than those in France, with more shallow ploughing, and a longer furrow-length. So, to obtain figures applicable to France, M. RINGELMANN multiplies the figures given above by 0.7.

According to the report, 72 holders out of 96 stated that the work done by tractor costs less than that done by horses. On the other hand, 40 holders having tractors of over 30 HP. were in favour of mechanical traction, while two years ago there were only 30 in favour. Amongst 27 holders having tractors of less than 30 HP., 33 declared in favour in the previous year, while in the present report only 30 were favourable to mechanical cultivation.

455 - **The Conversion of Motocars into Tractors** (1). — I. The "Shofield" Auxiliary Wagon. *Le Genie Rural*, Year X, No. 78, pp. 8-9, 3 Fig. Paris, 1918. — II. The "Tracford" Conversion Unit. *The Implement and Machinery Review*, Vol. XXXXIII, No 513, p. 958, 1 Fig. London, January 1, 1918.

I. — The SHOFIELD Co. of Kansas City, U. S. A., have a useful device which enables a motorcar to be used as a tractor with only slight change. The device consists of an auxiliary wagon which is towed on the road by the motor car, while the latter is mounted on the wagon in the field.

When on the wagon, the car is held firmly on a two U shaped rails in which the automobile wheels engage. The back wheels of the wagon, serving as driving wheels, have each a rim with internal teeth which engage with a gear whose axle turns on a bearing fixed on the wagon; this axle carries a sprocket wheel. Another sprocket wheel is mounted on the hub of each rear wheel of the car. The two sprockets are connected by a chain. The rear of the car is lifted until the 2 chain drives are sufficiently taut; then the driving wheels of the car turn freely, the movement being transmitted to the rear wheels of the wagon. The front wheels of the wagon can be steered by a wheel placed by that of the car, but which turns vertically. According to the inventor, mounting requires about 10 minutes.

II. — Another conversion unit to enable a FORD car to be used as a tractor, is the "Tracford", sold at £ 65 by the POWER FARM SUPPLY Co., Priory Lawn Chambers, Ellys Road, Coventry.

The device comprises a pair of large tractor wheels fitted with removable mud strokes, and mounted on a strong axle which is attached to the rear end of the frame of a FORD car. A pair of roller pinions replace the wheels at the end of the FORD axle and these pinions gear with a series of 8 gear sections of 7 teeth each, which are bolted to the inside of the tractor wheels.

The result is a 9 to 1 reduction in the gearing, the road speed being reduced  $\frac{1}{9}$ , while the power delivered at the axle is increased ninefold. A supplementary water tank is mounted over the engine, and a water circulator automatically provides forced circulation through the radiator. The tractor axle forms the draw bar.

The "Tracford" unit weighs less than 800 lb.; its axle is of 1. 15-16 in. solid steel and the wheels have a 10-in. face with angle-iron lugs attached.

456 - **Fuel Saving.** — STRITTMATTER, A., in the *Farm Implement News*, Vol. XXXIX, No. 1, pp. 36-38. Chicago, January 3, 1918.

While the actual production of petrol in the United States is 6 849 000 gallons per day, the Bureau of Mines estimates that 1 500 000 gallons are wasted daily through various losses, such as leaky tanks, badly-adjusted carburettors, motors running idle, waste in garages, etc. The Automobile Chamber of Commerce has suggested methods of economy which are quoted below:

1) Store petrol in underground steel tanks. Use wheeled steel tanks with measuring pump and hose. They prevent loss by fire, evaporation and spilling.

2) Don't spill or expose petrol to air — it evaporates rapidly and is dangerous.

(1) See R. June 1917, No. 577 and December 1917, No. 1204 (Ed.).

- 3) Don't use petrol for cleaning or washing — use other materials to remove grease.
- 4) Stop all leakages. Always shut off gas at tank or feed pipe.
- 5) Adjust brake bands so as not to drag. See that all bearings run freely.
- 6) Don't let engine run while car is standing. It is good for the starter battery to be used frequently.
- 7) Have carburetors adjusted by the makers or by automobile companies.
- 8) Keep needle valve clean and adjust carburetor (while engine is hot) to use as lean mixture as possible. A rich mixture is wasteful.
- 9) Preheat air entering carburetor and keep radiator covered in cold weather to ensure better vaporization.
- 10) Time spark correctly and drive with spark fully advanced — a late spark increases gas consumption.
- 11) Have a hot spark; keep plugs clean and spark points properly adjusted.
- 12) Avoid high speed. The most economical speed is 15 to 25 miles per hour.
- 13) Don't accelerate and stop quickly — it wastes gas and wears out tyres.
- 14) Avoid aimless and needless use of cars. Do a number of errands in one trip.
- 15) Find out the mileage per gallon. Fill tank full and divide odometer mileage by gallons consumed.

The author considers these rules at length: He points out that, with farm engines, carburetor adjustments are easily made while the engine is running, largely by watching the character of the exhaust and the noise it makes. Although the last three rules apply to motorcars, the last one is useful for a farmer using a tractor. He ought to know how much fuel the tractor uses in plowing a certain field or doing some piece of work, such as filling a silo.

457 - **Fire Prevention and Fire Fighting on the Farm, in U. S. A.** — TOLLEY, H. R. and YERKES, A. P., in *United States Department of Agriculture Farmers Bulletin* No. 904, pp. 16, 1 Fig., bibliography of 11 publications. Washington, D. C., January, 1918.

Organised fire prevention is still neglected in farms, as few farmers have considered the means to adopt for preventing and fighting fires. Yet millions of dollars' worth of agricultural wealth is destroyed by fire in the United States each year. At normal prices and with an average crop, the loss is about equal to the value of the potato crop in that country. This bulletin is intended to interest farmers in fire prevention on his own premises and to urge him to eliminate all unnecessary fire hazards, while providing all required facilities for fighting fires.

The writers consider the common fire hazards and point out that, as regards the spontaneous combustion of hay stacks, the first cut of alfalfa seems to be the most dangerous in that respect. In addition, precautions should be taken in buildings where incubators, brooders, evaporators, and other equipment requiring the use of fire are housed.

Farmers' Bulletin 842 of the U. S. Department of Agriculture gives directions for installing modern lighting rods. In some instances, farmers' mutual fire insurance companies make reductions on the premiums charged on rodded buildings.

As regards methods of fire fighting, water is the simplest and cheapest fire extinguisher; pails of water should always be placed in every farm building so as to be instantly available in case of need. Water-supply systems

which furnish water under pressure afford excellent facilities if the necessary hose and connection are always ready for use.

Amongst chemical extinguishers carbonic acid is that most generally used. More than 20 firms manufacture soda-acid extinguishers costing from \$7 to \$12. They are of simple construction and can throw a stream from 25 to 40 feet for about a minute. These extinguishers can be refilled and used many times.

Another type of chemical extinguisher consists of a metal syringe filled with carbon tetrachloride, a liquid that only freezes at  $-50^{\circ}\text{F.}$ , and which, at about  $200^{\circ}\text{F.}$ , turns into a heavy vapour which covers and smothers the fire. It is very useful in extinguishing burning oil, gasoline, or kerosene, on which water or carbonic-acid gas extinguishers have little effect. An extinguisher of this type costs about \$8 and liquid for refilling it can be purchased for about \$1.50; it is approved by all fire insurance companies.

In Department Bulletin 379 of the U. S. Department of Agriculture an automatic fire extinguisher (1) for use in grain separators is described which can also be used for general fire protection on the farm when the separator is not in use. Besides these types there are also dry-powder extinguishers consisting of metal tubes filled with powder, and hand-grenade extinguishers.

It should not be forgotten that sand is a very good extinguisher of burning oil; in such a fire, water is of no use, unless applied in large quantities. Sawdust mixed with soda at the rate of a bucket of sawdust to 1 or 2 lb. of soda is a good extinguisher of oil fires, especially if the oil is in a deep container.

459 - **The Construction of Poultry Houses, in U. S. A.** — SCHOPPE, W. F., in the *Montana Agricultural College Experiment Station, Circular No. 72*, pp. 49-69, Figs. 11, Bozeman Montana, September, 1917.

The proper and comfortable housing of poultry is essential to maintain their health and vigour. Abundance of sunshine and fresh air should be provided for, and the system of ventilation should be arranged so as to remove all dampness, while constantly changing the air.

The poultry house should be so high as to allow head room for the attendant. Such low houses are less affected by outside temperatures and are more comfortable for the birds. The width of the house more or less depends upon the type of roof. For northern conditions with cold winters, the wide house is to be desired. This allows the roosts to be placed at the back and keeps the birds away from the open front. The sun shining into a wide house warms it more easily. The house should be so placed that the sun shines in at the openings every hour of the day, especially in winter. A good rule for placing windows is to allow 1 square foot of glass for every 4 birds. The author describes the different types of houses, giving all details required for the construction of a house 16 × 26 feet. The poultry house in use at the Montana Experiment Station is narrow, 12 ft. wide and with a shed roof. It has proved fairly satisfactory, but would have been better if it had been built wider. The front of each pen is provided with a door and two windows, one glazed, the other of wire netting. The wire netting can be covered with a curtain to shelter the birds against winter cold and summer heat. Each pen is made 12 × 16 ft, thus housing 50 birds. The back wall is 6 ft. and the front wall 8 ft. high. This poultry house in reality consists of a number of pens joined up in a straight line.

The details of construction of the houses, which are particularly suitable for Montana conditions, are shown in figures.

## RURAL ECONOMICS.

460 - **Cost of Keeping Farm Horses and Cost of Horse Labour in the United States.** —

COOPER, M. R., in *United States Department of Agriculture, Bulletin No. 560* (Office of Farm Management), pp. 1-24, Washington, D. C., July 9, 1917.

The cost of horse labour has a bearing on the net return of every farm enterprise, but being chiefly made up of items of expense representing materials furnished by the farm and not involving a direct cash outlay is not fully appreciated by farmers who have not made a study of the subject.

This bulletin shows how the annual cost of keeping a farm work horse and the cost per hour worked may be determined, and points out that the cost per hour worked is the true measure of the profitableness of a horse to its owner.

The data presented were obtained from cost-accounting records for 316 horses on 27 farms in three States, namely Illinois, Ohio and New York. The cost records kept on these farms consisted of detailed daily reports of

all labour and financial transactions, complete inventories and other necessary information for determining not only the costs and returns of farm work horses, but also the costs of operation and returns from the entire farm business.

A detailed summary of the annual average cost per horse, and the percentage of the total gross cost represented by each item for the horses studied in each State, will be found in Table I.

TABLE I. — *Detailed summary of average annual costs and credits per horse by States (37 farms, 316 horses).*

GROSS COSTS

Item	Illinois (154 horses)		Ohio (72 horses)		New York (90 horses)	
	\$	%	\$	%	\$	%
Feed and bedding . . . . .	68.75	65.0	76.86	58.8	91.25	57.1
Labour . . . . .	13.99	13.2	27.48	21.0	22.09	13.8
Interest . . . . .	7.90	7.4	8.66	6.6	9.43	5.9
Stabling . . . . .	4.95	4.7	7.18	5.5	12.08	8.1
Use of equipment . . . . .	3.82	3.6	5.00	3.8	5.85	3.7
Shoeing . . . . .	0.86	0.8	2.35	1.8	4.56	2.9
Depreciation . . . . .	3.46	3.3	—	—	11.56	7.2
Net loss on colts . . . . .	0.04	—	1.24	1.0	—	—
Miscellaneous . . . . .	2.12	2.0	1.90	1.5	2.09	1.3
Total . . . . .	105.89	100.0	130.67	100.0	159.81	100.0
CREDITS						
Manure . . . . .	5.24	—	8.20	—	13.36	—
Horse appreciation . . . . .	—	—	2.10	—	—	—
Colt profit . . . . .	—	—	—	—	1.43	—
Total . . . . .	5.24	—	10.30	—	14.79	—
NET COST						
Cost of keeping, less credits . . . . .	100.65	—	120.37	—	145.02	—

These gross costs and net costs represent the average cost of the work performed by the horse. It will be seen that, with few exceptions, each item of cost was greater in Ohio than in Illinois, and still greater in New York.

This variation in average cost is discussed by the writer analytically for the different items of cost and credit.

*Kinds of Feed.* — The number of kinds of feed used were 11 in Illinois, 16 in Ohio and 18 in New York. In all cases the principal feeds used were maize, oats, hay, straw and pasture, representing 97 % of the total feed cost in Illinois, 94.5 % in Ohio, and 88 % in New York.

Corn was the principal grain fed in Illinois, oats in Ohio and New York. The greatest quantity of hay per horse was fed in New York, and the most pasture per horse was used in Illinois (4.93 months, against 2.26 in Ohio and 1.13 in New York).

*Cost of Feeds.* — In Table II the feeds are divided into three classes, namely, grain, roughage and pasture by States.

TABLE II. — *Average quantity and cost of grain, roughage and pasture per horse by States (27 farms, 316 horses).*

Kind of feed		Illinois (154 horses)		Ohio (72 horses)		New York (90 horses)	
		Average quantity per horse	Average cost per horse	Average quantity per horse	Average cost per horse	Average quantity per horse	Average cost per horse
Grain . . . . .	lb. 4 500		\$44.93	3 347	\$40.71	2 691	\$38.55
Roughage . . . . .	lb. 4 224		16.13	6 660	32.65	9 513	51.20
Pasture . . . . .	days 148		7.69	68	3.50	34	1..50
			\$68.75		\$76.86		\$91.25

These costs are based on the values of feeds at the farm for feed raised, and on actual cash costs for feeds purchased. The price of corn in New York f. i. as compared with Illinois is 42 per cent. greater, and of oats 36 per cent. greater, while the price of hay is only 9 per cent. more in New York than in Illinois.

It is evident that variation in feed prices had a marked influence on the total feed cost per horse in each State.

In Table III are shown the variations in monthly feed costs on three individual farms, one from each of the three States.

TABLE III. — *Variation in feed costs, by months, on three individual farms situated in Illinois, Ohio, and New York respectively.*

Month	Illinois \$	Ohio \$	New York \$
March . . . . .	8.68	7.75	7.94
April . . . . .	7.65	7.30	7.68
May . . . . .	7.34	8.42	10.39
June . . . . .	6.66	7.30	10.68
July . . . . .	7.00	7.20	7.93

September . . . . .	4.58	6.66	7.53
October . . . . .	4.32	6.29	6.23
November . . . . .	4.67	5.40	6.22
December . . . . .	4.40	5.70	6.56
January . . . . .	4.40	5.94	6.56
February . . . . .	4.23	6.42	5.92
Average . . . . .	5.72	6.74	7.62

*Labour costs.* — Labour includes the number of hours of both man and horse labour devoted to feeding and taking care of the horses, cleaning stalls, hauling feed and supplies, and to any other labour performed for the benefit of the horse. The hauling of manure from the barn and barnyards is not charged against the horses, but becomes part of the manure cost charged to the crop on which it is applied. The number of hours, cost per hour, and total cost per hours of man and horse labour devoted to the care of horses is shown in Table IV.

TABLE IV.—*Number of hours, cost per hour, and total cost per horses of man and horse labour devoted to the care of horses by States (27 farms, 316 horse).*

Kind of labour	Illinois (154 horses)			Ohio (72 horses)			New York (90 horses)		
	Hours	Cost per hour Cents	Total cost \$	Hours	Cost per hour Cents	Total cost \$	Hours	Cost per hour Cents	Total cost \$
Man labour . .	85.2	14.95	12.74	164.6	16.00	26.34	127.3	16.40	20.88
Horse labour . .	13.1	9.56	1.25	8.2	13.90	1.14	8.5	14.22	1.21
Total . . .			13.99			27.48			22.09

*Interest on value of horses.* — The average value of the horses studied in this work were as follows: Illinois, \$158; Ohio, \$173; New York, \$189.

*Stabling Cost.* — This cost, calculated on a 5 per cent. interest on the part of buildings used for stabling horses, varied from 4.7 per cent. of the total gross cost of keeping in Illinois to 8.1 per cent. in New York.

*Use of Equipment.* — In Illinois this cost calculated on a 5 per cent. interest on the average investment in harness and miscellaneous equipment used by horses, both cash and labour for repairs, insurance, taxes and depreciation, was about \$4 per head and \$1 and \$2 higher in Ohio and New York respectively.

*Shoeing.* — On many of the farms this expenditure was of minor importance, since the horses were not shod except when needed for heavy road work or when used on frozen ground. The average cost was therefore only \$0.86 in Illinois, \$2.35 in Ohio, but \$4.56 in New York.

*Depreciation and Appreciation.* — In determining depreciation and appreciation in value of horses a yearly inventory value was placed on each horse on the farm by careful appraisal and a record was kept of each horse bought and sold. Table V shows the percentage of horses that appreciated in value, the percentage that did not and the factors influencing the aggregate depreciation or appreciation by States.

TABLE V.—*Percentage of 316 horses that appreciated in value, percentage that did not appreciate, and the factors influencing the aggregate depreciation or appreciation, by States (27 farms, 316 horses).*

State and number of horses	Percentage of horses that showed		Num-ber of deaths	Num-ber bought	Num-ber sold	Num-ber of colts bought	Num-ber of colts sold	Num-ber of colts fed
	Appreciation	No appreciation						
Illinois (154 horses) . . . . .	18.75	81.25	3	21	21	2	—	43
Ohio (72 horses) . . . . .	21.95	78.05	—	9	17	2	1	7
New York (90 horses) . . . . .	4.95	95.05	6	6	3	1	2	18
The three States (316 horses) . . . . .	15.60	84.40	9	36	41	5	3	68

The average net depreciation of the 316 horses was \$4.50 per horse. Depreciation varied from \$11.60 per horse in New York, to an apprecia-

tion of \$ 2.10 per horse of Ohio. (On 378 farms studied in Chester County, Pa. the average depreciation resulting was \$ 7 per head, largely determined by the practice of farmers in disposing of horses while they are still saleable at a satisfactory price. On 14 New York farms in 1912 and 31 in 1913 the average annual depreciation was found to be \$ 14.03. Of the 35 farms studied, 12 showed an appreciation of horses. In Rice County, Minnesota, depreciation varied from \$ 0.98 in 1905 to \$ 15.48 in 1904, averaging for four years \$ 5.56 per head; in Lyon County it averaged \$ 6.94 and in Norman County \$ 5.82 per head.

*Profit and loss on colt account.* — Of the 43 colts fed on the Illinois farms 19 were born during the years of the survey and showed a loss of 4 cents per head, in Ohio \$1.24 per head, while on the New York farms the colts showed an average profit of \$ 1.43 per head. This survey proved that only under favourable conditions is the raising of colts one way of keeping down the cost of horse labour.

*Miscellaneous costs.* — Including insurance, share of taxes, veterinary services and medicine, etc., varied from \$ 1.90 on the Ohio farms to \$ 2.12 in Illinois.

*Manure.* — Horses were credited with only the manure recovered from the stables and feed lot, which was valued at \$ 1 per ton before removal. The average manure credit was greatest in the States where the horses were fed the largest quantities of grain and roughage and pastured the least number of days.

*Variations in net costs.* — Including in one group those years for which the net cost per horse was greater than the average for the State and in another group those years for which the net cost per horse was less than the average for the State, the following differences, shown in Table VI, between the group above the average cost and the group below the average cost were obtained.

TABLE VI. — *Detailed difference in costs and credits between records showing a net cost per horse above the average and below the average. (10 farms, 154 horses).*

State	Feed (cost) \$	Labour (cost) \$	Depre- ciation (cost) \$	Appre- ciation (credit) \$	Colt loss (cost) \$	Colt profit (credit) \$	All other costs \$	Manure (credit) \$
Illinois farms . .	18.05	4.24	1.96	—	3.92	3.38	2.59	0.39
Ohio farms . . .	32.11	7.59	0.07	4.50	2.86	0.34	4.78	2.19
New York farms	9.41	1.68	5.13	—	0.14	3.70	8.90	1.90

*Relation of the work performed to the total feed cost.* — In order to show the relation if any, existing, between the total work done by a horse and the total cost of feed, which is the greatest item of cost in keeping a farm work horse, the yearly records for each State were divided into two groups with reference to the average total work done per horse. The first group contains the data for those farms on which the horses worked more hours than the average for all records in that State. The second group contains data for those farms on which the hours worked per horse were less than the average for the State group. (See Table VII).

TABLE VII. — *Relation of work done to the total feed cost by States*  
(27 farms, 316 horses).

	Illinois (154 horses; average hours worked, 1053)			Ohio (72 horses; average hours worked, 867)			New York (90 horses; average hours worked, 1020)		
Records with work hours per horse	Aver- age hours worked per horse	Aver- age feed cost per horse	Aver- age feed cost per hour	Aver- age hours worked per horse	Aver- age feed cost per horse	Aver- age feed cost per hour	Aver- age hours worked per horse	Aver- age feed cost per horse	Aver- age feed cost per hour
Above the average (1) . .	1200	\$75.20	\$0.063	1055	\$89.00	\$0.084	1172	\$97.30	\$0.084
Below the average (2) . .	880	\$67.30	\$0.077	723	\$67.30	\$0.093	863	\$85.00	\$0.098
Difference . .	320	\$7.90	\$0.014	332	\$21.70	\$0.009	309	\$12.30	\$0.014

(1) Records: Illinois 8, Ohio 7, New York 9. (2) Records: Illinois 9, Ohio 9, New York 9.

This table shows that there is a relation between the work done and the quantity of feed consumed per horse, but the excess in feed cost for the harderworking horses is more than offset by the extra number of hours worked by them, so that the average feed cost per hour of labour in this group was about 1  $\frac{1}{2}$  cents less on the Illinois and New York farms and about 1 cent less on the Ohio farms.

On an average on the farms studied there was a fairly uniform difference between the average feed cost and the total cost per hour of horse labour, showing that the number of hours worked and the feed cost per horse are the controlling factors in the total cost per hour of horse labour.

*Cost of horse labour per hour.* — The cost of horse labour depends on the net cost yearly to keep a horse, and the total amount of work done (See Table VIII).

TABLE VIII. — *Cost of horse labour per hour* (27 farms, 316 horses).

State	Average hours worked			Average net cost per horse	Average cost per hour worked
	Per year	Per week day	Per Sunday		
Illinois (154 horses) . .	1053	3.30	0.10	\$100.65	\$1.0056
Ohio (72 horses) . . . .	866	2.70	0.46	\$120.37	\$0.1390
New York (90 horses) . .	1020	3.24	0.13	\$145.02	\$0.1422

*Labour performed by months.* — In each State very little labour was performed by the horses during January; February, 30 to 40 hours; about 60 hours in March. Thereafter the work increased until, during May, the maximum for any one month was reached (182 hours in Illinois, 168 in New York and 120 in Ohio). From then on to the end of the year there was a fairly uniform decrease in the hours worked per month. In New York and Illinois the increases in October and November (95 and 85 hours respectively) are due to grain threshing and maize harvest. In Illinois the greatest amount of extra horse labour was required during August, in Ohio, and October in New York. This extra horse labour was usually

exchange work among neighbours, the major part being used in grain threshing, maize harvest and autumn seeding.

Table IX shows the average number of week days when no horse labour was performed, by months.

TABLE IX. — *Average number of week days when no labour was performed, by months.*

Month	Illinois (10 farms)	Ohio (7 farms)	New York (10 farms)	Month	Illinois (10 farms)	Ohio (7 farms)	New York (10 farms)
January . .	8.3	9.7	12.4	July . . .	1.2	3.1	1.5
February . .	5.8	7.0	9.5	August . .	3.8	2.1	5.3
March . . .	7.0	6.8	12.0	September.	3.0	4.0	3.5
April . . .	2.7	4.6	4.6	October . .	3.5	5.4	4.8
May . . . .	5.0	2.2	1.3	November.	1.9	3.5	5.8
June . . . .	1.1	2.5	1.2	December .	5.1	7.6	11.3
				Total . . .	48.4	58.5	73.2

*Relation of total crop acres per farm to crop acres per horse.* — This relation is shown in Table X.

TABLE X. — *Relation of total crop acres per farm to crop acres per horse by States (27 farms, 316 horses).*

	Illinois (10 farms; average size 166 acres)		Ohio (7 farms; average size 74 acres)		New York (10 farms; average size 94 acres)	
	Average per farm	Average per horse	Average per farm	Average per horse	Average per farm	Average per horse
	Acres	Acres	Acres	Acres	Acres	Acres
Farms above the average size	230.2	22.2	93.7	17.8	112.74	20
Farms below the average size.	111.2	16.8	54.7	14.6	70.07	17
Difference . . .	119.0	5.4	39.0	3.2	42.67	3

From these figures it appears that the large farms permit of a more efficient use of horse labour than do the small farms. On the large farms in Illinois there were 22.2 acres in crops per horse while on the small farms there were but 16.8 acres per horse. Similar results were found on both the Ohio and the New York farms, though in these States the difference between the two groups was not as great as in Illinois.

## AGRICULTURAL INDUSTRIES.

461 — **New Method for the Separation and Estimation of Lactic, Succinic and Malic Acid in Wine.** — LABORDE, J., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXV, No. 23, pp. 793-795. Paris, December 3, 1917.

As the methods in general use are unsatisfactory, the author describes a new one which gives good results, not only with wines poor in sugar, but also in very sweet wines.

INDUSTRIE  
DEPENDENT  
ON PLANT  
PRODUCTS

I. — UNSWEETENED WINES. — In the case of red wines the tannic substances are first removed as follows :— 50.cc. of the wine is taken, and the acidity neutralised by a volume  $V$  of normal potash equal to the total acidity. A 5 % mercuric acetate solution is then added, avoiding an excess of mercury salts, until the tannic substances are almost completely precipitated ; the mixture is heated to about 50° C. and the precipitate washed twice with warm water.

In the case of white wines this preliminary operation is necessary only if the proportion of tannin is about 1 gm. per litre; it is sufficient to neutralise the acidity of the wine with normal potash.

To the liquid thus obtained is added a volume  $S$  of normal  $H_2SO_4$  so that  $S = V = n$ ; the volume  $n$  depends on the difference in the total alkalinity of the ash  $A$  expressed as cream of tartar and the alkalinity  $T$  of the cream of tartar corresponding to the tartaric acid of the wine ; if  $T$  is greater than  $A$ ,  $n = -(T-A)$ , and if  $A$  is greater than  $T$ ,  $n = +(A-T)$ .

The solution is then concentrated in an evaporating dish until the mixture is syrupy : 5 cc. of water are added and evaporation continued to drive off the volatile acids, the dry extract made syrupy again by the addition of a few drops of water; 0.20 gm. of pure bone charcoal is added, with sufficient pure sand to divide the mass and facilitate its removal from the dish. The mixture is then poured into a conical flask, the dish rinsed with a little sand and 25 cc. of 95° alcohol, which are used to extract the free acids. To facilitate this extraction 50 gm. of No. 4 lead shot are poured into the flask which is shaken with a circular movement to divide the lumps of sand ; 50 cc. of ether are added, the flask shaken, and after it has been left standing for a few moments, the solution is poured on to a flat filter, and the deposit washed three times with a mixture of equal volumes of ether and alcohol. The filtrate contains lactic, succinic and malic acid, but no tartaric acid, which remains in the deposit as cream of tartar. The liquid is distilled until only a few cc. of yellow-brown alcohol are left, which are decolourised with 0.20 gm. of bone charcoal and 10 cc. of water, filtered, and washed with tepid water. The aqueous solution of the acids is concentrated by boiling, neutralised in the presence of phenolphthalein until the pink colour caused by an excess of 0.5 cc. alkaline liquid remains for about 15 seconds in the boiling liquid. The calcium salt solution is concentrated to 8 or 9 cc., a drop of 50 % acetic acid added, and the calcium lactate separated by adding rapidly 90 cc. of 95° tepid alcohol. In this alcoholic liquid of about 85° the calcium lactate remains in solution; whereas the malate and succinate are completely precipitated. The mixture is boiled to coagulate the precipitate, and after cooling, is filtered and washed with 85° hot alcohol. The estimation of the calcium in the filtrate gives the corresponding quantity of lactic acid.

The precipitate left on the filter is treated with boiling water, which re-dissolves it completely (except for a little calcium phosphate), it is then concentrated to about 8 cc., 1 cc. of glacial acetic acid added, then 90 cc. of 95° alcohol, which precipitates the calcium malate only or the malate and nitrate if the wine contains citric acid. The solution is filtered and washed

with 85° slightly acetic alcohol. The estimation of the calcium in the filtrate gives the corresponding succinic acid. By treating in the same way the precipitate left on the filter, which is re-dissolved with boiling water, the malic acid is determined.

II. — SWEET WINES. — The wines are subjected to a preliminary treatment to separate the tannins, then acidified with normal  $H_2SO_4$ . The mixture is evaporated till syrupy, the lead shot added, together with 10 to 12 cc. of alcohol according to the amount of sugar and finally 50 cc. of ether a little at a time, shaking the lead meanwhile. A white emulsion, which turns into a syrupy liquid is formed. After it has been left for a short time the ether alcoholic liquid is poured on to a filter, and the extraction with alcohol and ether repeated 2 or 3 times. The mixture is then distilled, and the alcoholic residue contains the soluble acids. The mixture is evaporated to dryness in an evaporating dish and the dry extract obtained treated as in the case of unsweetened wines, or those poor in sugar.

The proportion of succinic acid in normal wine is about 0.70 gm. per litre, whereas the amount of lactic and malic acid varies considerably according to the origin and state of preservation of the wine.

462 — **Alcoholic Fermentation of the Jerusalem Artichoke.**— See No. 399 of this *Review*.

463 — **Characteristics and Quality of Montana Grown Wheat.** — LEVI, M. THOMAS, in *U. S. Department of Agriculture, Bulletin No. 522*, 34 pp., 13 Tables, 17 Fig. Washington, D. C., May 18, 1917.

Five distinct commercial classes of wheat are produced in Montana, which may be conveniently designated as hard spring, hard winter, western red, western white, and durum. The two first-named classes are of about the same milling quality, except that the spring wheat is decidedly superior in baking strength. The wheats of these two classes also resemble each other closely in physical characteristics and composition; both are best suited for the production of a bread flour.

The flour from the western red and western white wheat is very low in strength and absorption and has the general characteristics of other soft wheat flours. The flour is best adapted for the production of crackers and pastry products. The bread produced from this wheat is very close textured and heavy. Durum wheat is decidedly different from the wheat of any other class. Although generally yielding a high percentage of flour, the flour is usually very creamy or yellow in colour and consequently receives a low score for colour. In spite of the fact that the flour contains a very high percentage of crude protein (13.84 % in the 3-year average 1908, 1911-1912 of the analysed samples) it falls between the hard winter and western red wheats in baking strength. In water absorption the flour is slightly superior to that of all other classes. The flour from this wheat is not popular for bread-making purposes on account of its creamy colour but it is especially adapted for the manufacture of macaroni and similar products.

A comparison of the average results of tests with the wheat of the five classes is presented in the annexed table.

*Average results of all baking tests of each of the five classes of Montana wheat.*

Class of type	Number of samples	Yield of straight flour	Colour of bread	Tests of straight flour						Crude protein in wheat N $\times$ 5.7	Moisture in wheat
				Absorption of water	Strength		Crude protein in flour N $\times$ 5.7	Moisture in flour			
					Volume of loaf *	Texture of loaf					
		per cent.	Score	per cent.	C. c.	Score	per cent.	per cent.	per cent.	per cent.	
Hard red spring, 5 year average, 1908 to 1912 . . . . .	27	71.1	98	56.4	2.342	96	11.98	10.47	12.47	13.1	
Hard red winter, 5 year average, 1908 to 1912 . . . . .	79	71.8	97	57.1	2.142	94	11.73	9.89	12.20	12.4	
Durum, 3 year average, 1908, 1911, and 1912. . . . .	7	76.1	88	57.6	1.934	90	13.58	9.78	13.84	12.3	
Soft red winter (Western red), 4 year average, 1908 to 1911 . .	13	68.5	98	53.6	1.787	84	10.38	10.05	11.08	12.3	
Soft white wheat (Western white), 5 year average, 1908 to 1912. .	11	66.7	96	50.9	1.756	85	9.16	9.98	10.12	12.2	

(\*) 340 grams of flour were used in each instance.

464 — **The Catalase Activity of American Wheat Flours.** — BAILEY, C. H. (Division of Agricultural Bio-chemistry, Minnesota Agricultural Experiment Station), in *The Journal of Biological Chemistry*, Vol. XXXII, No. 3, pp. 539-545, 1 Table, 1 Fig. + Bibl. of 8 publications. Baltimore, December, 1917.

Nearly all animal and vegetable tissues have the power to decompose hydrogen peroxide with the evolution of molecular oxygen. This power was attributed to the action of several enzymes, till LOEW showed it to depend on one enzyme only, found in all living tissues, and called by him catalase. Its action, according to LOEW, is to destroy the peroxides, formed in the living cells by the action of other enzymes, called oxidases. This decomposition liberates the oxygen and isolates the radical of the peroxide. The presence of finely divided metals (spongy platinum, lead peroxide, manganese dioxide, etc.) also greatly hastens the decomposition of the hydrogen peroxide. The action of the catalase, however, shows it to be an enzyme; its activity is increased by raising the temperature 1.5 to 1.7 times per 10° C.; in a moist medium its activity is inhibited by a temperature of 70° C., although, in a dry medium, it remains active even at 100°. Certain toxic substances, such as hydrocyanic acid, hydrogen sulphide, ammonium, metallic nitrates, etc., make it inactive. These are properties common to all the diastases.

Many authors, particularly in Germany, had already shown that the quality of flour may be judged by the quantity of oxygen liberated from the hydrogen peroxide (WENDER, LEWIN, LIECHT, RAMMSTEDT), but most of the work done in Europe has not received sufficient attention in Europe. For this reason the author wished to ascertain whether the relation between the quality of the flour and the rate of decomposition of hydrogen peroxide also existed for American flours.

**APPARATUS AND METHOD.** — A 500 cc. capacity flask, submerged in a water bath kept at 20° C., is fitted with a three-holed rubber stopper; through

one of these holes is passed a 30 cc. separating funnel, with open top, through the second a delivery tube, through the third a tube connected with a 100 cc. Hempel-Winkler burette. All the tubes are fitted with glass stopcocks, and care is taken to see that the joints are tight.

One gram of flour is placed in a mortar and triturated with about 25 cc. of distilled water. This is poured into the flask, together with the washings from the mortar, and water added till a total of 100 cc. is reached. When the mixture is at the temperature of the thermostat (20° C.), 5 cc. of a perhydrol (30%  $H_2O_2$ ) solution made up of 1 part perhydrol and 4 parts water, is introduced through the funnel. When the water level in the burette is at zero, the stop-cock of the delivery tube and that of the funnel are closed, and the stop-cock of the tube communicating with the burette opened. Two readings are taken, one after 30 minutes, the other after 1 hour. The volume of gas in the burette is corrected to 20°C. and a pressure of 760 mm.

RESULTS AND CONCLUSIONS. — The appended table shows the results obtained from many flours supplied by various mills. The ash content is expressed in per cent., and the oxygen evolved in 30 and 60 minutes respectively in ccs. per 1 gm. of flour, and it is seen that, though the parallelism between the two is not exact, it is very close. With double the ash content the catalase activity increases about 340 % with treble the ash content, the activity increases about 500 %. The catalase activity, therefore, increases much more rapidly than the ash content, thus offering an advantageous method for grading flour which will dispense with the costly apparatus, — muffle furnace, platinum crucibles, etc. — generally used.

473 - **The Colon-Aerogenes Group from Silage.** — HUNTER, O W. (Bacteriological Laboratory, Kansas Agricultural Experiment Station), in the *Journal of Bacteriology*, Vol II, No. 6, pp 635-639; bibliography of 7 publications Baltimore, November, 1917.

A study of silage fermentation has shown the *colon* group to be a pre-dominating type in the early stages of ripening. Analyses of many samples of alfalfa, sugar-cane, maize and kafir forage at the time of filling the silo, gave counts varying between 1000 to 1 000 000 of these organisms per gram of fodder: Examination of various forage collected in the fields under aseptic conditions showed their presence in numbers ranging from 1000 to 100 000 organisms per gram. This shows that the common forage crops are natural hosts of the *colon-aerogenes* group, and that the large numbers found on the forage as it enters the silo are not due to contamination though handling and cutting, but represent, in a majority of cases, the actual number living in the forage.

Numerous workers have reported the presence of the *colon* group on grains, grasses and flowers, but have not agreed whether the presence of these organisms is due to faecal contamination or whether they represent a specific type characteristic of grains.

The author's preliminary investigations show that the *colon-aerogenes* group, common on forage, finds there an environment favourable to growth. Alfalfa was grown in the laboratory, all sources of contamination, except those from the soil, being prevented. Over 100 000 coli-like organisms per gram were found. The only possible source of infection from such organisms was through the root-system, which did not seem likely, or through contamination from the soil as the plants broke through, a source of undoubted importance.

The purpose of the author's experiments was to study the physiological activities of the *colon aerogenes* groups present in silage. He studied these activities in 110 cultures divided into four groups — *Bacillus coli-communis*, *B. coli-communior*, *B. (lactis) aerogenes*, *B. acidi (lactici)*. Of these cultures, 95 were isolated from various kinds of silage (53 from alfalfa, 39 from kafir, and 3 from maize), and 15 from alfalfa and kafir collected in the field under conditions as aseptic as possible.

The results showed 48.18 % of the microorganisms to be *B. (lactis) aerogenes*, 30.9 % *B. coli-communior*, 10.9 % *B. coli-communis* and 10 % *B. acidi (lactici)*. Classified according to origin by differentiation with methyl red, 79.08 % were of non-faecal strains and 20.9 % of faecal origin. All the strains represented by the *B. coli communis* and *B. acidi (lactici)* groups were faecal types, whereas those of the groups *B. coli communior* and *B. (lactis) aerogenes* were non-faecal types. A correlation between the Voges-Proskauer reaction and hydrogen-ion concentration was observed in all cultures; all cultures with a high hydrogen-ion concentration gave a negative Voges-Proskauer reaction, those with a low concentration gave a positive reaction. Litmus milk was coagulated by 90.9 % of all faecal strains, while 98.5 % of the non-faecal types showed only an acid reaction.

- 474 - **Preservation of the Roots of Jerusalem Artichoke.** — GÉNIN, JOSEPH, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 1, pp. 64-65. Paris January 9, 1918.

It is well known that, in April, the root grows, and that, in spite of all precautions, it empties and can no longer be used.

The author successfully employed the following method on his farm at Bourgain (Isère): — In March the whole harvest is gathered into a shed; the artichokes are passed through a root-washer and a root-cutter. They are then piled in empty wine casks. Before long they float in their own water; they are then weighted with a few stones and left till July or August when they are fed to livestock.

- 475 - **Cold Storage Butter.** — Abstract from the *National Food Magazine*, U. S. A., in *Cold Storage*, Vol. XXI, No. 238, pp. 10-11. London, January 17, 1918.

The preservation of the flavour of butter during cold storage has been the subject of close investigation by Dr. DON C. DYER, chemist to the Dairy Division of the U. S. Department of Agriculture. Dr. DYER's experiments show that the disagreeable flavours which arise in butter during cold storage result from a chemical change, caused by the slow oxidation of one or more of the non-fatty substances of the butter-milk; they are not due to oxidation of the fat itself. Moreover, the extent of this chemical change is in proportion to the acidity of the cream with which the butter is made. Dr. DYER overthrows certain accepted chemical theories. He believes that olein, which forms 35 % of the non-volatile constituents of butter fat, oxidises with great difficulty, and, probably, absorbs no oxygen whatever. For this reason the fault must be searched for elsewhere.

It is the butter-milk which, according to Dr. DYER, supplies the substance which decomposes during cold storage, and this decomposition is in proportion to the degree of acidity of the butter; the higher the acidity, the greater the decomposition. In order to avoid this decomposition, the dairyman who makes butter for cold storage must not use cream which is too acid, or, if he is obliged to do so, he must wash the butter well so as to free it, so far as possible, from the butter-milk. Butter made from fresh cream of low acidity is best for preserving, and at the present day, in the United States, all butter for the navy must be so made. Butter made with acid cream is suitable for immediate consumption, but not for cold storage. Navy butter was obtained as a result of a series of churning experiments on cream of various degrees of acidity. The degree admitted in the trade is from 0.5 to 0.6 % or even more. Butter as ripe as this is not suitable for cold storage, whereas the experiments showed butter having an acidity of from 0.2 to 0.3 % to keep perfectly. The United States navy butter meets the following requirements: — it must be made with pasteurised cream containing not more than 0.234 % of acid; it must not contain more than 13 % of water; the salt content must be between  $2\frac{1}{2}$  and  $3\frac{1}{4}$  %. This butter is stored at a temperature of 0°F. or less.

## PLANT DISEASES

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### GENERAL

476 - Fungi, Insects and Animals Injurious to Cultivated Plants in Norway in 1916. — SCHÖYEN, J. H., in *Aarsberetning angaaende de offentlige foranstaltninger til landbruksfremme i Aaret*, 1916, pp. 39-94, 2 f. Fies Christiania, 1917.

The plant pathology service in Norway is in the hands of a state entomologist helped by a specialist in mycology, so that, by a rational distribution of the branches of the work, results of increasing utility may be obtained. The central Bureau receives from all over the kingdom information on the appearance of diseases and injurious insects or animals; the material received is examined and instructions and information necessary to control pests of agriculture are given.

In 1916 the Director visited repeatedly the various districts and many agricultural centres, either to superintend the methods of control or to give lectures on questions and branches of plant pathology. The visits numbered 104 in all.

A course of 82 hours on plant pathology was also given at the High School of Agriculture, Christiania.

The law of July 21, 1916, gives detailed regulations regarding the importation of seeds and nursery plants, the isolation and disinfection of infected districts, the distribution of fungicides and insecticides, and the duties of the officers charged with superintending the execution of the law. By this law are considered injurious to agriculture in Norway: *Puccinia graminis* ("sortrust"), *Synchytrium endobioticum* ("potetkraeft"), *Sphaerotheca mors-uvæ* ("stikkelsbaerdraeperen"), *Tarsonemus fragariae* ("jordbaermidde"), *Euthrips pyri* ("paerens Blaerfot"), *Denarolimus pini* ("furuspinderen"), *Lymantria monacha* ("nonne").

The reports received at the Central Bureau in 1916 numbered 1102, distributed as follows:

Diseases attacking.	Caused by		
	Insects or other animals	Bacteria and fungi	Other causes
Agricultural and market garden crops . .	90	117	9
Fruit trees . . . . .	163	94	31
Berry-bearing shrubs. . . . .	54	90	11
Ornamental plants. . . . .	35	15	7
Foods, etc. . . . .	77	2	—
Parasites of man and animals . . . . .	28	—	—
Evergreens . . . . .	48	35	28
Deciduous trees . . . . .	29	9	12
<i>Total</i> . . .	524	362	98

The number of reports received from each district were: Smaalenenes, 58; Akershus, 292; Buskerud, 76; Jarlsberg and Larvik, 40; Hedemarken, 108; Christiania, 42; Bratsberg, 88; Nedenes, 35; Lister and Mandal, 63; Stavanger, 29; S. Bergenhus, 102; N. Bergenhus, 41; Romsdal 26; S. Trondhjem, 23; N. Trondhjem 27; Nordland, 14; Tromsø, 8; Finmarken, 4.

The most important data are given below, mention being made of the pests reported for the first time in Norway, and those already known there which have caused serious damage to agriculture in special districts.

CEREALS. — Larvae of *Tipula oleracea* ("kaalstankelbenet"), on barley and oats at Fyrisdal; larvae of *Hydrellia griseola* ("kornbladflue") on oats in the Trondhjem district; *Oscinella frit* ("fritflue") on oats and barley at Saetersdalen and at S. Land; *Cecidomyia aurantiaca* ("orangegule hvetemyy"), reported for the first time as injurious in Norway, where it was found in wheat fields at Dilling (Smaalenenes district). The two common aphids *Aphis avenae* ("havrebladlusen"), *Macrosiphum granarium* ("kornbladlusen") and *Thrips denticornis* ("blærefølter") did ever-increasing damage.

Among the fungi are mentioned the common species of *Ustilago*, *Tilletia*, *Puccinia*, *Erysiphe*, *Pleospora*, etc. The decree of September 8, 1916, gives measures for controlling *Puccinia graminis* by destroying plants of *Berberis vulgaris*.

POTATOES. — *Synchytrium endobioticum* ("potetkraeft") appeared in 1914 in the Kristiansand district in two localities near Grimsmo; by order of the Department of Agriculture the infected plants were immediately uprooted and the soil disinfected with a 1 % formalin solution, and it was strictly forbidden to plant tomatoes or potatoes in the infected zone for at least 6 years. In spite of these precautions the disease spread in 1915 and was reported from 27 other localities. From this moment the government spared no efforts to suppress this pest; it gave special facilities for the purchase of disinfectants, held lectures, distributed pamphlets, and finally issued the decree of September 8, 1916, which, besides regulat-

ing the control, imposed penalties on those farmers who, instead of co-operating with the State, attempted to evade the law. At Selbusstranden considerable damage was also done to potatoes by *Limax agrestis* ("aker-snegl").

VEGETABLES. — *Barynotus squamosus* caused huge losses in cabbages at Grytten, in the district of Romsdalen. To the author's knowledge this species, common in Europe, never did damage there, but imported into Canada, it ranks in that country amongst the insects most injurious to young cabbage plants.

At Stavanger, carrots suffered from the attacks of *Pseudomonas destructans* ("hvitraate"). All the varieties of carrots are not equally subject to *Pseudomonas*; while the Greystone variety is very easily attacked, "hvite maiturnips" is very resistant.

FRUIT TREES. — The winter 1915-1916, which was exceptionally severe, did considerable damage to trees, thus decreasing their resistance to insects and fungi which, together with adverse meteorological conditions during flowering, contributed to compromise seriously the crop. Larvae of *Euthrips pyri* ("paerens blaerefot"), which appeared in Norway for the first time in 1914, were frequently reported in 1916 as doing damage to fruit trees. For the moment the damage is slight, but as this insect is already known to be very injurious in North America, it is best to look for it and to take measures to destroy it immediately it appears. The mixture recommended consists of:—

4 % tobacco juice . . . . .	¼ litre
Water . . . . .	380 "
Soap or . . . . .	6 ½ to 15 ½ lbs
Paraffin emulsion . . . . .	8 ¼ litres

The mixture is applied three times: — 1) when the buds begin to swell; 2) when the inflorescences begin to open; 3) immediately after the flowers fall.

*Sphaerotheca mors-uvae* ("stikkelsbaerdraeperen") has spread considerably of recent years in the southern and eastern provinces of Norway and has done serious injury to gooseberry plantations. The decree of September 8, 1916 makes it obligatory for orchard owners to report this disease; it is moreover, strictly forbidden to plant gooseberries in the districts of Finnmarke, Tromsø, Nordland, Nordre Trondbjem, Søndre Trondbjem, Romsdal, and Nordre Bergenhus. In the experiments with different fungicides carried out by the State entomologist on behalf of the Department of Agriculture were used: —

1) a 0.4 % formalin solution (1 litre of 40 % formalin solution in 1 hectolitre of water); 2) 0.8 % formalin solution (1 litre of 40 % formalin solution in 50 litres of water); 3) 1.6 % formalin solution (1 litre of 40 % formalin in 25 litres of water); 4) sulphur-lime mixture (30° Beaumé, 25 % sulphur), 1 litre in 10 litres of water; 5) 55 % nitric acid, 2 litres in 1 hectolitre of water; 6) a 4 % sodium chloride solution with a little lime. Six plots were chosen, one being used as control. The efficacy of the fungicide was esti-

mated by the number of healthy plants expressed in percentage of the total number of plants in each plot. The results obtained were :

1.6 % formalin <sup>1</sup> . . . . .	87.50 % healthy plants
0.8 % " . . . . .	81.25 % " "
Sulphur-lime mixture. . . . .	78.13 % " "
Nitric acid . . . . .	53.13 % " "
Sodium chloride solution . . . . .	50.00 % " "
0.4 % formalin . . . . .	31.25 % " "
Control plot . . . . .	14.29 % " "

The best results, therefore, were obtained with 1.6 % formalin.

477 — **Fungi of Eritrea and Abyssinia.** — BACCARINI, PASQUALE, *Annali di Botanica*, Vol. XIV, Pt. 3, pp. 117-140. Rome, 1917.

The list includes 110 fungi isolated at different times by different botanists, chiefly in Eritrea, but also in Abyssinia. There are many species new to science, and several are new to the country explored ; others, which had already been reported there are now given as existing in new districts.

The following should be noted : —

1) *Melampsora Ricini* Pass., on leaves of '*Ricinus communis*,  $\beta$  africanus, at Nefasit (Eritrea);

2) *Puccinia Pruni-spinosae* Pers., on leaves of peach at Asmara (Eritrea) ;

3) *P. purpurea* Cke., on leaves of dhari and *Pennisetum spicatum* at Uechiro (Eritrea) ;

4) *Ustilago avenae* (Pers.) Jens. var. *levis* Kell. and Sw., on *Avena abyssinica*, at Asmara ;

5) *U. Hordei* (Pers.) Kell. and Sw., on *Hordeum* sp., at Asmara ;

6) *Sphacelotheca Sorghi* (Link) Clint., on dhari in Eritrea (Uechiro, Carcabat, Hari-Ieli, Addi-Cajè) and in material from the Ruspoli expedition without any indication of locality ;

7) *Graphiola Phoenixis* (Moug.) Poit., on *Phoenix* sp. at Asmara ; on *Ph. dactylifera*, at Archico and Embatcalla ; on *Ph. abyssinica* at Aidereso ;

8) *Exoascus deformans* (Berk.) Fuck., on leaves of peach at Asmara ;

9) *Sclerospora macrospora* Sacc., on maize, at Ghinda (Eritrea) ;

10) *Phoma Baldratii* n. sp., on stems of *Euphorbia Tirucalli*, at Addi-Ugri ; fungus evidently parasitic ;

11) *Septoria Dianthi* Desm., on leaves of *Dianthus Caryophyllus*, cultivated at Asmara ;

12) *S. graminum* Desm., on leaves of *Hordeum* sp., at Asmara ;

13) *Cercospora Raciborski* Sacc. and Syd., on leaves of *Nicotiana* sp., at Cheren ;

Mention is also made of *Bacillus Oleae* (Arc.) Trev., on leaves of rose-bay grown at Addi-Ugri.

478 — **The Resistance of Peanuts to *Sclerotium Rolfsii*.** — MCCLINTOCK, J. A., in *Science*, New Series, Vol. XLVII, No. 1203, pp. 72-73. Lancaster, Pa., January, 18, 1918.

Already in 1916 the author had collected at the Virginia Truck Experiment Station, Norfolk, Virginia, data concerning the difference between

[476-477]

peanut varieties in their sensibility to attacks of peanut-wilt (*Sclerotium Rolfsii*).

The soil of the plots in which the rotation experiment with this plant was made was known to be thoroughly infected by *Scl. Rolfsii*, and the Valencia variety had proved very subject to the attacks of this fungus. For this reason the Valencia variety was not included in the rotation experiment, its place, for the 1917 crops, being taken by commercial seed of the Virginia Bunch variety. Two plots were used for the 1917 crops; in one peanuts had been grown continuously since 1910, but in the other only in 1911 and 1914.

The two plots were observed up to harvest time (November 9, 1917). During this time a faded Virginia Bunch plant was found in each. An examination of the lower part of the stem showed the presence of mycelium of *Scl. Rolfsii*, proving the disease to be due to this fungus as in many cases in 1916.

The fact that none of the Virginia Runner plants faded confirmed the data of 1916 which showed this variety to be practically immune to wilt.

The resistance of the Virginia Bunch variety was much more marked in 1917 than in the preceding year. Whereas, in 1916, 60 out of 132 plants died, in 1917 only 2 out of 7 000 plants in the same soil were attacked by the disease.

These data are of practical value, especially in the south of the United States, where the peanut is being grown to an increasing extent in districts infested with boll-weevil (*Anthonomus grandis*), and where *Scl. Rolfsii* is already a serious parasite of many crops.

DISEASES  
OF VARIOUS  
CROPS

479 — On a Sudden Outbreak of Cotton Rust (*Aecidium Gossypii*) in Texas. — TAUBENHAUS, J. J., in *Science*, New Ser., Vol. XLVI, No. 1185. pp 267-269. Lancaster, Pa., September 14, 1917.

In 1917 an outbreak of cotton rust (*Aecidium Gossypii* E. and F.) occurred in different parts of Texas. The author's attention was first called to it on June 10, 1917, and the first specimens were collected at Mercedes and Edinberg.

The disease is characterised by round spots of varying size on the leaves of the plant. The aecidia develop on the upper part of the leaf. The disease seems to attack first the lower leaves, and especially well-developed plants on which the cotton bolls are already large. The bracts of the plants may also be affected, but the disease has never been found on the stem.

In his herbarium Dr. J. C. ARTHUR has specimens of this fungus collected by HEALD and WOLF at Falfurrias, Texas, on September 2, 1909, and two Mexican collections, one from San Jose del Cabos (September 2, 1893), the other from Tlahualilo, collected about 1907, probably by HERRERA. Dr. W. A. ORTHON also has specimens of this rust, collected at Miami, Florida, and others from Falfurrias and other parts of the Rio Grande valley, collected seven years ago. This shows that *A. Gossypii* was already present in Texas and elsewhere although it did not attract the attention of cotton-growers or pathologists.

Nothing definite is known as to the origin of the 1917 outbreak. Studies

are now being made with the object of determining the plant host of the perfect form (*Puccinia*) of this rust.

480 - **Vegetable Parasites of the Cacao-Tree in the State of Bahia, Brazil.** — See No. 493 of this *Review*.

481 - **Diseases and Pests of the Onion in Illinois, U. S. A.** — See No. 422 of this *Review*.

482 - **A *Phyllachora* of the Royal Palm in Cuba.** — JOHNSTON, J. R. and BRUNER, S. C., in *Mycologia*, Vol. X, No. 1, pp. 13-14, 1 Plate. Lancaster, Pa., January, 1918.

Recently while examining specimens of royal palm (*Roystonea regia* Cook) near Rincón (Cuba), the authors noticed on the midribs of the leaves, conspicuous black, charcoal-like masses of a fungus, several centimetres long. The masses were composed of more or less confluent groups of stromata developed beneath the epidermis of the host. The fungus was also present on the leaf segments, but development there was much less considerable than on the midrib.

An examination of the fungus showed it to be a *Phyllachora* (family Dothideaceae), which appeared to be distinct from the other species already described. It is distinguished from the other species living on palms, especially by the large size of its asci. The authors describe it here under the name of *Phyllachora Roystoneae*.

Hitherto this pyrenomycete has only been observed on a few palms and does not seem to do serious damage.

483 - **An Unidentified Fungus Injurious to the Conifer *Cedrus Deodara* in India.** — GLOVER, H. M., in *The Indian Forester*, Vol. XLIII, Nos. 11-12, pp. 498-499, 1 Plate. Allahabad, 1917.

A fungus which, according to the author, has not yet been identified, does great damage to *Cedrus Deodara* in the young regeneration plantations of the driest districts of the Bashar Division. So far as is known it does not exist where there are marked differences in rainfall.

The plants are attacked when about 1 ft. in height; those growing in the shade die first.

The plants attacked have a characteristic appearance. They are covered with spots; as a rule the leaves of the lowest branches turn brown first and die, the other branches being then infected. Sometimes the highest branches are attacked first and develop green spots; dying and dead leaves are seen on them at the same time. Sometimes the tree resists the attack, and large plants are found the lowest branches of which have been killed, the others remaining healthy; but more often the young seedlings and plants are completely killed.

If the roots are carefully examined, a yellowish-white mycelium is found, which seems to show that the fungus attacks the tree by the roots.

Up to the present the only method of controlling this fungus consists in cutting down the diseased trees, but the result has been unsatisfactory. Probably a more efficacious method would be to clear the ground so as to allow the young *C. Deodara* to develop under more favourable conditions. Control is necessary, for the disease threatens to do most serious damage in the regeneration districts, *i. e.*, those obtained after the regular regeneration pruning of 1905-1907.

## WEEDS AND PARASITIC FLOWERING PLANTS

484 — **Some Farm Weeds in Sindh, India.** — KAZI, A. M., in *The Poona Agricultural College Magazine*, Vol. VIII, No. 3, pp. 179-182. Poona, January, 1917.

Owing to the canal system of irrigation it is possible to grow crops of "kharif". As a result of the irrigation and absence of suitable cultural methods all the fields are infested with weeds, no precautions being taken to eradicate them. The only method adopted is to cut the weeds when they are sufficiently high and to feed them to livestock.

A list is given of some of the common weeds of the province, together with a short descriptive note on each of them.

1) *Eragrostis cynosuroides* Beauv. ("dubh"); 2) *Eleusine aegyptiaca* Desf. ("mandhani"); 3) *E. flagellifera* Nees ("gandheer"); 4) *Cynodon Dactylon* Pers. ("chabar"); 5) *Panicum colonum* L. ("savri"); 6) *Andropogon annulatus* Forsk. ("dinuhi"); 7) *Cyperus rotundus* L. ("kabah"); 8) *Cleome viscosa* L. ("dhanar-khathuri"); 9) *Digera arvensis* Forsk. ("lulur"); 10) *Euphorbia hypericifolia* L. ("kherol"); 11) *Tribulus terrestris* L. ("sarang").

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

## GENERAL

485 — **Observations on British Coccidae** (1). — GREEN, E. E., in *The Entomologist's Monthly Magazine*, Vol. LIII (3rd. Ser. Vol. III), No. 642, (35), pp. 260-264, 2 figs., No. 643 (36), pp. 265-269, 2 figs. London, November-December, 1917.

This fourth contribution includes the following species: —

1) *Physokermes abietis* Geoffr., abundant at Camberly on some small spruces and on many other spruces in the neighbourhood;

2) *Gossyparia ulmi*. Geoffr.; the young Cornish elm (*Ulmus campestris* var. *cornuliensis*) upon which the insect had been previously found (2) had been transplanted into the author's garden, where he was able to observe the life cycle of the insect; another small colony of *G. ulmi* was found by Mr. FRYER on a golden elm (*U. Dampieri* var. *aurea*) in a nursery at Knap Hill;

3) *Eriococcus devoniensis* Green; the author received from Dr. IMMS typical samples of this species taken at Newchurch Common, Dclamere, Cheshire, although this is the third locality only — the other two were Budleigh Salterton, Devonshire, and Camberley, Surrey — from which *E. devoniensis* has been reported, it probably exists wherever cross-leaved heather (*Erica tetralix*, not *E. cinerea* as stated in the original description) grows freely (3).

4) *Rhipisia halophila* Hardy, found at Camberley on roots of grasses, under stones.

(1) See R. Oct., 1917, No. 975. — (2) See R. June, 1916, No. 706. — (3) See B. Aug., 1915, No. 867 (Ed.)

5) *Pseudococcus nipae* Mask., the author received from Mr. Fyler living specimens of this species from *Kentia* sp. at London; later it was also found at the Royal Botanic Gardens, Kew (1);

6) *Ps. walkeri* Newst., found by Mr. H. Donisthorpe at Goring Woods;

7) *Ps. longispinus* Targ., on bananas bought at Camberley;

7a) *Ps. longispinus* Targ. var. *latipes* n. var. on a fuchsia in a greenhouse at Camberley; other specimens have been collected at Manchester, where they infest the cactus-houses.

8) *Ps. newsteadi* n. sp., on beech (*Fagus sylvatica*) at Camberley; larvae, presumably of the same species, were found by Mr. E. G. JOSEPH in unopened leaf-buds of beech at Chartridge, Bucks;

9) *Aspidiotus lataniae* Sign.; the author has specimens of this coccid taken on *Dracaena* at Tooting in 1899; this species has apparently not yet been recorded from the British Isles;

10) *Lepidosaphes gloveri* Pack.; this species, which has not previously been reported in British lists is often found on the rind of imported oranges;

11) *L. desmidioides* n. sp. on *Nephrodium* sp. in the Royal Botanic Gardens, Kew;

12) *Kuwania gorodetskia* Nasonov (2); after having reported this species on birch at Camberley in 1914, the author did not find it again till June, 1917, when it reappeared in some abundance; three dead and partially decayed males were found in the woolly material of the ovisacs, but it is doubtful whether they really belonged to this species; they had none of the special characters common to the males of other *Margarodinae*, but were more like those of a *Pseudococcus*; should these males be proved really to belong to the *gorodetskia*, the species must be removed from the genus *Kuwania* and returned to the genus *Steingelia*, which, in its turn, must be removed from the sub-family *Margarodinae*; the apparent disappearance of the insect for two years may possibly indicate an unusually prolonged nymphal period.

486 — **Animal Pests of Cultivated Plants in Norway, in 1916.** — See No. 476 of this Review.

487 — **African Aphididae.** — THEOBALD, FRED. V., in *Bulletin of Entomological Research*, Vol. VIII, Pts. 3-4, pp. 273-294, 15 Figs. London, February, 1918.

The author deals particularly with the following species, many of which are described for the first time as being new to science:—

1) *Macrosiphum dahliaefolii* n. sp., on leaves of *Dahlia* at Kampala (Uganda);

2) *Aphis durantae* n. sp.; on main and secondary veins, particularly on the upper surface of *Durania* leaves, at Ghezireh (Egypt);

3) *A. zizyphi* n. sp., at the extremities of young shoots of *Zizyphus Spina-Christi*, at Gizeh (Egypt);

4) *A. ficus* n. sp., abundant on leaves of *Ficus Sycomorus*, especially on those attacked by the Sycamore Fig Tree *Psylla*, in Egypt (Cairo, Gizeh), and in Uganda (Kampala);

(1) See R. Oct., 1917, No. 976 — (2) See B. Aug., 1915, No. 867 (Ed.)

5) *A. tamaricis* n. sp., on *Tamarix* sp., at Gizeh; this is the only species reported on this plant;

6) *A. bauhiniae* n. sp., on leaves of *Bauhinia*, at Gizeh;

7) *A. buddleiae* n. sp., abundant on leaves of *Buddleia madagascariensis*, at Cairo;

8) *A. mathiolae* n. sp., on ornamental stocks, at Ghezireh;

9) *A. mathiolellae* n. sp., with the preceding species, in the same district;

10) *A. pruniella* n. sp., on plum tree, at Nairobi (British East Africa);

11) *A. pomonella* Theobald, on apple tree, in the same district;

12) *A. pheidole* Theobald, associated with ants (*Pheidole* sp.) at Mwen-gera (Rhodesia);

13) *A. acetosae* Koch (not Linn., Fabr., Buckton), on *Rumex* spp. and *Papaver* spp., at Ghezireh; the same species has been found in England (Wye, Kent), and in Germany;

14) *Siphocoryne* (*Aphis*) *pseudobrassicæ* Davis; Prof. DAVIS of Lafayette (Indiana) informed the author that he received this species from the Cape from Mr. LOUNSBURY; it lives on *Raphanus sativus*, *Brassica Rapa* var. *depressa*, *B. Napus*, *B. oleracea* var. *acephala*, *Sinapis*; DAVIS reports it at Geneva (New York), Evansville (Indiana), Lafayette and College Station (Texas);

15) *Hyalopterus insignis* n. sp., in colonies on the lower surface of leaves of *Arundo*, at Ghezireh;

16) *Myzus pterisoides* n. sp., on fern, at Kampala.

New districts and hosts are mentioned for the following species:

1) *Rhopalosiphum dianthi* Schrank, on *Brassica oleracea* and *B. oleracea bullata major* in large numbers, with *Aphis brassicæ* L., at Cairo and Ghezireh;

2) *Aphis* (*Siphocoryne*) *brassicæ* L., on the same hosts in the same districts, with *R. dianthi*;

3) *Hyalopterus pruni* Fabricius (*Hyal. arundinis* Fabricius, *Hyal. phragmiticola* Oestlund), previously reported from Cairo, on *Prunus* spp. and *Arundo*; recently found at Ghizeh in abundance underneath apricot leaves and also on *Arundo*, the effect of the aphid is more marked on leaves of peach than on those of apricot, the author himself never found this species on either peach or apricot trees in England, but received from Wood-bridge (Suffolk) living species taken from apricot trees.

#### RESISTANT PLANTS

468 - "4 F", a Variety of Cotton Resistant to Insect Attack in the Punjab, India. — See No. 419 of this Review.

#### MEANS

#### OF PREVENTION AND CONTROL

489 - The Control of Locusts in Cyprus. — See No. 376 of this Review

490 - Patents for the Control of Plant Pests. — See No. 458 of this Review

#### INSECTS, ETC., INJURIOUS TO VARIOUS CROPS

491 - *Tylenchus penetrans* n. sp., a New Nematode Parasite of Cotton, Potatoes and other Plants. — COBB, N. A., in *The Journal of Agricultural Research*, Vol. XI, No. 1, pp. 27-33, 5 Figs. Washington, D. C., October 1, 1917.

Under the name of *Tylenchus penetrans* the author describes, as a species new to science, a nematode which, already in 1911, he found to be injurious

to roots of *Viola* spp. at Rhinebeck, New York. It has been reported as a parasite of Upland cotton at Millington, North Carolina, and at Statesboro, Georgia, of potato roots near Kalamazoo, Michigan, and of *Cinnamomum* *Camphora* roots at Orlando, Florida.

The presence of the nematode may easily be recognised externally by the presence on the roots or tubers of small, abnormal lesions, a few millimetres in size; these are sometimes in the form of blisters, but more often in that of discoloured, slightly depressed spots. Each of these diseased spots, when fully developed, contains about fifty *T. penetrans* in various stages of growth.

The fact that this parasite is found under such varying climatic conditions and on such different hosts, shows that it is a species which adapts itself to most diverse conditions.

Nothing definite is known of the extent of the damage caused by *T. penetrans* to cotton and camphor, but the damage to *Viola* spp. is known to be very great. Information collected with reference to the potato shows the injury often to be considerable, so that great care must be taken to use only perfectly sound seed potatoes.

Mercuric chloride, used against potato scab (*Oospora Scabies*), has been found to reduce the vitality of the insect to a considerable extent.

492 - **Animal Pests of Onions, in Illinois.** — See No. 422 of this *Review*.

493 - **Insect and Vegetable Parasites of the Cacao-Tree in the State of Bahia, Brazil.**

TORREND C., in *Broter a, Serie de Vulgarização Científica*, Vol. XV, Pt. 6, pp. 263-279, 4 Figs and. *Serie Botânica*, Vol. XV, Pt. 3, pp. 106-127, 1 Fig., 4 Plates. Braga, 1917.

The State of Bahia has for some years been the principal centre of cacao-tree production. The last statistics show it to come immediately after the English Gold Coast Colony. The cacao-tree producing district occupies a large part of the south of Bahia, between latitudes 14° and 16° in the midst or in the place of huge virgin forests.

In view of its importance this crop has become one of the chief sources of revenue of the State. The news, therefore, that hitherto unknown diseases were appearing in the Ilheos and Itabuna plantations caused great alarm, and the government immediately nominated a Commission to study these diseases; the author was president of this Commission. The investigations showed the diseases to attack both the fruit and foliage of the trees.

Among the diseases of the fruit are: —

1) that commonly known among growers as "ferrugem" (rust), caused by *Physopus rubrocinctus*. The innumerable small holes made by the larvae of this thysanopteron, which forms numerous colonies on the fruit, cause an abundant secretion of the subepidermal tissues which eventually covers the whole surface of the fruit with a thin rust-coloured or brick red layer, making it impossible to recognise the ripe fruit at the time of harvest. The simplest preventative method of control would be to crush the colonies of the insect, after the fruit attacked has been completely and carefully surrounded with the hands. The use of insecticides is difficult

(1) See R. 1917, No. (Ed).

because of the size of the plantations. An enemy of this insect whose action seems very efficacious is an ant, commonly known as "caçarema", belonging, perhaps, to the species *Dolichoderus bituberculatus* (1), which should be protected and propagated, contrary to the custom adopted up to the present ;

2) numerous black spots, about 2 mm. in diameter, which cause more or less deep cancerous formations, and, generally, drying up of the green fruit. This disease is due to holes made by a hemipteron, closely resembling *Helopeltis antonii* (2), called provisionally by the author and Dr. ZEHNTNER *Mosquilla vastatrix*, because they believe it to be identical with the insect known to Equador planters as the "mosquilla" (little fly). Besides using a torch for burning the insects on the fruit, it is advisable to propagate the "caçarema" which probably destroys the eggs of this hemipteron ; the female insect, perhaps instinctively, never lays its eggs near this ant ;

3) a kind of rot characterised either by numerous spots, isolated at first, but converging later, or one single spot, yellowish or dark brown at first, then black, which begins at one extremity and finally covers the whole fruit. This rot is usually caused by *Phytophthora Faberi*, more or less associated with other microorganisms. To control this disease care must be taken to avoid lesions on the fruit, to burn or bury the remains of fruit as when they decompose in the air they form a seat for cryptogamic diseases. Care must also be taken to air thoroughly the infected parts of the plantation and to cut and burn contaminated fruit.

All the diseases which cause the leaves and young buds to dry up are known locally as "queima" (burn), but the causes are numerous, and among them the following may be specially mentioned :

1) the action of the adult *Physopus*, which pricks the young leaves ;

1) the holes made by *Mosquilla* in the buds and young leaves.

To control these pests, in additions to the methods already mentioned, it is advisable to keep the plantation well shaded ; the trees attacked should also be strengthened by rational lopping.

In the district examined the presence of epiphytic phanerogams and various species of fungi, largely saprophytic, was noticed. A fungus which should be specially mentioned is *Corticium lilacino-fuscum*, which lives on the green branches. Attention should also be drawn to a mycelium called by English workers "thread blight", which in every way resembles the mycelium of certain *Corticium*. It appears in the form of long threads on the branches and leaves ; the leaves are eventually enclosed in a sort of network and gradually dry up.

The chief cause of the diseases observed lies in the little care planters took of their large plantations in the past. To this must be added the use of unsatisfactory tools for the harvest and cultivation of the plants. The result is a large number of lesions which open the road to cryptogamic invasion. Another factor is also the atmospheric and climatic changes produced in these districts of recent years, due especially to the clearing of the virgin forests.

- 494 - *Euxoa excellens*, a Little Known Cutworm, in British Columbia. — GIBSON, ARTHUR, in *The Canadian Entomologist*, Vol. XLIX, No. 12, pp. 401-403. London December, 1917.

In British Columbia the larvae of *Euxoa excellens* Grt. have been so abundant in certain years that they have seriously damaged many varieties of vegetables. This species was first reported in 1885, when it did much damage in market gardens around Victoria, Vancouver Island. Larvae were also collected in British Columbia in 1888. In 1903 the insect was again troublesome on Vancouver Island, but, from that date it was not reported till May 30, 1916, when it was found at Sechelt near Vancouver. The larvae had damaged various vegetables, in some gardens spinach, lettuce, onion, etc. had to be sown three times before the end of May.

Larvae received at Ottawa in June, 1916, pupated early in July. Three specimens which pupated on July 2, produced moths on July 29 and 30. Other moths emerged in August. In the collections at Ottawa are three specimens reared by FLETCHER in 1885 from larvae collected in May; the dates of emergence were August 15, 18 and 22 respectively. According to the author's observations the moths of *E. excellens* fly, in British Columbia, in the latter half of August and during September. The insect, which was first described from Vancouver Island specimens, is widely distributed; it is found in the United States, in the States of Oregon, Colorado (in September) and in California (in September and October). Nothing definite is known of the early life history of the species; the winter appears to be passed in the egg stage; in certain seasons hibernation may also occur in the young larval stage.

After describing the mature larva, pupa and moth, the author adds that, from the larvae reared at Ottawa in 1916, were obtained several ichneumonid parasites belonging to the species *Amblyteles subfuscus* Cress. and *Ambly. nuncius* Cress; both species emerged in August. A large percentage of the larvae were destroyed by the fungus *Sorosporella uvella* (1).

Treatment at Sechelt with the well-known mixture of bran, Paris green and molasses gave very good results. By this method 95 to 100 % of the larvae was destroyed. Untreated plants were completely eaten up by the insect, which did not touch those to which the mixture had been applied.

- 495 - *Insects Injurious to the Cranberry in the United States* (2). — SCAMMELL H. B., in *United States Department of Agriculture, Farmers' Bulletin No. 860*, pp. 45, 39 Figs. Washington, D. C., 1917.

Commercial cranberry (*Oxycoccus macrocarpus*) growing is an intensely specialised industry, confined to certain districts of the United States, especially Massachusetts, New Jersey, Wisconsin, Long Island, and part of the north-western coast of the Pacific, near Columbia.

A morphological and biological description is given of the insects attacking the cranberry, most of which are also of economic importance for other plants, together with the most satisfactory measures of control.

The list includes: —

(1) See R. June, 1917, No. 611. — (2) See R., April, 1916, No. 470. (Ed.)

## a) Insects attacking the leaves :

- 1) *Rhopobota vacciniana* Pack. (blackhead fireworm) ;
- 2) *Peronea minuta* Rob. (yellowhead fireworm) ;
- 3) *Gelechia trialbamaculella* Cham. (red-striped fireworm) ;
- 4) *Dasyneura vaccinii* Smith (cranberry tipworm) ;
- 5) members of the *Geometridae* family (spanworms) ;
- 6) *Cirphis unipuncta* Haw. (army worm) ;
- 7) *Laphygma frugiperda* S. et A. (fall army worm) ;
- 8) *Systema frontalis* Fabr. (cranberry flea beetle) ;

## b) insects attacking the fruit : —

- 1) *Mineola vaccinii* Riley (cranberry fruitworm) ;
- 2) *Eniglaea apiata* Grote (cranberry blossom worm) ;
- 3) *Scudderella texensis* S. and P. (cranberry katydid) ;
- 4) grasshoppers — especially *Schistocera alutacea* Harr. and *Melanoplus bivittatus* Say — and members of the *Gryllidae* family (crickets) ;

## c) insects attacking the stem : —

- 1) *Crambus hortuellus* Hübner (cranberry girdler) ;
- 2) *Phylloscelis atra* Germar (cranberry toadbug) ;
- 3) *Amphisepea bivittata* Say (cranberry vinehopper) ;
- 4) *Clastoptera proteus* Fitch (cranberry spittle insect) ;
- 5) *Pseudococcus adonidum* L. (mealybug) ;
- 6) *Aspidiotus ancylus* Putnam (Putnam scale) ;
- 7) *Lepidosaphes ulmi* L. (oystershell scale) ;

## d) insects attacking the roots : —

- 1) *Rhabdopterus picipes* Oliv. (cranberry rootworm) ;
- 2) other coleoptera, especially *Phytalus georgianus* Horn., *Dyscinechus trachypygus* Burm. and *Lachnosterna grandis* Sm. (white grubs).

496 — **Important Pecan Insects Pests and Their Control** (1). — GILL, JOHN B, in *U. S. Department of Agriculture, Farmers' Bulletin* 843, pp. 1-48; Figs. 1-59. Washington, D. C., September, 1917.

The pecan (*Carya olivaeformis*) industry has developed rapidly in the south of the United States. This development has, however, been accompanied by a notable increase in the number and in the destructiveness of the insects attacking the crop. The loss from insect attacks amounts to hundreds of thousands of dollars annually and, in the absence of preventive measures, is certain to increase.

This bulletin gives the results of work done by the Bureau of Entomology on the most important insect pests of the pecan. The morphology and biology of each insect are described and the most efficacious means of control given.

The following species are discussed : —

## a) Insects injuring the nuts : —

- 1) Pecan nut case-bearer (*Acrobasis hebesella* Hulst.) ;
- 2) Pecan shuckworm (*Laspeyresia caryana* Fitch) ;

(1) See also R. Sept., 1917, No. 884. (Ed.)

- 3) Pecan weevil (*Balaninus caryae* Horn) ;
- b) Insects injuring the foliage and shoots : —
  - 1) Pecan leaf case-bearer (*A. nebulella* Riley) ;
  - 2) Pecan cigar case-bearer (*Coleophora caryaefoliella* Clem.) ;
  - 3) Pecan bud-moth (*Proteopteryx bolliana* Sling) ;
  - 4) Fall webworm (*Hyphantria cunea* Drury) ;
  - 5) Walnut caterpillar (*Datana integerrima* G. and R.) ;
  - 6) Hickory phylloxera (*Phylloxera caryaecaulis* Fitch) ;
  - 7) Little hickory aphid (*Monellia caryella* Fitch) ;
- c) Insects injuring the trunk and branches : —
  - 1) White ants ; of these *Leucotermes flavipes* Kollar is the most widespread and common in the eastern States ;
  - 2) Oak or hickory cossid (*Cossula magnifica* Strecker) ;
  - 3) Flat-headed apple-tree borer (*Chrysobothris femorata* Fab.) ;
  - 4) Red-shouldered shot-hole borer (*Sinoxylon*] *Xylobiops basilaris* Say) ;
  - 5) Belted chion (*Chion cinctus* Drury) ;
  - 6) Hickory twig-girdler (*Oncideres cingulatus* Say) ;
  - 7) Oak pruner (*Elaphidion villosum* Fab).

The pecan is not immune to attacks from scale insects, but on account of the limited infestation up to 1917 they are not included among the most important pests of this tree.

### FIRST PART. ORIGINAL ARTICLES

#### **The Live Stock Industry in Australia.**

by

W. A. N. ROBERTSON, B. V. Sc.

*Chief Veterinary Officer, Live Stock Division,  
Department of Agriculture, Victoria, Australia.*

In dealing with the Live Stock Industry in Australia it is necessary, in the first place, to draw attention to a few geographical details in order that readers may be familiar with the diverse conditions of soil and climate met with. The Continent has been settled for only a little over 100 years. It has an area of 2 974 581 square miles, being approximately three-fourths as large as Europe; 14 times as large as France; 24 times as large as the United Kingdom of Great Britain, and 26 times as large as Italy. It is situated between the 12th and 40th degrees of South Longitude. This will give some idea of the vast area, the great distances and the variation of climate and herbage met with. The influence of such varying conditions upon the Live Stock Industry will be readily recognised.

I. — THE HORSE. — In the early days of colonization the horse required was one capable of carrying his rider for long distances over all classes of country, either for a journey — 60 to 100 miles a day was lightly thought of — or for rounding up and mustering cattle in the unfenced areas of scrub and timber land or undulating plain. The qualities required for this work were stamina, speed, and agility. These were found in the English Thoroughbred and there quickly developed, in the rising generation, a love for racing and an inherent love for the horse. As time passed, and Settlement advanced, it became necessary to introduce the draught horse, crosses with the Thoroughbred were obtained and the light horse industry divided into two channels.

As Settlement of the country proceeded along the sea board and railways were laid down, the necessity for long journeys in these areas diminished, but the love of racing progressed. The Thoroughbred came under control

of a Stud Book and has developed along such lines until his reputation is known the world over. The other channel produced a thicker set and heavier horse from the various crossings which had taken place and a type was evolved which held its own against the product of other lands for military purposes. A large export trade in remounts was established, particularly with India. The love of racing, the extension of race meetings, and the desire of almost every owner (and nearly every boy owned at least a pony) to breed a winner for the local events now acted adversely upon the Industry. Horses not speedy enough, nor of sufficient stamina for classic events, were used on ponies and rejected remounts, and a somewhat light nondescript horse was bred which became a drug on the market and remount buyers had to travel further and further back into the country, remote from railways, to find the type required.

Of recent years more attention has been devoted to the breeding of this remount type of horse and for this the big boned thoroughbred is used. Light horse breeding, as distinct from the thoroughbred for classic races, has been pushed back into the sparsely populated interior of the country as settlement extended and the land became more valuable for other purposes. At this time the Government examination of stallions, referred to later, was introduced, and efforts were made to swing the pendulum back to remount breeding. A Conference of representatives from all parts of Australia, which recently met in Melbourne, made recommendations which are summarised below:—

That the first step to be taken was the elimination of unsuitable stallions and provision of suitable ones to stand at a reasonable fee.

That Mares suitable for breeding remounts be registered under district Committees who would advise as to matings, etc., and that fees for carrying on the work be obtained by a tax on the Totalizator.

The Conference was of opinion that in any scheme for improvement the Thoroughbred Stallion was essential and the right type should be encouraged by providing more valuable stakes to be run for. Further, that Mares not suitable for breeding horses could be profitably used for Mule breeding

Importations of Arabs and various classes of ponies have been made from time to time and all have left their representatives which have had an influence to a greater or lesser degree upon the Industry.

The future holds great possibilities. There are vast tracts of country still unused which are admirably adapted for horse breeding on an extensive scale.

**THE DRAUGHT HORSE INDUSTRY.** — During the early days of settlement horses of medium weight were found suitable for the limited amount of cultivation carried on, but as this extended it became necessary to develop a more weighty animal and many importations of the Scottish Clydesdale Stallion were made. As the export trade in wheat developed and large areas were thrown open to cultivation, weight was required to pull the 3, 4, and 5 furrow ploughs over the hundreds of acres each farmer worked and to cart the produce over bad roads to the railways. Two classes of fanciers arose, one favouring the Clydesdale, the other the heavier Shire Horse. Many importations were made but no Stud Books

were in use and the breeds became mixed and the individuality of the respective types somewhat lost.

Then a school of breeders arose who considered the horse with the weight of the Shire and the activity of the Clydesdale was the one required and an attempt was made to evolve an Australian draught horse. Prizes at the various Shows were given for draught horses, and Clydesdales and Shires competed in the same ring. This led to some confusion and resulted in an educational campaign being undertaken by the respective Governments with the object of impressing upon breeders that whilst the cross between the two breeds might be best for utility purposes, it could only be obtained by keeping the two parent types distinct and pure. Gradually the larger Agricultural Societies took the matter up and at their shows separated the two classes and the Clydesdale and Shire are now shown separately. The former is the more popular horse and Stud Books for control are now in operation in the Southern States of New South Wales and Victoria, while the system is extending to the other less settled ones.

**METHODS OF IMPROVEMENT.** — The most noteworthy method of improvement of the Industry that has been adopted by the Governments of Australia is that which is referred to as the Government Certification of Stallions. For the successful understanding of the scheme it is necessary to know that the Governments grant a subsidy to Agricultural Societies throughout the States to assist them in the holding of Annual Shows. In 1907 the State of Victoria introduced a system of issuing a Certificate to any stallion which, on being submitted to examination by a Government Veterinary Officer, was found to be free from hereditary unsoundness and to be of suitable breed, type and conformation to be approved as a sire. The following year it was decided that any Society desirous of obtaining the subsidy should arrange that no prize was to be awarded to any Stallion three year's old or over unless he held the Certificate. The scheme was readily adopted by breeders and within a few years extended to the other States of the Commonwealth. At the present time all States are in unison on this subject. The result of the examination for the past ten years, so far as the State of Victoria is concerned, is set forth in the accompanying Table.

An examination of the Table shows that the percentage rejections on account of unsoundness over the ten years have been as follows : —

1907/8,	1908/9,	1909/10,	1910/11,	1911/12,	1912/13,	1913/14,	1914/15,	1915/16,	1916/17
15.04	17.17	15.04	17.09	10.42	11.59	10.38	13.76	14.93	11.25

At first sight this does not appear encouraging, but closer investigation shows that the unsoundness in light horses and ponies is slight, while the inclusion of these classes in the totals and the varying numbers submitted makes considerable changes in the ratio of unsoundness. A far better index of the value of the examination is to take only that breed in which unsoundness is prevalent, namely the draughts, and for the past ten years the figures run :—

1907/8,	1908/9,	1909/10,	1910/11,	1911/12,	1912/13,	1913/14,	1914/15,	1915/16,	1916/17
23.82	27.33	23.52	21.57	12.13	12.03	11.0	15.5	19.67	16.49

By dividing this period into two of five years each and so eliminating the seasonal fluctuations, we see that for the 1st quinquennial period an average of 20.8 per cent. was rejected, while in the 2nd period the percentage was only 13.4 or a difference of 7.4 per cent and a decrease of 35 per cent.

When it is realized that certain horses though pronounced unsound have not been discarded from breeding operations altogether and that, therefore, many of their progeny are still coming forward, this result can only be regarded as satisfactory.

A Bill has now been drafted to provide for the registration of Stallions and it is hoped that it will shortly be placed upon the Statute Book. When the measure becomes law no person will be permitted to use a stallion for breeding purposes unless the same is registered and only those which obtain a Certificate, issued by a Government Veterinary Surgeon will be eligible for such registration. Examinations will be conducted on similar lines to those in existence at present. Parades are arranged and a Veterinary Officer is in attendance to conduct the examination. He determines two things:

1) Is the animal free from Hereditary Unsoundness, and for this purpose the following diseases are scheduled.

Bog Spavin,	Ringbone,
Bone Spavin,	Roaring,
Cataract,	Sidebone.
Chorea, "Shivering" or "Nervy",	Stringhalt.
Curb,	Thoroughpin.
Navicular disease,	Whistling.
Nasal disease (Osteo-porosis).	

2) Is the animal of suitable type. Inferior and common bred animals are refused a Certificate.

Should an owner feel aggrieved at the decision of the Veterinary Officer, he may appeal against the rejection on either ground by lodging a deposit of £ 5 (to prevent frivolous appeals) and a Certificate from a Veterinary Surgeon or three Judges of repute, according to the ground for rejection, to the effect that the decision was against the evidence. A Board of Appeal is then appointed consisting of the Chief Veterinary Officer and two practising Veterinary Surgeons, or the Chief Veterinary Officer and two Judges, according to grounds of rejection, who examine and determine the case. If the Appeal is upheld the deposit is refunded, if dismissed the deposit is forfeited.

It is a peculiar fact that our genial climate has been instrumental in no small degree in producing a loss of weight in our draught horse. The reason for this is that when weaned the majority of breeders leave the foals running on natural pasture. When a cold or wet spell of weather occurs the young animals receive a set back, whereas in a more rigorous climate it would be imperative to house the young stock and hand feed them over such periods and keep them growing all the time. By educational lectures delivered throughout the country the breeders are becoming more conversant with the necessity to eliminate this factor and feeding and housing are receiving more attention. When properly managed, it

is universally admitted that there is no finer country for horse breeding operations than Australia.

The Suffolk Punch breed is one which has a few representatives in our Northern States but is not a popular breed. There have been small importations of other breeds such as Percherons, etc., but they have not found favour nor have there been sufficient to keep the type distinct.

STATISTICS. — As indicating the growth of the Industry from the early days, the following Table showing the number of horses in one State of the Commonwealth, for which the figures are available, viz—Victoria, will be of interest.

Year	Number	Year	Number
1836 . . . . .	75	1850 . . . . .	21 219
1838 . . . . .	524	1852 . . . . .	34 021
1840 . . . . .	2 372	1854 . . . . .	27 038
1842 . . . . .	4 065	1856 . . . . .	47 832
1844 . . . . .	7 076	1858 . . . . .	68 323
1846 . . . . .	11 400	1860 . . . . .	76 536
1848 . . . . .	16 495		

Similar growth occurred in other States and from 1860 the numbers in the Commonwealth are as shown hereunder.

Year	Number	Year	Number
1860 . . . . .	431 525	1895 . . . . .	1 680 419
1865 . . . . .	566 574	1900 . . . . .	1 609 654
1870 . . . . .	716 772	1905 . . . . .	1 673 805
1875 . . . . .	835 393	1910 . . . . .	2 165 866
1880 . . . . .	1 068 402	1912 . . . . .	2 408 113
1885 . . . . .	1 143 064	1914 . . . . .	2 489 000
1890 . . . . .	1 521 588

### STUD CLASSES.

*Draught Stallions.* — The price varies very considerably. Inferior classes change hands at £ 60 to £ 100, good classes at £ 300 to £ 500 which a few superior horses realize up to 1 000 guineas.

*Mares* range from £ 50 to £ 200 and higher.

*Light Horses.* — Thoroughbred Stallions suitable for use in breeding remounts range from £ 100 to £ 300, a few going to higher figures, while Mares suitable for mating vary from £ 16 to £ 30.

*Thoroughbred Mares* are of course higher with wide range of values according to breeding.

ASSES AND MULES. — The breeding of Mules has received very little attention, there being only 8 215 Asses and Mules in the Commonwealth.

EXPORTS. — The export trade in horses is one which has fluctuated considerably from 32 474 in 1901 to as low as 7 807 in 1909, the average being 13 700. The possibilities under this heading are enormous. There is space to breed sufficient to supply the world and the endurance of the Australian horse as shown in the theatre of war indicates that he is second to none. The distance of Australia from the thickly populated areas of Europe and the question of freights are the adverse factors.

SECOND PART  
ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

497 - **Agricultural Development of British Guiana.** — SPENCE, R. O. H., in *United Empire, The Royal Colonial Institute Journal*, Vol. IX, No. 2, pp. 61-65 + Map. London, February, 1918

DEVELOPMENT  
OF  
AGRICULTURE  
IN DIFFERENT  
COUNTRIES

British Guiana, the only British possession on the continent of South America, contains an area of 89 480 square miles, with a population of about 300 000, and produces the world-famous "Demerara Sugar" which might more correctly be designated "British Guiana Sugar".

The staple industry is really sugar, and the approximate area under canes at the end of 1916 was 75 000 acres; there is suitable land available to extend the cultivation of sugar to ten times or more the present area, and thus increase the export of sugar to over one million tons per annum. The essentials for such expansion and, indeed, for all development of any magnitude in connection with the Colony are 1) an increased labour supply, and 2) capital.

Rice cultivation now embraces about 50 000 acres and is capable of large expansion. Coconuts grow and yield well, as do also cocoa and coffee. Cotton was extensively grown when the colony was owned by the Dutch and in the early years of the British occupation, and with a plentiful supply of labour and fair prices could be again cultivated with profit. Para Rubber grows and yields well; its present area, about 5 000 acres, could be extended to a large extent as far as suitable and available land is concerned. Limes grow well wherever planted, and in properly selected areas could undoubtedly be grown at a profit. Bananas, plantains, and other ground provisions and fruits grow well, and with a proper system of cold storage and shipping facilities could be produced in quantities sufficiently large to admit of export.

Horses and cattle thrive on the coast lands, and the coastal and hinterland savannahs. There are 11 700 square miles of savannah lands suitable for stock rearing, but owing to the want of facilities for transport, the cat-

tle that can be raised on 6 000 square miles of this area adjoining the Rupuni and Ireng rivers cannot be brought to market in the Colony.

British Guiana produces some of the finest timbers in the world. Those that are at present most commonly exploited are Crab wood (*Carapa* sp.) (sp. g. 0.47 to 0.7); Greenheart (*Nectandra Rodioei*) (1.06), largely used in the construction of the Manchester Ship Canal and in the construction of lock gates for the Panama Canal; Wallaba (0.98); Belata or Bullet Wood (*Mimusops globosa*) (1.00); Mora (1.06); brown and yellow Silverballi (0.77 and 0.62), Lettei or snake wood (1.30); red Cedar (0.45). These woods are suitable for building purposes and the making of furniture. Wallaba and several other kinds of wood are used for fuel as a substitute for coal. The forests also abound in soft woods which are suitable for making paper pulp, yet not a single pulp-making factory exists in the Colony.

Other products are Balata, the dried latex of the Bullet tree; the exports of this gum are over 1 000 000 lbs. per annum, the bulk going to the United Kingdom; Locust gum, used in the preparation of varnishes; Tonka beans; Vanilla beans; Palm nuts of various kinds which are plentiful and could doubtless be turned to commercial value as oil producing factors; Souarri nuts, larger and finer than Brazil nuts. Plants of medicinal value also abound, of which no use whatever is now made.

#### RURAL HYGIENE

498 - The Organisation of the Rural Hygiene Service in Spain. — *Boletín de Agricultura técnica y económica*, Year IX, No. 103, pp. 612-619. Madrid, July, 1917.

The Spanish Service of Rural Hygiene Inspection ("Inspección de Sanidad del Campo") was re-organised by the Royal Decree of August 8, 1916. It is as yet too early to appreciate the results obtained, but there is no doubt that great advantages will be gained by the collaboration of the new service with other technical services of the Ministry of Agriculture. The sanitary police collaborate with the agricultural engineers in many kinds of work, particularly in the improvement of malarial districts and the rational cultivation and improvement of rice and medicinal plants. The appended table gives data on malaria obtained by the District Inspectors and compares the conditions of 1915 with those of 1913. The geographical distribution of malaria in Spain, the intensity and diffusion of the disease (there is an acute summer and autumn period), the microscopical examination of the blood of malarial patients in different rural districts, and even in small villages where the disease is rampant, have been studied with the greatest care, and the present malarial conditions in each of the 14 agricultural districts of Spain has been deduced from numerous details. It should be noted that, if the number of malarial municipal centres has increased, the number of cases of sickness and of death has decreased, in spite of the increased cost of quinine and food owing to the war. This is due to the ceaseless propaganda of the sanitary inspectors in matters of hygiene. In 1917 the General Administration of the Ministry of Agriculture, Mines and Forests took steps for the encouragement by the Agricultural Stations ("Granjas agrícolas") of the cultivation of medicinal herbs and the reafforestation of marsh lands, in order to reclaim, in part at least,

the 741 330 acres which form the principal centres of malaria in Spain at the present day.

*Malaria in Spain: Extent of Infected Districts and Loss  
Caused by this Disease.*

	1913	1915
Number of municipal centres . . . . .	9 261	9 261
Number of malarial municipal centres . . . . .	1 428	1 492
Total extent of malarial centres (1), . . . . . acres	1 089 924	754 748
Present value of malarial land . . . . . £	963 400	902 111
Approximate value of malarial land if reclaimed . . . £	6 134 626	5 014 334
Number of annual cases (2) . . . . .	233 404	209 420
Annual mortality (2) . . . . .	2 540	2 139
Annual consumption of quinine . . . . . cwt.	38.23	37.33
Value of annual consumption of quinine (3) . . . . . £	42 862	83 032
Days of work lost through malaria (15 per case) . . . .	3 515 595	3 141 300
Value of days lost (at 1s. 7d. a day) . . . . . £	293 192	249 098
Value of lives lost (at £ 198 each) . . . . . £	515 435	819 644
<i>Total annual losses to the nation through malaria (4) £</i>	<b>5 347 806</b>	<b>4 771 472</b>

(1) Not including the centres formed by badly cultivated rice fields and badly kept banks of rivers and canals. — (2) Figures for the years 1913 and 1915. — (3) Valued at 4 3/4 d a gram in 1913 and 9 1/2 d a gram in 1915. — (4) These figures represent the total of the differences between the present value of malarial land and the value such land would have if reclaimed; the value of quinine; the value of days lost; the value of lives lost.

In the budgets of 1915 and 1916, £ 29 740 were allotted to the distribution of water to rural centres. This has resulted in a considerable decrease in the number of cases of disease and death through infection by water. In Spain the water problem is usually limited to the protection and canalisation of local water, rather than to obtaining it from a distance, for most districts have a good supply of drinking water.

499 — **Public Health Studies Concerning Cheese.** — SCHROEDER, F. C. and BRETT, G. W., in the *Journal of the American Veterinary Medical Association*, Vol. LII, No. 6, pp. 674-685. Ithaca, N. Y., February, 1918.

The primary and special purposes of these studies on cheese were to determine the frequency with which it is contaminated with virulent tubercle bacilli at the time it reaches the consumer.

The number of samples of cheese in these investigations on which the tests are now complete is 256, and among these 19, or 7.42 %, were found to be infected with virulent tubercle bacilli. The bacilli in all cases were of the bovine type.

Leaving the samples of cheese of the varieties that require some time to ripen before they are marketed out of consideration, none of which were found to be contaminated with tubercle bacilli, the 194 samples of fresh cheese may be divided as follows: —

- 131 samples of cream, 18, or 13  $\frac{3}{4}$  %, infected with tubercle bacilli  
 31 samples of cottage, 1, or 3  $\frac{1}{4}$  % infected with tubercle bacilli  
 32 samples of Neufchatel, all free from infection.

These studies seem to warrant the following conclusions: —

1) that cheese of the kind which requires some time to ripen rarely if ever contains true, living, pathogenic bacteria when it is marketed and it does not seem likely that such cheese is apt to contain dangerous products of bacterial origin;

2) that cream cheese is often heavily contaminated with tubercle bacilli of the bovine type and should therefore be made either from pasteurized milk and cream or from milk and cream obtained from cows which have been proved free from tuberculosis. This pasteurization of milk would also destroy dangerous germs of the colon and septicemia groups;

3) that cottage and skim milk Neufchatel cheeses are much less frequently infected with the tubercle bacilli than cream cheese; but this should not be used as a reason for making them from raw milk.

500 — **The Digestibility and Utilization of Egg Proteins.** — BATEMAN W. G. (Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXVI, No. 1, pp. 263-391, 8 Tables, Bibliography of 74 publications. Baltimore, Md., August, 1916.

By means of experiments carried out on dogs, rats, rabbits and man, the author arrived at the following conclusions:—

Raw egg-white is found to be a decidedly indigestible substance. It causes diarrhoea in dogs, rats, rabbits, and man when ingested in any large quantity. Its utilisation by the body is poor since it is used only to the extent of 50 to 70 per cent. Subjects can acquire a certain tolerance for the native protein after ingesting it for several days so that it no longer causes diarrhoea and is somewhat better utilized.

Raw egg-white can be made digestible through coagulation by heat; by precipitation with alcohol, chloroform, or ether; by incubation with dilute acids or alkalies; by partial digestion by pepsin; by conversion into alkali-metaprotein.

The indigestibility of native egg-white probably lies either in its anti-tryptic content or in its chemical constitution. Its physical texture appears to play a minor part in its behaviour. Of the individual proteins constituting egg-white, the albumin fraction appears to be the indigestible component.

The whites of the hen's egg and duck's egg act alike in causing diarrhoea and in being poorly utilized.

Egg-yolk either raw or cooked is excellently utilized. It sometimes causes digestive disturbances in dogs, apparently because of its high fat content.

A review of the literature shows that dietitians have relied, in general, upon the early observations of BEAUMONT as support for the use of raw eggs. These observations were in the main exact; but, so far as the digestibility of raw egg-white is concerned, were misinterpreted. In

current dieto-therapy raw whole eggs, raw egg-white, and albumin-water are extensively prescribed. There appears to be little in their conduct as foodstuffs, however, to warrant such faith in their nutritive value or ease of assimilation.

501 — **The Vitamine Content of Brewers' Yeast.** — SEIDELL, ATHERTON (Hygienic Laboratory, United States Public Health Service, Washington, D. C.), in *The Journal of Biological Chemistry*, Vol. XXIX, No. 2, pp. 145-154, 4 Diagrams. Baltimore, March, 1917.

The author has studied the vitamine content of brewers' yeast as regards its efficacy for curing beriberi caused by a diet consisting exclusively of polished rice. His conclusions are given below.

In pigeons, the lack of vitamine in a diet consisting exclusively of polished rice can be exactly compensated for by daily doses of 0.5 to 1.0 cc. of the clear filtrate from autolysed brewers' yeast; doses of dried freshly-pressed yeast equivalent to about 1 cc. of autolysed yeast does not effectively replace the vitamine deficiency of a diet of polished rice.

Of 2 samples of dry yeast, one of which was autolysed before being dried and the other not, pigeons receiving the latter lost weight on a ration of polished rice much more rapidly than those receiving the former. The autolysis thus seems to have a favourable influence on the activity of the vitamine of brewers' yeast.

On the assumption that all the nitrogen contained in fullers' earth which has been shaken with autolysed yeast filtrate is derived from vitamine, the maximum quantity of the latter which can be present in the original yeast filtrate is 0.18 gm. per 100 cc.

The daily vitamine requirement of a grown pigeon is somewhat less than 1 mgm. A diet containing 0.0033 % of vitamine, given in quantities ordinarily consumed by pigeons, will supply this requirement.

## CROPS AND CULTIVATION

502 — **The Effects of Meteorological Factors on the Growth and Yield of Rice in the Vercelli District, Piedmont, Italy.** — MARCARELLI, B., in *Giornale di risicoltura*, Year VIII, No. 1, pp. 7-16. Vercelli, 1918.

AGRICULTURAL  
METEOROLOGY

At the "R. Stazione sperimentale di risicoltura" of Vercelli, Prof. MARCARELLI has, for some years, carried out a series of agricultural meteorological studies by the modern scientific method of parallel observations. His object was the determination of the critical periods of rice in relation to the various meteorological phenomena and factors of the district.

The apparatus is in a cage specially placed at 3.94 ft. above the ground (average height of a fully grown rice plant); the air, water and soil temperatures are determined simultaneously by three Richard's recording thermometers, the bulbs of which are in the air, water, and soil (at a depth of 5 cm.), respectively.

The experiments on the *temperature of the irrigation water* are of great importance in the rice fields, because the possibility of cultivating rice in a

more or less unfavourable climate depends both on the initial heat of the water and the rise in its temperature as a result of its exposure to the sun in shallow sheets over large surfaces. It is, indeed, only the influence of the specific heat of the water which can reconcile to any extent the extremes of temperature in the atmospheric layer immediately in contact with the vegetation and prevent the great changes in temperature so harmful to rice. It is also under this influence that the heat of the submerged soil is modified during the day and remains higher, thus favouring a maximum development of the roots.

According to the author's previous experiments, the factors necessary for a good rice yield are : — a total of average daily temperatures amounting to 3 500 to 4 500°C. for the period from April to the end of September ; a rainfall not exceeding 200-250 mm. ; a clear sky, expressed approximately by a total of fine and semi-cloudy days amounting to 140 to 170.

The *heat total* exceeds the other climatic factors in effect, but it must be regularly distributed without too frequent or excessive variations in the daily temperature. In Piedmont rice cultivation certainly does not suffer from the maximum temperature limit, for it is favoured by very hot seasons, but the minimum limit of resistance to low temperature is of great importance because of the phenomena connected with it during the various stages of the plant's development :— imperfect germination, yellowing of the young plants, limited stooling, non-setting, delayed ripening, etc.

The period in which rice is most sensitive to the air temperature coincides with the stooling stage. Although it is not exactly known if the marked need of the plant for heat at this period is due to the process of stooling itself or to the development of secondary rootlets, there is no doubt that if the meteorological conditions are unfavourable at this stage the rootlets develop slowly and do not take a firm hold in the soil, so that the development of the plant is weak, causing it to succumb to the slightest disturbance, and lodge when ripe.

Temperature also has a marked influence on the flowering stage and the setting of the grain, which are more affected by the frequency and intensity of cold nights than by the normal average daily temperatures. Frequent low early morning temperatures during the last period of the development of rice are nearly always the cause of the failure suffered in the cultivation of late rice in the Vercelli district.

The *clearness of the sky* follows immediately on the "heat" factor in the importance of its effects, especially on the quality of the product, and, within certain limits, abundant light may compensate for slight deficiencies in heat, as rice, by reason of its origin, demands sunny days.

*Rain* is harmful because it produces disturbances in the temperature round the rice field and decreases the clearness of the sky. Excessive moisture in September and October stimulates the development of the grain, causing it to germinate in the drying sheds and sometimes even in the ear in the sheaves. This explains why the summer of 1917, whose severe and prolonged drought was detrimental to the production of all other cereals, was so extremely favourable to rice. The low temperatures, the negative

action of which on the vegetative growth and maturation of the plant has already been mentioned, remained within the limits of 10 to 17°C. for the air, 18 to 21°C. for the water, and 18 to 25°C. for the soil, so that the most important biological phenomena of rice, such as stooling, flowering, setting of grain, were in every case favoured by excellent temperature conditions, and gave most satisfactory results.

As a result of the great stability in the distribution of the climatic factors in 1917 for all varieties of cultivated rice (except "Bertone", subject to "brusone" [scorching]), the critical phases of development, the period of which varied according to the earliness of the rice and the date of sowing, always coincided with favourable meteorological conditions, which caused a luxurious growth and a grain harvest as good as it was abundant.

### 503 - Plants Resistant to Adverse Meteorological Conditions Obtained by Selection.

— See No. 519 of this Review.

### 504 - New Experiments in Dry Farming in Italy — DE ANGELIS D'OSSAT, G., in *Le Stazioni sperimentali agrarie italiane*, Vol. LI, Pt. 1-2, pp. 41-55 + 1 Diagram + 1 Fig + 6 Tables. Modena, 1918. (Author's abstract, in Italian).

SOIL PHYSICS,  
CHEMISTRY  
AND  
MICROBIOLOGY

The author, professor at the "R. Istituto Superiore Agrario" at Perugia, carried out his previous field experiments on dry farming at the farm of this Institute (1). The characters of the soil were investigated by determining: — 1) its formation; 2) its lithological nature; 3) its mechanical constitution; 4) its chemical composition; 5) its physical behaviour.

The experiment field contained two adjacent plots; the soil of one was left hard, the surface of the other was frequently worked to a depth of from  $\frac{3}{4}$  to 1 inch. The soil samples for the various determinations were taken from a depth of 8 to 12 inches.

A table gives the data obtained from May 11 to August 3, 1917, for the weight and volume of moisture in the unturned and turned soil and also the atmospheric precipitation, daily moisture and air temperature.

The second part of the experiment (from June 27) gave positive results: — the average volume of the moisture in the turned soil was 13.095 %, but only 9.385 % in the unturned soil. The maximum, minimum and average differences were 7.45 %, 1.30 %, 3.71 % respectively.

From these results it may be concluded that:

1) In superficially turned soils (dry-farmed) the moisture content exceeds that of unturned soils.

2) to prevent damage by drought the soil should, therefore, be prepared in two ways: — a) during the rainy season it should be prepared so as to allow the water to penetrate as much as possible; b) during drought evaporation should be prevented as much as possible by dry-farming.

By means of a special apparatus the author attempted to determine the relative capacity of clay and sand to raise underground water during surface evaporation. Although this experiment, made in the laboratory, is of no real practical value it has given interesting results. For a distance

(1) See R. Feb., 1917, No. 119. (Ed.).

of 8 ½ inches between the evaporating surface and the water table, clay evaporated 265.7 cubic yards of water per acre monthly, and sand 234.6 cubic yards, or 31.1 cubic yards less.

**505—A Correlation Between Bacterial Activity and Lime Requirement of Soils.** — BEAR, F. E. (Department of Agricultural Chemistry and Soils, Ohio State University), in *Soil Science*, Vol. IV, No. 6, pp. 433-462 + 3 Figs, Bibliography of 14 publications. Baltimore, December, 1917

The fertility of limestone regions is well known. It is also known that soils lacking in carbonate of lime are made more productive by liming. Alfalfa, clover and maize are the plants which do best in lime soils. Many workers have, however, noted that certain plants flourish in non-calcareous soils, and are even injured by applications of lime. Strawberries, potatoes, rye, oats, millet, buckwheat, carrots, turnips, cowpeas, crimson clover, soy beans, serradella and lupins, are adapted to acid soils. These facts suggested to the author the possibility of a system of acid agriculture, *i. e.*, in acid soils, in districts some distance from a lime supply. In the first place he studied the relation between the activities of soil bacteria and nitrogen accumulation and transformation, and the nitrogen requirement of certain soils containing from 0 to 2300 parts of calcium carbonate per 1 million parts of soil. To various portions of this soil were added gradually from 0.01 to 2 % of calcium carbonate.

The results obtained from these experiments show that the various groups of soil organisms respond differently to applications of lime. Ammonification is fairly satisfactory in most soils, even without the addition of lime, but, as a rule, the addition of moderate amounts of lime increases the rate of ammonification, and small applications are relatively more efficacious than large ones.

On the other hand, the rate of nitrification is directly correlated with the amount of lime added; excessive applications are not injurious to the nitrifying bacteria, and soils with a high lime requirement show practically no nitrification until calcium carbonate has been mixed with them.

Nitrogen fixation by non-symbiotic soil organisms is also considerably increased by liming, but the addition of mono-calcium phosphate is necessary for maximum nitrogen fixation.

Pot experiments with soy beans showed that a lime requirement of 1500 parts of lime per 1 million parts of soil was not sufficient to prevent good growth of soy beans in a soil well fertilized with acid phosphate or manure.

**CONCLUSIONS:** — 1) Plants which are able to utilise ammonia nitrogen do not suffer from nitrogen hunger when grown on soils having lime requirements not exceeding those studied in the investigations.

2) Plants which derive their nitrogen from nitrates may suffer from the lack of available nitrogen in soils having a high lime requirement unless this requirement has been at least partially satisfied.

3) The supply of nitrogen in acid soils may be maintained by growing acid-resistant legumes, of which the soy bean is one. There is no doubt that acid phosphate aids nitrogen fixation in acid soils.

4) As a rule, small applications of calcium carbonate are relatively more effective than large applications for increasing bacterial activity in acid soils.

506 - **Drainage Ditching of Irrigated Lands in Colorado, U. S. A.** - *Engineering News Record*, Vol. CXXX, No. 6, p. 263, 2 Figs. New York, February 7, 1918.

The San Luis valley, Colorado, is level and without rivers or ravines to afford natural drainage for the water coming from higher levels. Beneath the gravelly subsoil there is water under pressure, and nearly every ranch has a flowing well, many of which run continuously, causing an additional amount of surface water. Under these conditions the land in the valley has become waterlogged and therefore requires drainage.

The drainage work is being done by the CHARLES & GIBSON Co. of Alamosa, Colorado, which owns large tracts of the land and develops them for settlement.

The drainage ditches, of which over 100 miles have already been excavated, are made by 3 AUSTIN excavators. The ditches are 8 ft. wide on the bottom, with slopes of 1 on 1 1/2. They are mainly 6 to 8 ft. deep; but the machines can cut to a depth of 11 ft.

The excavated material is deposited on both sides of the cut, leaving 8-ft. banks, so that in the future a machine can be run over the ditch for the purpose of cleaning and reshaping it. The machine works night and day (except Sundays), being equipped with an electric plant for lighting. The day shift consists of 5 and the night shift of 4 men. The machine can excavate 800 to 1000 cu. yd. per 10-hour shift.

507 - **Irrigation of Alfalfa in the United States.** - I. BECKETT, S. H. and ROBERTSON, R. D., in the *College of Agriculture, Agricultural Experiment Station, Bulletin* No. 280, pp. 273-294 + 2 Figs. + 4 Tables. Berkeley, California, May, 1917. - II. FORTIER, SAMUEL, in the *U. S. Department of Agriculture, Farmers' Bulletin* No. 865, pp. 40 + 36 Figs. + Tables. Washington, December, 1917.

I. - Experiments carried out during six years at the Farm of the University of California at Davis, and observations made during one or two years on 54 alfalfa-growing farms in the Sacramento Valley, California, yielded the following data with respect to the irrigation of alfalfa in this district: -

Soil	Depth of water required to produce good yields per annum. inches	Depth of water required per irrigation, depending on depth of soil. inches	Number of irrigations per season.	Size of border strip checks		Suitable grade. inches per 100 feet	Size of irrigating head per second, per check cu. ft.
				width feet	length feet		
Medium loam.	30-36	6-9	3-5	30-50	300-600	3-6	2-10
Very gravelly or sandy . . . .	48-60	3-4	2-3 per cutting	1 00	1 00	—	5-6
Heavy . . . .	30-36	2-4	2-3 per cutting	30-50	300-600	1-3	1-4

PERMANENT  
IMPROVEMENT,  
DRAINAGE  
AND  
IRRIGATION

The experiments, the results of which are given in the above table, aimed at determining:— 1) the amount of water necessary to produce good yields of alfalfa in the light and heavy soils of the Sacramento Valley; 2) the amount of water required for irrigation; 3) the most suitable heads; 4) the soil moisture required to prevent wilting; 5) the amount of water necessary to assure the best growth of alfalfa. These experiments are described in the bulletin under review which itself is but a summary of a more complete description of the investigations.

II. — *The Farmers' Bulletin No. 865* on the irrigation of alfalfa in the United States is a revised edition of *Bulletin No 373*, published in 1909. The various methods of irrigating lucerne are described, together with the methods of preparing the soil. A description is given of the different types of levellers and other apparatus for constructing the dikes, as well as information necessary for constructing the canals, ditches, gates, and outlet valves. In the United States 95 % of the alfalfa fields are subjected to surface irrigation, the other 5 % to sub-irrigation. Near the towns of St. Anthony and Sugar City, Idaho, where the soil is composed of sand and gravel, 60 000 acres are irrigated from below.

The amount of water to be applied to alfalfa in the various districts of the United States is set out in tables. On account of the rapidity of its growth and the number of cuttings during a season, alfalfa requires more water than other crops. This sometimes leads to the use of too much water, which should be avoided. No fixed dates for irrigating alfalfa can be given; the appearance, and, more especially the colour of the plant, are the best indications of its need of water.

#### MANURES AND MANURING

508 -- **The Progress of the Nitrogen Industry.** -- BERTRAND, A., in *Anexo al Boletín de Mayo de la Asociación Salitrera de Propaganda*, pp XXXVIII + 363 Valparaíso, 1917.

Review of publications relating to the nitrogen industry in the chief producing countries, especially during the war. There are 5 parts, dealing with Germany, Chile, United States, France, Great Britain. In 11 appendices are given: — a paper by the Badische Anilin- und Sodafabrik on the monopoly of nitrogen in Germany; a study by P. FÄRENBERG, professor of Agricultural Chemistry at the University of Göttingen, on the organisation of this monopoly; the nitrogen question at the United States Congress; a list of publications on the net cost of nitrate of soda; a list of the members of the Nitrate of Soda Council since its foundation; a list of information regarding propaganda for nitrate of soda in various countries; a list of articles published in Chilean periodicals from 1907-1914 on the efficaciousness of the propaganda for nitrate of soda; a list of articles published in the above-mentioned periodicals on synthetic nitrogen products; a bibliography of the Chilean press relating to the organisation of the nitrate industry; a list of studies, projects and inventions relating to that industry; a general bibliography of the names of authors arranged in alphabetical order.

It constitutes a very full compilation of information relating to the production of nitrogenous fertilisers and their application.

The author shows that in Chili there is a lack of a publication giving nitrate of soda statistics in full and giving information as regards the production, consumption, price, etc., of other nitrogenous products. He finds that that want has been provided for:—

1) by the monograph on the "Production and Consumption of Chemical Manures in the World", published by the International Institute of Agriculture in 1914, followed by a second edition in the same year;

2) by the half-yearly publications on the "International Trade in Fertilisers and Chemical Products useful to Agriculture", commenced in September 1914, and based on the above monograph, by the Bureau of Agricultural Intelligence of the above-mentioned Institute;

3) by Part IX of the Yearbook of Agricultural Statistics, also published by the International Institute of Agriculture, which gives data regarding the production, trade and prices of chemical fertilisers for the preceding 10 years.

The author hopes that these publications will be distributed as widely as possible in Chili, and that they will lead to treating nitrate of soda statistics in the same way as others, especially if the review of "International Trade in Chemical Fertilisers" is published quarterly and then, as soon as possible, monthly.

The author considers that the war has shown that combined nitrogen is the elementary chemical basis of explosives as well as feeding and textile stuffs, so that the importance of a country can very well be measured, whether in peace or in war, by considering its capacity for producing combined nitrogen.

509 — **Spanish Mineral Products Employed in Agriculture.** — NAVARRO, B., in *Iberica*, Year V, No. 216, pp. 121-124. Tortosa, February 23, 1918.

Of the various mineral products of Spain the following are of value in agriculture, either for their use in the manufacture of fertilisers, or in the control of insects and disease:—

**PHOSPHORITES.** — These are obtained in the province of Cáceres, where there are four mines the total yield of which in 1916 amounted to 14 200 metric tons, giving an average of 50 % phosphoric acid, valued at about £ 10 000.

There are 14 superphosphate factories: — 3 at Barcelona, 1 at Cáceres, 1 at Huelva, 1 at Seville, 1 at Córdoba, 2 at Málaga, 1 at Murcia, 1 at Navarre, 1 in the Asturias, at 2 at Valencia. The total production of superphosphates rose, in 1916, to 315 180 metric tons, valued at £ 1 389 000 (1).

**AMMONIUM SULPHATE.** — There are 17 factories at Barcelona and others at Oviedo, which, by distilling coal, produce 2 720 metric tons of ammonium sulphate. The figures quoted are for 1916; those for 1917 are believed to be much higher.

(1) The superphosphates are chiefly produced from imported phosphates. Cf. *Intern. Inst. of Agriculture, The International Trade in Fertilisers and Chemical Products Employed in Agriculture* (Half-yearly review). (Ed.)

**SULPHUR.** — Sulphur-containing material ("tierras azufrosas") is obtained from a number of deposits:— 1 at Alicante, 2 at Almería, 5 at Murcia and 2 at Teruel. The total yield in 1916 amounted to 47 000 tons, with an average sulphur content varying from 12 to 25 % (Almería). The amount of sulphur obtained from raw material was 11 000 tons, worth about £ 109 000. This production is believed to have made Spain independent of imports.

**COPPER SULPHATE.** — Until recently this was not produced in Spain in spite of the many deposits of copper-containing minerals. In 1916 two factories at Barcelona and one at Córdoba produced a total of 7 600 tons, valued at £ 400 400.

**510—Fertilizers in Australia.** — in *Commonwealth of Australia, Advisory Council of Science and Industry, Report of Executive Committee for the Year 1916-17*, pp. 32-34. Melbourne, 1917 (1).

Australia is largely dependent on outside sources for the raw material of artificial fertilizers and the Executive Committee of the Advisory Council of Science and Industry appointed in 1916 by the Governor-General has devoted much attention to the consideration of possible local sources of phosphates, potash, and nitrogenous fertilizers with a view to reduce this dependence of Australian agriculture on foreign countries.

**Potash.** — Of most pressing importance is the need for developing local sources of potash, since Australia, in common with the rest of the world, was before the war dependent on the potash deposits of Stassfurt, Germany, for her supply of this chemical. Besides the use of potash for fertilizers, it is required in various secondary industries, such as the manufacture of soap, cyanides, explosives, and fireworks. The problem is not peculiar to Australia, and the Committee have obtained reports and other information as to the inquiries into new sources of potash which have been conducted in the United Kingdom and the United States of America. The sources of potash which have been suggested are a) alunite; b) kelp; c) suint; d) molasses; e) wood-ashes; f) ground igneous rocks; g) saline deposits.

a) Alunite is a mineral consisting of the sulphates of potassium and aluminium, of which there is a very large deposit at Bullahdelah, in New South Wales, and smaller though purer deposits in South Australia. The Bullahdelah deposit was formerly mined and shipped to England for the manufacture of alum, but this industry is now at a standstill. A special Committee was appointed to consider the best means for utilizing alunite, for which the Australian deposits are the most extensive in the world, specially with a view to ascertaining the best treatment for the extraction of the potash. This Committee has almost reached a stage when it can definitely state that no serious technical difficulties stand in the way of any one desirous of producing sulphate of potash and alumina from Australian alunite, but having regard to the nature of the operations involved the manufacture of sulphate of potash could be carried on with profit if done on sufficiently large scale by means of modern appliances, always provided that a local market for the output of the plant could be obtained; in other words the difficulties, if any, in the way of developing the alunite industry are economic rather than technical.

(1) See INT. INST OF AGR., *Production et consommation des engrais chimiques dans le monde*, II ed., 1914, and the half-yearly reviews *The International Movement of Fertilizers and Chemical Products Useful to Agriculture*. (Ed.)

b) The large brown seaweeds known as kelp contain a considerable quantity of potash, but species from different localities vary considerably in their content, and few investigations appear to have been made as to the composition of Australian seaweeds.

From press reports it appears that a small plant for treating kelp has been established in Tasmania, and is producing potassium chloride. The Committee are making further inquiries on this subject.

c) Suint, or wool-grease, contains a certain amount of potash, and if the whole Australian wool clip were scoured in Australia and the potash extracted, this would probably suffice for local needs. The recovery of potash in wool-scouring must be considered in connexion with the production of lanoline.

d) The recovery of potash from molasses has been considered by a sub-committee of the Queensland State Committee appointed to review the possible means of utilizing molasses. They had before them details of a proposed method, which had been brought before the Executive Committee, for absorbing the molasses with megass, producing charcoal and gas therefrom, and then burning the charcoal to an ash from which the potash could be recovered. They reported that all methods hitherto tried for recovery of potash from molasses have led to only small proportions being finally recovered, and that the prospect of burning to ash with megass did not appear at all promising, even in war-time.

e) The extraction of potash from the wood ashes of saw-mills and of eucalyptus distillation plants has been suggested, and the Executive Committee has collected evidence on the subject which points to the conclusion that the amount of potash is too small to render this a commercially profitable source. It is understood that experiments are being conducted as to the feasibility of extracting the potash from the ash left when prickly pear is burnt.

f) The utilisation of ground igneous rocks as potash fertilizers has often been discussed, particularly in the United States. These discussions have related chiefly to orthoclase feldspars or orthoclase-bearing rocks, but it was suggested to the Committee that leucite-bearing rocks might be more suitable from this point of view. The subject was referred to the Chemical Committee, which came to the conclusion that these rocks were unlikely to be able to compete with alunite as a source of potash.

g) The most satisfactory solution of the potash difficulty would be the discovery of a saline deposit in Australia rich in potash salts. It seems not improbable that such a deposit might exist in some of the lake basins of Central Australia, and it is worth consideration whether an investigation of the deposits in the beds of the salt-lakes of the Commonwealth should be undertaken.

*Phosphates.*—The possibility of increasing the local supply of phosphatic fertilizers depends on either a) the discovery locally of rock phosphates suitable for the manufacture of superphosphates, or b) the discovery of means whereby the phosphates of iron and aluminium, of which there are considerable deposits in Australia, can be made available as sources of phosphorus to crops.

The Executive Committee has made inquiries in all the States as to the likelihood of discoveries of rock phosphates, but the replies received are not very encouraging. Islands off the coast of North-western Australia and Queensland are regarded as the most probable localities to search, and prospecting in these localities should be encouraged. The known deposits of calcium phosphate on the mainland are small. Experiments as to the fertilizer value of iron and aluminium phosphates under different conditions are in progress in Victoria and Western Australia, and the Committee is considering the appointment of a Special Committee to co-ordinate these researches.

*Nitrates.* — The question of the production of nitrates from atmospheric nitrogen has also been considered. The utilization of atmospheric nitrogen, to be commercially successful, depends on the presence of a cheap source of power, and it seems possible that ultimately the Tasmanian hydro-electric scheme may be utilized for this purpose. Three different processes are at present in operation in other countries, but under present conditions it is impossible to obtain evidence as to which of these should be established in Australia, and it is certain that an expert familiar with them would need to be employed in the establishment of plant for the purpose in Australia. The Committee have come to the conclusion that, as there is no immediate prospect of Australia being cut off from the supply of Chili saltpetre, the matter should be left until the conclusion of the war.

512 — **Cyanogenesis in Plants. Studies on *Tridens flavus* (Tall Red Top).** — VIEHOEGER, A., JOHNS CARL O and ALSBREG, CARL L. (Bureau of Chemistry, United States Department of Agriculture, Washington), in *The Journal of Biological Chemistry*, Vol. XXV, No. 1, pp. 111-149. Bibliography of 7 publications. Baltimore, Md. May, 1916

The authors confirm the presence of notable quantities of hydrocyanic acid in *Tridens flavus*, a common grass widely distributed in the United States, occurring from Massachusetts to Kansas and south to Texas. The whole plant, including the roots, collected in August and examined without drying yielded 0.0075 per cent. of hydrocyanic acid. These plants after drying in desiccated air at 50°C. retained 0.0066 per cent. of hydrocyanic acid, and this quantity still remained after the dried plant had been ground and left exposed to the laboratory atmosphere for 3 months. The August plants dried for more than a month at 0°C. gave the following distribution of the hydrocyanic acid: — inflorescence tops stripped of flowers, 0.0037 %; stems, 0.0030 %; green leaves, 0.0017 %, dead yellow leaves, 0.0000; root, trace. Thus the maximum quantity of hydrocyanic acid was found in the inflorescence tops. The ripe seed did not contain hydrocyanic acid. Only a trace of hydrocyanic acid was found in plants collected in September, and none in October plants.

No free hydrocyanic acid was obtained by direct distillation with steam; by maceration with water, and subsequent distillation with acid, less hydrocyanic acid was obtained than by direct distillation with acid. Distillation of the macerated or unmacerated plant without the addition of acid resulted in a partial or complete loss of the available hydrocyanic acid.

The quantity of hydrocyanic acid obtained from *Tridens flavus* was not increased by macerating with emulsin.

When the plant was macerated in water containing a known weight of potassium cyanide, considerable loss of potassium cyanide resulted. If tartaric acid was present during the maceration of the plant with potassium cyanide, all the latter could be recovered; when sodium hydroxide was

present the loss of potassium cyanide was complete. The loss of cyanide during maceration is probably due to a chemical reaction.

*Tridens flavus* contains an enzyme which hydrolyses amygdalin.

513 — **Researches on Carotin and Its Possible Toxicity.** — See No. 542 of this *Review*.

514 — **The Origin of the Resins in the Pine.** — DUFRENOY, J., in the *Revue générale des Sciences*, Year XXIX, No. 1, p. 3. Paris, January 15, 1918.

The origin of resins in plants may be explained either histologically or cytologically, according to whether they are the transformation products of the cell membranes or of the cell contents or reserves (leucites).

Lignified membranes may become resinous; in such a case they give the reactions for pectic membranes; they can fix metallic bases and are stained orange with safranin (which stains lignin cherry-red).

In the bacterial tumours of *Pinus maritimus* the contents of the tumour become resinous.

In the needles of *Pinus maritimus* attacked by rust (*Peridermium*) the resin proceeds directly from the secretion or transformation of the chloroplasts. In unfixed sections stained directly by Soudan III in glycerine, the resinous globules can be seen forming and growing in contact with the chlorophyll grains; several globules may unite into one while the various chloroplasts that took part in their formation remain in the periphery of the globules.

In a healthy needle, the oleo-resinous globules are also less abundant in the chlorophyll-free perisperm than in the green parenchyma.

The secretion of resin is thus a very complex phenomenon, and the process of formation varies greatly according to the case under consideration; but it is never formed by the *secreting* canals, which are probably only collecting organs.

515 — **The Effect of One Growing Plant on Another.** — RUSSELL, E. J., in *The Gardeners' Chronicle*, Vol. LXIII, No. 1621, pp. 23-24. London, Jan. 19, 1918.

From time immemorial gardeners have been convinced that certain plants injure others, and, in many cases, it is firmly believed that the harmful effect remains in the soil for months, if not for years. This has led to the opinion that certain plants excrete something from their roots which is poisonous to other plants of the same kind, though not necessarily so to those of a different kind. For a long time the plant was considered as completely analogous to the animal, and, thus, the scientist agreed with the practical man in admitting the existence of a poisonous excretion in plants. Of recent years, however, much doubt has been thrown on the idea of a poisonous excretion, and serious obstacles have been shown to hinder its acceptance. In a good grass field, for example, the plants are as crowded as they can be, yet they show no signs of "sickness" or poisoning. If the soil be poor the plants may go hungry, but this may be remedied by applying suitable fertilisers; there is nothing in the appearance of the plants to suggest that any other factor is concerned.

On the other hand, some years ago Dr. WHITNEY, chief of the Bureau of Soils of the U. S. Department of Agriculture, expressed the opinion that

plants do excrete a toxic substance which may, however, be precipitated or rendered inactive by fertilisers. Therefore the improvement of plants by fertilisers is due, not only to the food they supply, but also to the above-mentioned action, and perhaps to others as well. WHITNEY'S hypothesis gave rise to much discussion, which led to a great deal of progress being made on the subject.

British investigators have usually taken the view that there is no evidence of a persistent toxic excretion. The experiments at Rothamsted seem to bear this out. At the present time the famous Broadbalk field is carrying its 75th. successive crop of wheat, and the plants look as well as any on the farm, and better than a good deal of the wheat in the district. The last crop of mangolds was the 42nd. ; it was well above the average and has rarely been exceeded during the whole period. Similarly, barley has been grown for 57 years in succession without showing any signs of suffering. Leguminous crops, however, cannot be grown in this way, and, after a short period, fail; they are the only crops which experimental evidence has shown cannot be grown year after year on the same land. Observations show, nevertheless, that other plants also fail in the same way; thus foxglove grows splendidly in the soil of a freshly cleared wood (provided the soil is suitable, e. g., the clay patches on the Downs) but for one year only, not longer. It is also said that flax and onions may fail if grown too often in the same soil. These, however, are all simply observations which, even if exact, may have some other explanation.

The idea that plants excrete poisonous substances has been investigated by Mr. SPENCER PICKERING. The growth of plants was found to be considerably decreased if they received water which had washed part of the roots of another growing plant. This effect seems to be general; the washings from the roots of mustard check the growth of mustard; those from grass check the growth of fruit trees, and so on. It was possible to establish the important point that these washings lose their poisonous quality very rapidly, so that they do not necessarily affect the soil after plant growth has ceased. These experiments are, therefore, perfectly consistent with those of Rothamsted described above.

Another set of Rothamsted experiments is, however, more difficult to reconcile with Mr. PICKERING'S results. Dr. WINIFRED BRENCHEY grew wheat alone, weeds alone, and wheat mixed with weeds. She observed that when poppy (*Papaver Rhoeas*), black bent (*Alopecurus agrestis*) and spurry (*Spergula arvensis*) were grown with wheat they made less growth than when grown alone; on the other hand, wheat made more growth per individual plant (1). This, of course, does not mean that wheat should always be grown with weeds; the plants would have done better had no weeds been present, but they suffered less from the presence of the weeds than they would have done from an equal number of wheat plants. In these experiments spurry proved more harmful than the other weeds because, by its straggling habit it badly checked the young wheat,

(1) This work is summarised in R. July, 1917, No. 625. (Ed.)

which never recovered properly. Charlock and wheat settle down to some sort of equilibrium as neither masters the other.

So far as could be seen, the effect was solely one of competition for food, and it made no difference to the individual wheat whether it competed with another wheat plant or a plant of a completely different order. The whole phenomenon could be explained by the supposition that the number of plants the soil can carry depends on the amount of plant food present in the soil and the amount of space available for growth; if the food and space are to be divided, each individual will get a smaller share and will, consequently, make less growth than if there were fewer plants present. At first sight these results seem difficult to reconcile with those of PICKERING's experiments, which seem to prove that a large number of plants suffer not only from starvation, but also from mutual poisoning, so that growth would be less both individually and collectively than when a smaller number is grown. The apparent disagreement may, however, be explained. In another of Mr. PICKERING's experiments plants grown in plots divided into compartments so that each individual root was kept separate from its neighbour made no better growth than did plants in undivided pots where the roots of the different plants mixed freely. Thus, the toxin produced by one individual plant does it as much harm as that produced by its neighbour. Further Mr. PICKERING found, in open soil, that the total growth was the same whatever the number of plants (within certain limits of distance apart) or, in other words, that the weights of the plants were inversely proportioned to the bulk of soil available. This is in full agreement with Dr. BRENCHLEY's results and may be explained perfectly well, without assuming the existence of a toxin, simply by the fact that the full crop-bearing capacity of the soil has been reached. If, with Mr. PICKERING, a toxin is assumed to be present, it must be supposed to be at least as harmful to the plant itself as to any other. This assumption involves possibilities which new experiments should investigate.

516 - **Action of Magnesium Salts on Wheat.** — VOELCKER, J. A. (The Woburn Experimental Station of the Royal Agricultural Society of England, Pot-Culture Experiments, 1916), in *The Journal of the Royal Agricultural Society of England*, Vol. LXXVII, p. 260-262. London, 1916 (published in 1917).

In continuation of the experiments on the action of magnesia the author considered it desirable to study the action of magnesium compounds other than the oxide and carbonate. To this end he used the chloride and the sulphate (in the anhydrous state) in quantities equal to 0.10, 0.15, 0.20 and 0.40 % of the soil. The soil used contained 0.30 % of lime and 0.22 % of magnesia, giving, with the addition of the magnesia salts, a ratio of 1 : 0.88. The experiments were made with pot-cultures of spring wheat; growth was observed and the harvest analysed. The results obtained, as well as those from previous experiments (1), led to the following conclusions : —

(1) See B. 1915, No 900. (Ed.)

1) The action of magnesium compounds on wheat varies very greatly according to whether they are present as the oxide, carbonate, chloride, or sulphate.

2) The chloride may be used beneficially up to quantities of 0.10 % of the soil (1 ton per acre); in larger quantities it injures or totally destroys the crop.

3) Magnesium sulphate may be used safely and advantageously in quantities up to 0.40 % of the soil (say 5 tons per acre).

4) Increased nitrogen content, such as obtained in cereals by the use of magnesium oxide, is not produced by magnesium sulphate.

**517 - Action of Sodium Compounds on Wheat.** — VOELCKER, J. A. (The Woburn Experiment Station of the Royal Agricultural Society of England, Pot-Culture Experiments, 1916), in *The Journal of the Royal Agricultural Society of England*, Vol. LXXVII, pp. 262-264. London, 1916 (published in 1917).

In correlation with his work on magnesium (1) and by the same method, the author carried out experiments with pot-cultures of wheat using anhydrous sodium hydrate, carbonate, chloride and sulphate in quantities of 0.01, 0.03, 0.10, 0.15 and 0.20 % of the soil for the two first compounds and 0.10, 0.15 and 0.20 % for the last two. The hydrate was applied in solution, the other compounds in the solid state.

CONCLUSIONS. — 1) The different sodium compounds have very different effects both on the germination and the growth of the wheat.

2) The hydrate and carbonate at first retard germination, but eventually have a beneficial effect even when applied in amounts equal to 0.20 % of the soil, or 2  $\frac{1}{4}$  tons per acre. Besides an increase in grain there is also an increase in nitrogen content.

3) Sodium chloride has a beneficial effect if not used in quantities exceeding 0.10 %, i. e., 1 ton per acre, but is harmful to germination and production when used in larger quantities, and, if applied in amounts of 0.20 %, corresponding to 2  $\frac{1}{4}$  tons per acre, may destroy the plant entirely.

4) Sodium sulphate affects neither germination nor production and may be used without detriment in quantities up to 0.20 %, or 2  $\frac{1}{4}$  tons per acre.

5) Both sodium hydrate and carbonate cause "caking" of the soil; this was noticed neither with the chloride nor the sulphate. The first two compounds also darken the soil. In practical agriculture caking would doubtless prevent proper aeration of the soil and free growth of the plants.

**518 - The Toxic Action of Soluble Aluminium Salts upon the Growth of the Rice Plant.** — MIYAKE, K. (*Rudolph Spreckels Physiological Laboratory of the University of California, Berkeley*), in *The Journal of Biological Chemistry*, Vol. XXV, No. 1, pp. 23-28. Baltimore, Md., May, 1916.

The matter of soil acidity is one of the chief topics of the day among soil investigators. There has been a vast amount of investigation on the subject and it has come to be quite generally recognized in recent years that

(1) See No. 516 of this Review (Ed.)

by the addition of various kinds of salt solutions to soils, soluble acids or acid-acting salts are set free : that is, cultivated soils tend to become acid year by year as a consequence of the application of manures and fertilizers containing soluble salts, because when nitrates, chlorides, and sulphates are added to soils, the tendency is for the base to combine with the organic matter and the silicates in the soil, and for the acid radicle to combine with aluminium and to a less extent with iron. The soluble aluminium and iron salts which are formed are more or less hydrolyzed in solution, with consequent setting free of soluble acid ; that is, the presence of excess of acid in the soil. Of course the acid radicles combine with the stronger bases, such as calcium and magnesium, but the acid condition of any soil is due to the fact that it does not have a sufficient supply of the strong bases ; hence in many soils aluminium and iron necessarily supply the basic radicle. It thus happens that in many cases the apparent acidity of the extract from the soil as determined by titration with standard alkali in the presence of phenolphthalein, is found to be proportional to the amount of aluminium salts present in the solution, and evidently represents the amount of alkali required to precipitate the aluminium rather than actual free acidity. Accordingly, the addition of strong bases as calcium to the soil or treatment such as ignition which makes soil constituents less reactive, will stop or decrease the production of acid by the application of soluble salts to the soils.

From the view of soil acidity above stated, it appeared to be of interest to investigate the toxicity of soluble aluminium and iron salts and its relation to their acidity. As the soluble iron salts are generally present in negligible traces in the soil solution the author has confined his investigation to aluminium salts.

A review of the available literature shows that, although there is evidence that aluminium salts are toxic, there has been no research work done on the question of the relationship of the toxicity of aluminium salts to their acidity except one article by ABBOTT, J. B., CONNER, S. D, and SMALLEY, H. R. (*Indiana Experiment Station Bulletin* 170, p. 329, 1913) which touches on this matter.

The author employed cultures of young rice seedlings 10 mm. high in solutions of aluminium chloride in concentrations of  $\frac{N}{1000}$  to  $\frac{N}{20000}$  and of hydrochloric acid of the same concentrations for comparison, while cultures in distilled water served as a control. After 13 days the plants were measured ; their difference in development was striking. The concentration of hydrogen ions in some of the solutions of aluminium chloride was measured by the method of the gas chain. From the results the following conclusions are drawn :—

Aluminium chloride is toxic to the growth of rice seedlings even in dilute solution. This toxic effect appears in concentrations greater than  $N/7500$  ; it seems to be approximately equal to that of hydrochloric acid of the same normality ; it is not due to the hydrogen ion formed by hydrolysis of the salt in solution.

The concentration of hydrogen ions formed by the hydrolysis of aluminium chloride is less than that formed by dissociation of hydrochloric acid of the same normality. Since the chlorine ion is not toxic to the growth of rice seedlings in such dilute solution, colloidal aluminium hydroxide or unhydrolysed aluminium chloride molecules or aluminium ions may be the toxic factors.

The toxicity of soluble aluminium salts is dependent upon the amount of aluminium itself. The determination of soil acidity by titration in which the soil extract is titrated with standard alkali is a logical method of determining the amount of bases which should be added to the soil for the improvement of its infertility; because, although the titration does not indicate the true acidity of the soil, yet it does afford a measure of the bases which must be added to neutralize the free acid and decompose the aluminium salts, either or both of which may be responsible for the infertility.

PLANT  
BREEDING

519 — **The Selection of Plants Resistant to Diseases, Animal Pests and Adverse Meteorological Conditions.** — MoLz, E., in the *Zeitschrift für Pflanzenzüchtung*, Vol. V, Pt. 2, pp. 121-241. Berlin, 1917.

Amongst the individual specimens of some variety of plant liable to attack by diseases and pests, it is not uncommon to find some whose resistance surpasses not only the average resistance of the variety under consideration, but even surpasses the average resistance of varieties considered as resistant. In addition, the cross between two susceptible individuals sometimes gives progeny notable for a high resistance. This leads up to the problem of the creation of resistant types by means of individual selection and suitable crossings, and it suffices to consider the enormous expense due to the application of fungicides and insecticides to obtain an idea of the economic importance of varieties which, without any treatment, can remain free from pathogenic agents, or which, if they are attacked, do not suffer.

There are 2 forms of immunity:—

1) *Mechanical immunity*, due to the formation of differentiated corky layers around the infected part so as to isolate it completely and prevent pathogenic agents from penetrating into the body of the plant.

2) *Chemical immunity*, due to the presence of substances which repel or poison the pathogenic agent; for instance, the resistance of the African cacao tree to the attacks of the larvae of *Ephestia elutella* is due to the richness of the bark in tannic matter, which is, on the contrary, present in but small amount in the fruit of the Guatemalan and Venezuelan varieties, which are more liable to be attacked by these larvae.

In the apple the tannin is replaced by a phenol which, under the action of an oxydase, may change into a tannoid substance, and this change takes place just at the time when, owing to a wound or other cause, the fruit is particularly exposed to infection.

In the vine, varieties resistant to mildew and oidium, like *Rupestris*, *Berlandieri*, *Riparia* and their various hybrids, have leaves with sap of 4.3 to 10.3 % acidity (expressed as tartaric acid and calculated on the dry matter), whilst hybrids very sensitive to these fungi, like *Vitis vinifera*, *Gutedel* × *Berlandieri*, *Cabernet* × *Berlandieri*, *Aramon* × *Rupestris*, have

leaves with an acid content of not more than 0.5 to 2.6 %. Similarly, resistant varieties give a more acid must than susceptible ones.

The defensive action of citric acid is very feeble. In the apple, malic acid is no protection whatever against *Botrytis cinerea*, which even develops more vigorously in presence of that acid.

Generally speaking, substances which favour the development of mycelium are called "chemotaxic", such as the sugars, for example. But on the other hand they increase the plant's resistance to low temperatures.

As regards the plant's resistance to diseases and pests, chemical immunity is of the greatest importance, so much so that the plant breeder has to take into consideration the results of analyses and to know intimately the chemistry of the plant cell.

INDIVIDUAL SELECTION — may be carried out in two ways:

- 1) by isolating those individuals that are not attacked;
- 2) by isolating those plants which, although attacked by the pathogenic agent, are not severely damaged.

In any case the first selection should be made from as large a number of individuals as possible, since the special resistance of a number of them is not intrinsic and hereditary, but depends on special environmental conditions, such as more suitable soil, the exposure to light, good manuring, etc.

In order to produce varieties of vine resistant to phylloxera, cuttings from plants having shown special resistance are planted in separate groups by purelines; after 4 years, from each are taken 3 groups of cuttings which are to be planted in 3 localities having very different topographical, agro-geological and cultural conditions; those lines that give positive results in all the tests will afterwards provide the material for forming a plantation of resistant varieties.

The presence of correlations between the character "resistance to a given disease" and certain other characters will be of very great help to the plant breeder. Some examples of this are given below.

1) The spelt (*Triticum Spelta*) varieties from Turkestan and Samara, which are very subject to brown rust (*Puccinia triticina*), can be distinguished from the resistant west European types by the shape of the glume, which is not obtuse, but has a mucronate point bent inwards to form a hook.

2) According to Swedish observers, there is a positive correlation between the characters "resistance to cold" and "resistance to disease". This is specially the case with *Phleum pratense*, *Poa serotina* and *Festuca pratensis*, as far as regards resistance to *Sclerotinia trifoliorum*.

3) According to BABO and MACH, plants of *Vitis Berlandieri*, which had done well in the chalky soils of the Charente district, without showing signs of chlorosis, can be distinguished by golden-yellow, velvety leaves.

4) The hybrids *Berlandieri* × *Riparia Teleki*, whose shoots have a red, smooth and brilliant epidermis, while the tip is bronzed (not red), are the most resistant to chlorosis.

5) The colour of seeds shows correlations which are easily noted and which may be of practical use. Thus, the more the spermoderm of the seed of *Trifolium pratense* and *Lupinus hirsutus* is dark-coloured (reddish-yellow to deep red), the more the plants obtained from such seeds will be resistant to mildew.

HYBRIDISATION. — The resistance of a hybrid may surpass that of its parents. For example, the two wheats "Bore" and "Line 0728"

are affected by rust to different degrees, corresponding respectively to the figures 4 and 2. In their  $F_3$  cross, numerous forms were obtained, some of which were more resistant to rust than the more resistant parent, as is shown by the following figures:—

6 forms having a degree of resistance equal to 0									
6	»	»	»	»	»	»	»	»	1
6	»	»	»	»	»	»	»	»	2
2	»	»	»	»	»	»	»	»	3
3	»	»	»	»	»	»	»	»	4
3	»	»	»	»	»	»	»	»	5
2	»	»	»	»	»	»	»	»	6

In cases like this, the degree of resistance of the hybrid evidently corresponds to the sum of the factors present in each of the parents ( $A, B, C \times D, E, F = ABCDEF$ ). In a similar way the possibility can be shown of obtaining resistant types by crossing susceptible ones, when, in order to determine the "resistance", both groups of factors must be present simultaneously. Thus in crossing "Up to Date" and "Yellow Norwegian" potatoes, both susceptible, NILSSON obtained in the  $F_2$ , 29% of individuals having a high degree of resistance to *Phytophthora infestans*.

But as, on the other hand, it is impossible to find out what are these determining factors and what is their number, at least one parent in each crossing should have a high degree of resistance.

Excellent material for hybridisation is to be found in wild varieties, or in native varieties cultivated since time immemorial in some given locality and completely acclimatised. In time, by natural selection the weak or susceptible forms will have disappeared, leaving the progeny of the most resistant parents. In 1840 a terrible invasion of *Phytophthora infestans* destroyed the potato crop over a great part of Europe; the few surviving plants became the parents of new varieties possessing a great resistance to this disease.

By crossing wild varieties of fruit trees with cultivated forms, HANSON has obtained, in the United States, types of fruit trees showing great resistance to cold.

In this and similar cases, it is most important to use abundant material, for, in the great mass of possible combinations (given the large number of determinants), only a small number of individuals will present the desired characteristics, so that, if the observations are limited to a small progeny, it may easily happen that the desired type will not be found.

By means of selection and hybridisation followed by selection, types may be created that are specially resistant to diseases, pests and adverse weather conditions, as is shown by the results already obtained in many countries:—

1) GERMANY. — Since 1896, BEHRENS has obtained, by suitable crosses, a type of tobacco resistant to *Bacillus maculicola* Delacr., just as STRUBE was able, by selection, to increase the resistance of his spring wheat "Schlanstedter" to the attack of *Ustilago triticea*. On the other hand, ARNIAN has obtained potato varieties resistant to *Phytophthora*, and VON LOCHOW has isolated from the "Wohltmann" variety of potato, some types resistant to leaf-curl caused by *Fusarium* spp.

WANNER and RASMUSSEN are trying to obtain varieties of vine resistant to phylloxera, and H. C. MÜLLER and the author started a series of trials in 1912 in order to obtain a type of sugar-beet resistant to *Heterodera Schachtii* A. S.

UNITED STATES. — The work of several agricultural Stations is almost exclusively that of selecting plants resistant to diseases and adverse weather conditions. Thus the Pomological Station situated near Lake Minnetonka (Minnesota) has produced, by methodically carrying out a continuous series of crossings, some fruit-trees that have a great resistance to low temperatures. Very encouraging results have been obtained for apples and about a thousand of the most promising hybrids are being grown in the nursery of the Station. Further, by crossing the Japanese Burbank plum with the American Wolf plum, the same Station was able to fix the characters "resistance to cold", "early maturity", and "fine, tasty fruit" (which are almost seedless) in very good proportions in the new hybrid.

Other results that are very interesting from the scientific point of view have been obtained by crossing apricots, peaches and plums; by repeatedly crossing hybrids (plum  $\times$  apricot)  $\times$  plum with the apricot or peach, hybrids are obtained that give fruit resembling the apricot and which are very resistant.

Equally important results have been obtained with the vine in a relatively short time. The hybrids Beta  $\times$  Concord and Beta  $\times$  Brighton, with suitable selection, have given varieties with fruit having the quality of the varieties Concord and Brighton together with the vigour and resistance to cold characteristic of the Beta vine.

At the New York Agricultural Station work has been in progress for 26 years in order to improve the vine and between 1898-1903, at least 1500 hybrids were tested, only 5 being found worthy of notice. Since 1905, in the crossing and selection experiments, possibilities suggested by studying Mendelian laws have been taken into account.

Thanks to the initiative of the Massachusetts Asparagus Growers' Association, a series of experiments were started in 1906 which have helped to improve the asparagus considerably (1); some types have been obtained that are completely resistant to *Puccinia Asparagi*.

By crossing the common water-melon, susceptible to *Fusarium nivum*, with an aberrant type, resistant to that fungus, but with non-edible fruit, ORTON obtained intermediary forms in the  $F_1$ ; in the  $F_2$ , a large number of very varied combinations; in the  $F_3$  a plant which was isolated not only bore typical water-melon fruit, but also had the resistance to *Fusarium* of the aberrant parent. From this individual was isolated the Conqueror variety with excellent fruit and resistant to *Fusarium*.

On the other hand, the Iron variety of *Vigna Catjang*, resistant to *Fusarium tracheiphilum* and *Heterodera radiculicola*, was crossed with the Black and Whippoorwill varieties by ORTON, who obtained some lines uniting the resistance of Iron to the vigour and seed characters of the more valuable parents.

(1) See R., March, 1918, No. 285. (Ed.)

In the United States, types of gooseberry resistant to *Puccinia Ribis* D. C. (HANSON) have been obtained, as well as potatoes resistant to *Phytophthora infestans* and *Chrysophlyctis endobiotica*, vines resistant to blackrot (*Guignardia Bidwellii*) (HERFF) and oats resistant to *Ustilago Avenae* (NORTON).

FRANCE. — For a long time numerous crossings have been made, in accordance with a definite programme, between American and European vines in order to obtain disease resistant varieties.

According to CASTEL, the hybrids of *Vitis europaea* with *V. Labrusca* give the best results, both against mildew, oidium and blackrot. The hybrid Maurice Baco 22 A (Folle Blanche × Noah) is very productive and is resistant to *Botrytis cinerea*. As regards mildew, the following is a list of the most resistant hybrids:

*Hybrids with red grapes*: Malègue 2094-3; Malègue 2183-3; Baco 1; Jurie 580; Gaillard 194; Couderc or Coutassot 7120; Couderc 106-46; Seibel 873; Seibel 1082; Seibel 4121; Malègue 829-6.

*Hybrids with pink grapes*: Seibel 2857; Seibel 4464; Malègue 474-5.

*Hybrids with white grapes*: Seibel 793; Seibel 880; Seibel 2653; Seibel 4645; Seibel 4991; Malègue 57-1; Malègue 1157-15; Malègue 1647-8; Malègue 1897-12; Couderc 235-120; Couderc 272-60; Girerd 157.

INDIA (Pusa), AUSTRALIA, NEW ZEALAND. — In these 3 countries, varieties of wheat have been obtained that are resistant to rust, to *Tilletia laevis* Kuhn and *T. tritici* Wtr., and in New Zealand a rust-resistant oat (Ruakura Rust Resistant).

EAST INDIES. — After the terrible epidemic of *Hemileia vastatrix* the *Coffea arabica* was replaced by *Coffea liberica* resistant to the disease but giving coffee of inferior quality. By suitably crossing these two species, MANES obtained hybrids uniting the valuable qualities of both parents.

On the other hand, KOBUS obtained good results by crossing the "Tjeribon" sugarcane, very good, but not resistant to disease, with the Hindu variety "Tschun" which, however, is very resistant.

RUSSIA. — Selection for resistant types is carried out at the Saratov Agricultural Station. By crossing the sunflower cultivated in Russia with a Californian variety, STEBURT and KARSIN obtained varieties resistant to *Homœosoma nebulella* (1).

520 - Varieties of Egyptian Cotton Produced by Mutation. — KEARNEY, THOMAS H., in *The Journal of Heredity*, Vol IX, No. 2, pp. 51-61 + 8 Figs. Washington, February, 1918.

Egyptian cotton is much in demand on the American market for the manufacture of articles requiring a high degree of tensile strength, such as sewing thread, durable hosiery and motor-car tyre fabrics. At the suggestion of the U. S. Department of Agriculture, and under the direction of Dr. H. J. WEBBER numerous comparative cultural experiments were begun in 1900 at agricultural stations in the south and south-west, using cotton seed imported directly from Egypt. These experiments showed that it is possible to cultivate Egyptian cotton in the United States if it is grown on

(1) See R., April, 1917, No. 321. (Ed.).

the irrigated lands of the south-west. Nevertheless, even under the most favourable conditions the newly-imported varieties produced little, ripened late and varied greatly. This is probably due to the fact that in Egypt the cotton fields are often exposed to cross fertilisation with hybrid varieties, particularly with the "Hindi" cotton, which grows wild in the fields.

Careful selection was, therefore, required to obtain earlier, more productive, and more uniform types. Selection experiments begun at Yuma (Arizona) gave very satisfactory results in a few years, involving the improvement and gradual fixing of the desired characters without altering the structure and appearance of the original type, "Mit Afifi".

In 1908 a new era began with the unexpected appearance of two lines obtained by selection differing greatly from the parent stock and from each other. These two lines gave rise to the Yuma and Somerton varieties. The second variety had to be discarded because of its excessive production of sterile branches, but the first became the basis of the Egyptian cotton industry in Arizona. This new variety differs from the Mit Afifi variety in longer and more pointed bolls, and in a longer ( $1\frac{1}{2}$  inch) and lighter fibre.

Mr. E. W. HUDSON obtained a third variety, Gila, from a plant selected in 1908 in a field of acclimatized Mit Afifi cotton at Sacaton, Arizona. Although differing less from the original stock than the Yuma and Somerton varieties, Gila is sufficiently distinct to be considered as a new variety.

The Yuma, Somerton and Gila varieties are, thus, all derived from the Mit Afifi Egyptian cotton.

In 1910, in a field of Yuma cotton at Sacaton, a specimen was selected and kept separate because of its superior productiveness and length of fibre. From this plant was derived the Pima variety which differed from the Yuma variety in fewer vegetative branches and better developed fruiting branches, by its plumper, more sharply pointed and less deeply pitted bolls, lighter, silkier, and longer ( $1\frac{5}{8}$  to  $1\frac{3}{4}$  inch) fibre.

The new varieties spread rapidly, especially in the Salt River Valley, where they were grown over ever-increasing areas: — in 1912, Yuma, 200 acres; in 1917, Yuma, 23 000 acres, and Pima, 7 000 acres (a total of 30 000 acres); in 1918 it is estimated that the crop will cover 100 000 acres.

The Yuma and Pima varieties supply first quality material for spinning and for motor tyres. Pima is preferred on account of its earliness and long fibre, and will undoubtedly completely supersede Yuma. It is not easy to solve definitely the problem of the origin of these varieties; certain phenomena point to roguing, whereas others point rather to true mutation.

I. — ROGUING. — 1) Mit Afifi cotton probably originated towards the middle of the 19th century from hybridization of Sea Island with a brown linted African tree cotton; 2) as has been already stated, Egyptian cotton fields are frequently exposed to cross-fertilisation. Consequently the presence of many heterozygous characters would explain the frequent appearance of rogues.

II. — MUTATION. — The following phenomena, however, are in favour of the mutation hypothesis: 1) the sudden appearance and fixation of the new types; 2) the total absence of forms intermediate to the original and new types; 3) the differential characters of the new type, which are entirely

new and of which no trace is found in the species or varieties of cotton which are likely at any time to have come in contact with *Mit Affi*.

521 - **Variations in Eucalyptus Trees in Plantations; Eucalyptus Hybrids Observed Chiefly in Algeria.**— TRABUT, L. (Professor of the University of Algiers, Director of the Botanical Service of the General Government of Algeria), in *Bulletin de la Station de Recherches Forestières du Nord de l'Afrique*, Vol. I, Pt. 5, pp. 140-155 + 6 Pls. + 6 Tables, Algiers, 1917.

Eucalyptus trees were introduced into France towards 1854 and, since 1862 plantations have been made in Algeria. In 1876 a private collection, started in 1864, contained 10 000 trees belonging to 120 species, all of which did more or less well.

The author's observations and propagation experiments show that, in Algeria, the eucalyptus trees contained in collections may be crossed with the greatest ease. This is very valuable knowledge from a practical point of view because hybrid plants are stronger and better suited to the climate than the stock from which they are derived. For this reason there is no doubt that plantations should be formed with such hybrids.

After artificial hybridisation, which will give important practical and scientific results, has been carried out, the cultivation of the eucalyptus tree will become essential in the Mediterranean district, where it renders extremely valuable services.

#### AGRICULTURAL SEEDS

522 - **The Production of Forage Plant Seeds in Denmark.**— *Statistiske Entretæninger*, Year, X, No. 1, pp. 5-6. Copenhagen, January 23, 1918.

The extraordinary rise in the price of forage plant seeds has caused in Denmark a considerable increase in the area cultivated for the production of such seed; this is shown by the following figures:—

#### *Area cultivated for the production of forage plant seeds in Denmark.*

Seed	July, 1917 acres	December 5, 1917 acres
<b>Roots:—</b>		
Swede . . . . .	2 528.6	7 125.0
Turnip . . . . .	1 875.5	12 490.1
Carrot . . . . .	1 487.1	5 042.2
<b>Forage Leguminosae:</b>		
Clover, alfalfa, etc. . . . .	2 210.8	1 513.0
<b>Forage grasses:—</b>		
Cocksfoot . . . . .	18 265.6	22 502.3
Meadow fescue . . . . .	2 993.5	3 585.0
English ray-grass . . . . .	5 751.0	2 866.5
Italian ray-grass . . . . .		4 222.0
Field brome grass . . . . .	3 199.3	7 028.0
Other forage grasses . . . . .	2 012.0	1 476.5
<b>Total . . .</b>	<b>40 323.4</b>	<b>67 851.5</b>

It is seen that the increase in seed production for root crops is considerable, whereas that for grasses only forms about 30 % of the total.

523 - **The Identification of Varieties of Barley.** — HARLAN, HARRY V., in *United States Department of Agriculture, Bulletin No. 622*, 32 pp + 4 Plates, Bibliography of 41 publications. Washington, 1918.

The variations that occur in barley are of importance to the student agronomist, plant breeder, and pathologist. They offer a wide opportunity for selection, breeding, and study of disease resistance. In barley the forms are unusually numerous and clearly defined. The number and character of the types existing are more concisely indicated by a classification of variations than in any other way. The groups of barley were arranged upon the basis of species, varieties, and sub-varieties. Only major characters have been used in describing species and varieties; less important characters have been utilized in describing sub-varieties. Under each sub-variety there may be an unlimited number of agronomic varieties. Four species and 32 varieties are recognized as follows: — *Hordeum vulgare* with the varieties: *pallidum*; *nigrum*; *Horsfordianum*; *atrum*; *coeleste*; *duplicatum*; *trifurcatum*; *aethiops*; *H. intermedium* with the varieties: *Haxtoni*; *Mortoni*; *subcornutum*; *atricornutum*; *nudi-haxtoni*; *nudi-mortoni*; *cornutum*; *subaethiops*; *H. distichon* with the varieties: *palmella*; *nigricans*; *angustispicatum*; *Rimpasi*; *nudum*; *nigrinudum*; *laxum*; *nigrilaxum*; *H. deficiens* with the varieties: *deficiens Steudelii*; *tricerus*; *tridax*; *nuidedeficiens*; *decorticatedum*; *sublaxum*; *gymnospermum*.

All groups have been made to conform with previous usage as far as possible. One of the principal aims of the writer has been to state clearly the form or group intended to be described by each published name. Except for their historical significance, the sub-varieties would not have been continued, and no forms have been added to them.

Four varieties have been added.

Lists of rejected terms and varieties are included.

The keys can be adapted to the identification of thrashed grain by a number of characters. In the common agronomic varieties the chance of error in the identification of thrashed grain is slight.

524 - **Sorghums for Forage in South Dakota.** — CHAMPLIN, MANLEY and WINRIGHT, GEORGE, in *Agricultural Experiment Station, South Dakota State College of Agriculture and Mechanic Arts, Bulletin No. 174*, pp. 624-645, 9 Tables, 15 Figs. Brookings, S. Dak., March, 1917.

FORAGE CROPS  
MEADOWS  
AND PASTURE

Sorghum is commonly used for forage in South Dakota. In the United States, three fourths of the total herbage produced by all sorghums is consumed as coarse forage. The most promising forage sorghums are the black and red seeded amber canes and Sudan grass. Dwarf milo, feterita, kafir, shallu and others are also grown in some localities.

This bulletin gives the results of comparative trials of the producing power of these crops and directions for growing the crop based on the writers' experience at the South Dakota Experiment Station farms at Brookings, Cottonwood, Eureka, Highmore and Vivian. They are summarized as follows: —

Sorghum as a forage crop is worth considering carefully in South Dakota because it matures quickly, yields fairly well and is adapted to

hot weather and limited moisture conditions; it may thus be used as a catch crop. Sorghum as a forage crop is not superior to maize in seasons that are reasonably favourable to maize.

Several difficulties are encountered in growing sorghum on account of the small seed, danger of planting too deep and the slow growth of the young plants.

Variety tests of sorghums in South Dakota indicate that Sudan grass is best for hay, the amber canes for coarse fodder and dwarf milo for silage. The average yields of fodder as compared with maize in variety tests at Brookings in 1914-1916 were as follows: —

Crop	Yield in lbs. per acre
Minnesota Amber. . . . .	5 110
Sudan . . . . .	4 580
White Amber . . . . .	4 000
Freed Sorgo . . . . .	3 680
Dakota Amber . . . . .	3 680
Kaoliang. . . . .	3 300
Dwarf White Kafir. . . . .	3 220
Feterita . . . . .	2 500
Kaferita . . . . .	2 000
Brookings 13, Maize. . . . .	6 637

The soil preparation necessary for maize is sufficient for sorghum.

Where moisture is plentiful Sudan grass gives the best results drilled in 6 or 12-inch rows. It can be used as an intertilled crop if desired.

All varieties of sorghum except Sudan grass gave the best results in method of seeding tests when drilled in rows 36 or 42 inches apart and cultivated.

In date of seeding experiments Sudan grass gave best results when seeded between May 20th and June 1st. It is safe to assume that these dates are also best for the amber canes and dwarf milo, as these sorghums have practically the same temperature requirements.

Head selection should be practiced in securing sorghum seed.

Sorghum drilled in 36 or 42-inch rows may be harvested with an ordinary corn binder. Shocks must be built small.

Sorghum drilled in 6 or 12-inch rows or sown broadcast may be harvested with a mower or grain binder.

525 — *Medicago falcata*, a Yellow-Flowered Alfalfa (1). — OAKLEY R. A. and GARVER, SAMUEL, in *United States Department of Agriculture, Bulletin* No. 428, pp 70, 9 Tables, 23 Fig., Bibliography of 67 publications. Washington, 1917.

The first recorded importation of *Medicago falcata* in the United States was made in 1897. The first systematic introductions for the purpose of utilizing the species as a cultivated forage crop were made in 1906 by Prof. N. E. HANSEN under the auspices of the U. S. Department of Agriculture. Since that date many lots of seed representing various forms of the species have been introduced by Prof. HANSEN, Mr. F. N. MEYER

(1) See also R., 1917. No. 333. (Ed.)

and various others. Approximately fifty lots have been introduced, mostly from Russia and Siberia.

At the present time *Medicago falcata* is found growing without cultivation in most parts of Europe and the western two-thirds of Asia. Over a large portion of this area it is probably indigenous. It is found throughout a wide range of soil and climatic conditions and at depressions and elevations ranging from below sea level to 13 000 feet above. It is much wider in its adaptations than *Medicago sativa*.

The species was recognized by botanists early in the history of modern botany, if not long before. Recent botanists differ somewhat with regard to its taxonomic relationship to *Medicago sativa*. Some give it the rank of a true species, while others regard it as a variety or subspecies of the latter. The natural relationship of the two, however, is quite clearly shown by the readiness with which they hybridize and the fertility of their hybrids.

It is an extremely variable species, many forms of which are difficult to classify satisfactorily on account of their varying combinations of characters and the difficulty of determining whether they are of pure or hybrid origin. A classification or grouping has been attempted in this paper largely upon the basis of habit of growth. Four groups have been established, ranging in habit from prostrate to almost erect. The first two are referred to as pasture groups, as they are not sufficiently erect to be harvested satisfactorily for hay by machinery. The last two are sufficiently erect to be harvested for hay and are referred to as hay groups.

Botanists have named and described several of the species, many of which have proved to be hybrids of *Medicago falcata* and *Medicago sativa*.

*Medicago falcata* has never been extensively cultivated in Europe or Asia, although it has been utilized as a wild forage plant since a very early date. Many attempts have been made to cultivate it in Europe, but so far as can be found it is now being cultivated only in India and, possibly, to a very limited extent in south-eastern Russia and Chinese Turkestan.

The erect forms of *Medicago falcata* closely resemble those of *Medicago sativa* in their mass effect, but on an average they produce a heavier yield in comparison with their bulk, partly because of the more numerous stems and partly because of the texture of their herbage. Under similar conditions of soil and stand of plants the best strains of *Medicago falcata* frequently outyield the best varieties of *Medicago sativa* for the first cutting of the season.

A very serious drawback to the general utilization of *Medicago falcata* as a cultivated forage crop is its inability to recover quickly after cutting. Under conditions such as exist in the West and Northwest, where it appears to offer its greatest possibilities, it can be depended upon to make only one crop in a season. It produces seed sparingly and does not hold it as retentively as does *Medicago sativa*. This is also a serious handicap to its use as a cultivated crop.

The natural range of distribution of the species, its adaptations, and its behaviour under field conditions in the United States warrant the conclusion that it is relatively hardy and drought resistant.

Chemical analyses and general feeding tests indicate that it is approximately as valuable from a feeding standpoint as common alfalfa.

The cultural requirements of *Medicago falcata* appear to be much the same as those of *Medicago sativa*. On account of the hard seed which the former produces and the slow growth of the young plants it is difficult to secure a satisfactory stand from seeding, either broadcast or in rows. When grown in broadcast stands the procumbent forms are inclined to be more nearly erect than when grown in rows or hills. The plants of this species bear transplanting better than do those of *Medicago sativa*.

Data from broadcast plants of *Medicago falcata* and *Medicago sativa* indicate that in seasons when only one cutting of the latter can be procured the former produces the heavier yield, but in favourable seasons, when two or more cuttings can be procured, the latter excels appreciably in yield.

Sowings of *Medicago falcata* have been made on unbroken native sod land and a fair stand of plants secured. The plants appear to lack sufficient aggressiveness to make them really valuable under such conditions.

The greatest possibilities offered by the species appear to be in the field of selection and hybridization. In a few cases it is probable that the development of promising pure strains by selection will prove to be advantageous. As the result of hybridizing with *Medicago sativa* and subsequent selection it is believed that superior varieties of alfalfa can be developed and that the greatest value of the species is for this purpose.

Much time and effort will be required before *Medicago falcata* will be ready for general cultivation.

CROPS  
YIELDING OILS,  
DYES AND  
TANNINS

526 - Cultivation of the Castor-Oil Plant in North Africa. — COUSTON, F., in *Journal d'Agriculture pratique*, New Series, Vol. XXXI, No. 3, pp. 45-47, February 7, 1918; No. 4, pp. 71-73, February 20, 1918; No. 5, pp. 94-95, March 7, 1918. Paris.

The castor-oil plant grows abundantly in many ravines on the North African coast. The severe winters prevent its growing in the Upper Table Lands and in the Atlas Mountains, but it re-appears in the Sahara zone and is found in many oases where it was originally imported as an ornamental shrub. The author has observed it from the Biskra district (foot of the Atlas) to Ain-Salah and Aoulef, more than 600 miles further south, in the midst of the Sahara.

The castor-oil plant is perennial. It is injured by hard frosts and prolonged cold, and requires much water in summer, when its growth is most active. It would do well all along the coast, and in the south in the Sahara district, wherever it is assured of sufficient moisture during the summer growing period. In its climatic and cultural requirements it resembles cotton; *in North Africa the castor-oil plant thrives wherever the cotton-plant does well*. It seems to withstand slightly more cold than cotton.

The variety chosen should have the following characters: — abundant yield of well-filled seed; fruit ripening as much as possible at one time; in particular, *moderately dehiscent* capsules; varieties the indehiscent fruit of which require excessive threshing and husking should be rejected, as well as those the capsules of which open suddenly when ripe, often casting the seed a distance of some yards.

The Marseilles industry, consulted in 1917 by the Administration of the South Algerian Territories on the varieties most suited to the manufacture of oil, replied that the various samples of castor-oil seed received at different times from Algeria were perfectly suitable. As this industry chiefly uses seed from India, mostly from Bombay, the General Government of Algeria obtained at Marseilles, seed from Bombay (of the ordinary small castor oil plant = *Ricinus communis minor*) for free distribution. According to Dr. TRABUT, this plant is the one best suited to the dry Algerian climate from the point of view of dehiscence of the capsules.

The author then discusses the systematic cultivation of the castor-oil plant and the planting of uncultivated land moist in summer (bottom of ravines, banks of canals, irrigated gardens and oases, beds or banks of "oueds", ditches, railway embankments, etc.), and draws attention to the uses of the castor-oil plant and its by-products. Finally the necessity for establishing castor-oil factories in Algeria is pointed out.

527 - Rubber in North Borneo. — *The Tropical Agriculturist*, Vol XLIX, No. 4, pp. 197-200. Peradeniya, Ceylon, October, 1917.

RUBBER, GUM  
AND  
RESIN PLANTS,  
ETC.

The area planted with rubber at the end of 1916, according to returns received from managers of estates was 30 910 acres. Small holdings planted by Chinese and natives are not included in these figures. The amount of new land planted during the year, was only 529 acres. The number of trees in tapping at the end of the year was 2 030 150 or a little over half the total number planted, which is returned at 4 049 050. The area in full tapping was 14 720 acres as against 9 806 acres at the end of the previous year.

According to the figures supplied by the Customs Department the export in 1916 was 1937.7 tons, an increase of 84.4 per cent. on the total of 1050 tons shipped in 1915. In January the price of smoked sheet reached 4s. 2d. but dropped quickly to about 3s. 6d.; it then declined steadily until August, when it had fallen to 2s. 1 1/2d., after which it rose to about 3 s. 0d. in December.

The extension of tapping operations necessitated an increase in the labour force at most estates. At the end of the year the total number of coolies employed was 12 334, an increase of 2 698 over last year's total. Whereas in 1915 one coolie was sufficient for three acres, in 1916 the average was one for 2.5 acres. Of the coolies 5 179 were Chinese and 4 280 Javanese; 2 875 belonged to other races, all but a few being natives of North Borneo.

The rainfall in 1916 was heavier than in the previous year. Estates on the West Coast had an average of 165 inches of rain in 199 days, in the Interior 66 inches on 202 days, in the Kudat residency 89 inches on 176 days, in the Sandakan residency 133 inches on 212 days, and in the East Coast residency 95 inches on 130 days. On no estate was there a single month entirely without rain.

- SUGAR CROPS** 528 — **Chemical and Biological Researches on Sugar Beets, in Bohemia.** — URBAN, G., Über Alkalien in den Rübenpflanzen. *Zeitschrift für Zuckerindustrie in Böhmen*, Year XLI, Pt. 7, pp. 415-420. Prague, 1917. — II. STENLIK, W., Über die Wirkung von Röntgenstrahlen auf die Keimung des Rübensamens und das Wachstum der Zucker- und Futterrübe. *Ibid.*, pp. 424-427, 2 Fig. — III. URBAN, G., Über die Farbe des Rübenkrautes früh und spätreifender Rüben. — *Ibid.*, pp. 281-287, 1918. — IV. BARTOS, W., Der Einfluss der Veredlung auf den Wert der Rübe *Ibid.*, pp. 299-302.

I. — **ON THE ALKALIS IN BEETS.** — Analyses of the leaves and roots of 75 sugar-beets gathered in mid-August from the same row and derived from the same parent plant; the intention was to study the potash and soda content. This, as with the sugar and nitrogen content, and other characters, shows variations both for the roots and the aerial part of the plant. Such fluctuations are even found in the progeny from a single parent-beet. The following summary of the data obtained illustrate this point.

	Minimum	Maximum	Average
Potash content of roots . . . . .	0.135 %	0.301 %	0.218 %
Soda " " " . . . . .	0.018	0.150	0.0508
Potash content of leaves (calculated as dry matter) .	1.35	3.13	2.14
Soda " " " ( " " " ) .	5.88	12.33	7.54

It was found that the corresponding beets were poorer in sugar as the soda content of the roots and, consequently, that of the whole plant, was higher in relation to the potash; but this relation, found in the average of an important series of analyses of beets, is not always present in the case of a single beet.

II. — **ACTION OF RADIUM ON BEET SEED.** — The seeds of cereals, leguminous plants and beets were treated with Röntgen rays at the Beet Seed Selection Station at Samčic near Dobrovic. Both for sugar beet and mangold seeds treated by Röntgen rays, nothing special was noted when they had germinated; but later on, when the first leaves were formed, the young plants obtained from seeds exposed for 1-2-3 minutes to Röntgen rays, clearly showed a difference in development in comparison with the plants obtained from untreated seeds. This difference in development was maintained in the following stages: young plants exposed to the rays for 2 minutes developed better, while those exposed for 7 minutes showed signs of atrophy.

In short, moderate action of Röntgen rays on beet seed has a favourable effect on the growth of the plant; but more intense action is harmful. It still remains to be ascertained whether the rapid growth of the young beet plants, caused by a moderate action of the rays, does not result, by reaction, in fatigue and weakness during the ultimate phases of vegetative growth. Two minutes was found to be the best exposure for mangolds.

III. — **COLOUR OF BEET FOLIAGE.** — The more or less intense colour of beet leaves depends on the degree of maturity and the content in food material, depending in turn on the nature of the manuring and on the soil

moisture ; again, the colour shade of the foliage is a type character of the different varieties of beet.

It appears to result from a series of observations and determinations carried out over several years on 2 descendants of sugar beets, one with light-coloured leaves, the other with dark leaves, the other conditions (soil, manuring, etc.) remaining the same, that a dark green leaf contains more nitrogen than a light green leaf, so that there would be a direct relation between the colour of the leaves and the corresponding nitrogen content. On the other hand, light-coloured foliage does not always indicate early maturity or a high sugar content in the roots ; there may be beets with light coloured leaves that are early and richer in sugar, but the contrary may also happen. In experiments lasting 2 years, the progeny with dark leaves yielded better and produced more sugar than the light-leaved ones ; they form sugar very rapidly in late autumn.

In 1 year experiments, analysis showed that the darkest leaves contained more potash and less soda, but this observation, based on one case only, can not be applied generally. It seems rather that there is a certain relation between the highest potash content of the leaves and the greatest sugar content of the roots. Both in beets with light coloured foliage and those with dark leaves, the potash rapidly increases in the leaves, while the soda content decreases as the beets mature.

IV. — INFLUENCE OF SELECTION ON THE VALUE OF BEETS. — The analytical data collected each year by the various Czech Sugar Associations give an idea of the averages for 20 years as regards Bohemia : —

Periods	Sugar Content	Weight per beet, in gm			Percentage of foliage in relation to the root
		Root	Sugar	Foliage	
1897-1901 . . . . .	14.88 %	354	52	244	69 %
1902-1906 . . . . .	16.4 »	355	58	239	67 »
1907-1911 . . . . .	16.8 »	374	63	268	72 »
1912-1916 . . . . .	17.6 »	467	82	332	82 »

These figures clearly show the influence of selecting beets on the value of their yield. It may be said, it is true, that the higher yield of the modern beet varieties is due to better cultivation and heavier applications of manure and fertilizer ; but that does not weaken the influence of selection on the increased yield ; in fact, the new high-yielding varieties allow of heavy manuring, especially nitrogenous, which could not have been used previously because the commercial value of the beets would have so been affected that the extraction of the sugar would not have been sufficiently profitable. The present varieties, owing to their higher yield, not only allow of heavier manuring, but even require it their yielding powers are to be fully utilised.

It should be noted that the increased yield of the various sugar beet varieties is accompanied, both absolutely as well as relatively, by an increase in the quantity of foliage produced ; as the dry matter content has

also increased and as it is well known that beet leaves make excellent fodder, the new beet varieties have the advantage of producing a better quality and greater quantity of fodder than the old ones.

The lack of terms of comparison and the influence of meteorological factors may nullify these conclusions, but the mass of data, the extent of the determinations and the long period of years compensate the disturbing influence of these factors so as to show up still more the effect of selection.

529 - Experiments on the Catalytic Fertilisation of Seed Sugar Beets with Manganese Sulphate in Austria. — GREISENEGGER, J. K. (Mitteilung der Chemisch-technischen Versuchs-Station des Zentralvereines für die Rübenzucker-Industrie), in *Oesterreichisch-ungarische Zeitschrift für Zuckerindustrie und Landwirtschaft*, Year XLVI, Pt. 1-2, pp. 13-21 Vienna, 1917.

In view of the importance and uncertainty of the influence of manganese on plants, especially sugar beets, the author undertook an investigation not only into beets grown for fodder (1), but also into second year seed beets.

To 15 pots containing sand and peat were added 24 litres of KNOP'S nutritive solution and manganese in the form of sulphate in amounts equivalent to 22.3 lb. per acre to 5 pots and four times the quantity to 5 others; the remaining 5 pots were used as controls.

Although the smaller quantity had no *obvious* effect on the seed yield it had a reflex action in that it increased slightly the sugar content of the beets obtained from the seeds. The larger quantity of manganese markedly increased the production of seeds, but the beets obtained from them weighed less and contained less sugar.

In using manganese fertiliser a deceptive amount must not be applied. Many further experiments are necessary to determine if the limit is the same for all seasons and all varieties of beets.

STIMULANT,  
AROMATIC,  
NARCOTIC  
AND  
MEDICINAL  
PLANTS

530 - Cacao in the Dominican Republic. — MC LEAN, A., in *Commerce Reports*, No. 283, pp. 876-877. Washington, D. C., 1917.

Cacao is, after sugar, the leading export of the Dominican Republic. The Spaniards introduced cacao in the Dominican Republic from Venezuela in the early part of the 18th century, but it is only within the past 25 years that the tree has been cultivated extensively. The Provinces of La Vega, Samana, Espailat, and Pacificador, in the northeastern section of the island, lead in the production of cacao in the Dominican Republic, but no statistics are available as to the total area planted.

Native methods of cultivating and preparing cacao for market are primitive and unsatisfactory. Almost all of the cacao is grown on small farms, and there are few large and scientifically managed plantations. These farms are mainly owned by Dominicans and are cultivated by labourers of the same nationality. Farm labourers receive from 50 to 60 cents a day, with a small shack and a patch of land to cultivate for themselves. There is no agricultural school nor experiment farm in the Dominican Republic.

(1) See R. 1916, No. 52. (Ed.)

lic, although both are badly needed in order to teach the people how to obtain the best results from their lands through the use of modern and scientific methods of cultivation.

The cost of land suitable for the cultivation of cacao in this Republic varies greatly, depending largely on its fertility and accessibility. The rich, black, alluvial lands in the humid and well-watered regions within easy reach of the Samana & Santiago Railroad and Samana Bay are considered the most desirable. Such lands are held at \$ 60 to \$ 75 an acre uncleared and from \$ 75 to \$ 90 cleared, the cost of clearing being from \$ 12 to \$ 18 an acre. The value of the lumber on the lands, which sometimes includes cedar and mahogany, would more than pay for the clearing but it is burned for lack of sawmills and means of transportation. Lands with bearing-cacao trees are valued at \$ 120 to \$ 150 an acre, with a rising tendency.

The cacao seeds in this island are planted directly in their permanent place in the field and not in nurseries as in some other countries. The seeds are planted in October to take advantage of the winter rains. Several seeds are usually planted together and when the seedlings are a year old the strongest are left to mature and the weakest destroyed. As a rule about 175 trees to the acre are left.

The variety of cacao planted most frequently in this Republic is known as "calabacillo", which bears small yellow pods with flat beans. The varieties known as "forastero" and "criollo" are also planted, but to a much less extent than the "calabacillo".

While the small plants are growing corn, yucca, bananas and plantains are planted between them, primarily for shade, but also to afford some returns while the cacao is maturing. As the cacao trees grow larger amapola trees are planted to give them shade. The ground between the cacao trees is cleaned with hoes and machetes, as ploughs are rarely used in the Dominican Republic. No windbreaks are used to protect the growing plants, nor is there any system of drainage on the plantations. As the lands on the island are very rich, the Dominicans have not as yet begun to use fertilizers.

The cacao trees begin to bear the fourth or fifth year, when they yield from one-half to 1 ½ lb. From about the seventh until the twenty-fifth year they are at their best, yielding as high as 3 ½ to 4 lb. per tree on the most fertile lands. Cacao trees have been known to live for more than 100 years, but they seldom bear after the sixtieth year. The trees are pruned every year, usually after the harvest.

The aphids and a number of other insects attack the cacao trees. It is said that these pests may be exterminated by merely spraying the trees with a solution containing refined petroleum, yet growers rarely make any attempt to get rid of them.

Cacao is usually transported from the farms to the towns on mule or horse back, as the roads are as yet impassable for carts and wagons. The principal towns in the cacao growing region — Moca, Salcedo, La Vega, and San Francisco de Macoris — are connected by railroad with the port of Sanchez, whence steamers sail fortnightly for New York. Cacao in this

market is usually packed in jute sacks, weighing 65 kg. net and 66 kg. gross. Prior to the war the freight was 45 cents per 100 pounds from Sanchez to New York, although at present it is exactly double that figure.

In the past five years cacao has been shipped from the Dominican Republic as follows.

*Cacao exported from the Dominican Republic, 1912-1915.*

Year	Kg.	\$
1912 . . . . .	20 832 602	4 248 724
1913 . . . . .	19 470 827	4 119 955
1914 . . . . .	20 744 517	3 896 489
1915 . . . . .	20 223 023	4 863 754
1916 . . . . .	21 053 305	5 958 659

In 1916, 22 249 540 kg. of cacao were shipped into the port of New York from the Dominican Republic. That was a greater quantity than from any other country. The next largest importations of cacao at New York during 1916 were 20 266 313 kg. from Ecuador, 15 805 710 kg. from Trinidad, and 14 471 783 kg. from Brazil.

Cacao from the Republic is known as "Sanchez" on the world markets. The cacao is bought up from the growers by the local exporters, who make them advances on their crops. The exporters usually ship their cacao to New York commission houses on consignment.

Despite the fact that it is one of the great cacao producing countries of the world, little or no chocolate or confectionery is manufactured in the Dominican Republic; practically all that is consumed is imported.

531 - **Hop-Growing in Galicia, Spain.** — I ROBBED, L. H., in *El Progreso agrícola y pecuario*, Year XXIII, No. 1036, pp. 506-507 Madrid, November 22, 1917; II. *El Cultivador Moderno*, Year VII, No. 2, pp. 11-12, 3 Figs Barcelona, February, 1918

At the present time there are in Spain about 20 breweries using, on an average, 196  $\frac{1}{2}$  cwt. of hops annually. The price of hops varies greatly in Spain, in 1912, the average price was 4s. 4d per pound; in 1916, American hops fetched 1s. 3d. per pound, and German hops, 1s. 9  $\frac{1}{2}$  d. per pound at the breweries. The hops used by the author at the Agricultural Station of Corunna in 1917 cost 1s. 11  $\frac{1}{2}$  d. per pound.

As hops grow wild in Galicia, the author introduced from England, in 1915, the varieties Golding, "dorado de Inglaterra", white, and green, and cultivated them at the Corunna Station. The deep, sandy soil, rich in humus, was given 16 tons of manure per acre, and was ploughed to a depth of 16 in. Cuttings were planted about 5  $\frac{1}{2}$  feet apart in squares. At the beginning of May the scarifier was used once, and the land twice hoed lightly. The harvest was in mid-September. The hops were dried in the kiln on frames one above the other, with a distance of about 8 inches between each one. At the end of October the plants were cut down to about 12 inches above the ground. The highest yield in 1916 was obtained from the variety "dorado de Inglaterra", which gave 28.61 cwt. per acre of green fruit, corresponding to 9.16 cwt. of dried fruit. This is an excellent result,

especially considering that it was obtained in the second year of cultivation, that is to say, before the plants had attained their maximum yield. The quality was excellent. The cost of cultivation amounted to £ 2.17.9 per acre.

532 - **Results Obtained in Italy from the Sowing of Wild-Fig Seed.** — LONGO, B., in *Atti della Reale Accademia dei Lincei*; Series V, *Rendiconti*, Vol. XXVII, Pt. 1, 1st. Half-year, pp. 55-57. Rome, January 6, 1918.

FRUIT  
GROWING

M. CAVOLINI, M. GASPARRINI, and the author in Italy, and M. LECLERC DU SABLON in France, have shown that *Ficus Carica*, both when wild and when cultivated, occurs in two forms — the ordinary fig and wild-fig. It has also been shown experimentally, first by M. GASPARRINI, then by M. TRABUTI that if the fig (*i. e.*, the small fruit of the second figs) is sown, the ordinary and the wild-fig are obtained. It remained to show what would be obtained by sowing the few small fruits found between the galls of the second figs of the wild-fig tree. In 1912, the author sowed both wild and cultivated wild-fig seed; the plants obtained began to bear fruit in 1917, and proved to be partly ordinary figs, partly wild-figs. The seed of wild-fig, like those of the ordinary fig, thus gave both types of plant.

533 - **The Native Bananas of the Hawaiian Islands.** — MACCAUGHEY, VAUGHAN (College of Hawaii, Honolulu), in *The Plant World*, Vol. XXI, No. 1, pp. 1-12. Baltimore, January, 1918.

As amongst all the Polynesian peoples, the banana was an important article of food amongst the ancient Hawaiians, and all explorers mention its abundance round the settlements. This profusion was doubtless due to the ease with which the plant is propagated, the little attention needed to cultivate it, its great productivity, perennial character, and its nutritious and palatable fruit. The decrease in the native population lowered the value of the banana as a food. As its cultivation gradually increased again, foreign varieties (chiefly the Chinese variety) were imported from time to time and superseded the native varieties both in the plantations and on the market. Among the imported foreign varieties are: —

*Musa Cavendishii*, a Chinese banana introduced from Tahiti about 1855; it is the most important and widely-grown commercial variety and there are extensive plantations of it round Honolulu; the local consumption is large and considerable quantities are exported to California; owing to its dwarf size and deep roots it suffers less from storms than the taller varieties.

*Musa Fehi*, also imported from Tahiti; the stem of the bunch is erect instead of hanging pendant as is the case with most bananas; the fruit is of fair quality when cooked.

The Brazilian banana was also imported from Tahiti about 1855; it reaches a height of from 26 to 35 feet; it is firm-rooted and is often used as a windbreak for more fragile varieties; the fruit is of excellent flavour, slightly acid.

Other foreign varieties are Bluefields, Ice Cream, Apple, Lady Finger and Abaca, or Manila hemp (*Musa textilis*).

The cultivation of the native varieties is beginning to develop in all the plantations. All the native varieties, of which the author describes 22, are derived from *Musa sapientum*. They may be divided into three groups,

each belonging to one of three dominant types, known locally as Maoli, Iho-lena and Po-po-ulu.

All the native varieties are seedless and could only have been introduced into the islands by human agency; the roots and "suckers" are quickly killed by sea-water, and could, therefore, not have been carried by ocean currents as is the case with many seeds with impervious tegument. The banana, with other plants and animals must have been imported by the Hawaiians when they immigrated. The first villages were along the coast, and the primitive agriculture of the native naturally developed in the near valleys and lowlands rather than in the mountainous districts of the interior. However, as the rainfall in the plains was not sufficient to satisfy the requirements of the plant, which needs much moisture, the banana plantations gradually spread along the wet upper valleys, where the plant was also sheltered from the strong winds, and the inland rain-forests. The banana does not suffer from shade, and coolness does not seriously retard the ripening of the fruits.

It thus happened that most of the groves were at some distance, often several miles, from the villages. The plants propagated spontaneously, and when the native population declined, formed practically wild groves, wild in the sense that they have escaped from cultivation, but they are not indigenous.

Banana groves are sometimes found at heights of 3 500 to 4 500 feet. The plants are usually dwarfed and produce little, and the fruit rarely ripens, being eaten by rats before it reaches maturity, which is considerably retarded by the cold.

The banana trunk may reach a diameter of 3 or 4 feet. It emits numerous shoots by which the plant may be indefinitely propagated. The plants are easily uprooted, and, in rainy districts, are often torn up by mountain streams which carry them some distance till they lodge in a suitable crevasse, where they root take and sprout again.

All these varieties are, therefore, easily transplanted, and many private groves in Honolulu contain plants collected from the mountain districts of the interior and from the other islands. For transplanting a sucker or offshoot 2 or 3 feet tall is generally taken. This is carefully separated from the parent plant so as not to injure its base, and planted in mellow soil with about half of the shoot underground. It grows rapidly and bears fruit 10 or 15 months later. The ancient natives used the fibre from the leaf-sheaths as a textile, but since the introduction of cheap cotton thread its use has gradually died out. The tissues of the plant contain a watery latex which turns dark brown or black when exposed to the air, and was used by the Hawaiians to stain their household utensils, gourds, etc.

Many of the native varieties are only edible after having been cooked; these are known as "cooking bananas". Heat changes the starches into sugars and the flesh of the fruit is saturated with a delicious sugary syrup. The cooking bananas are also largely used by the white settlers; they fetch a good price and their popularity is bound to increase as their food value becomes better known.

The native Hawaiian banana has, then, re-won its position as a food. The author believes the best varieties will be put on the market in increasing numbers and will finally become one of the most important exports of the Pacific Islands. There is no reason why it should not become an important food in America with a commercial development similar to that of canned pineapple.

534 - **The Mango in Porto Rico.** — KINMAN, C. F., in *Porto Rico Agricultural Experiment Station, Bulletin* No. 24, pp. 33, 2 Tables + XI Figs. Washington, 1918.

These observations are drawn from the work of several years during which trees of many varieties have been imported, propagated and in some cases brought into satisfactory production.

The common mango of Porto Rico, which is one of the most important fruits of the island, is not cultivated but grows wild in all localities. Superior varieties lately imported have proved satisfactory and should be planted extensively for market and home use.

Mango trees are adapted to a wide range of soil types and will grow satisfactorily in practically all Porto Rican soils, provided there is a good subdrainage.

While the climate throughout the island is suitable for the growth of mango trees, in some localities, notably through the interior and along the northern slopes, rains are sometimes too frequent during the blossoming season to permit the setting of a good crop of fruit. Along the western and northern lowlands rainfall is light during the blossoming season and good crops are almost invariably secured.

As the prevailing winds and morning sun seem to be very beneficial, both for growth of trees and setting of fruit, open, exposed sites should be selected for the mango orchard.

Inarching and bark grafting are satisfactory both for use in the nursery and for topworking large trees.

Large seeds which produce only one plant are most satisfactory for stocks. The East Indian varieties produce larger and more thrifty plants, as a rule, than the native kinds. Both nursery and other mango trees may be transplanted successfully if they are not making a new growth and rainfall is plentiful.

The present confusion in the classification of types of mangoes, as well as the great variation in growth and productiveness of trees, and quality of fruit, necessitates a thorough study of varieties before a mango orchard can be successfully planted in Porto Rico.

Among a number of imported varieties that have fruited there, the most productive of the thrifty kinds with fruits of high quality are Cambodiana Totafari, Amini, Bennett, and Paheri. Cambodiana and Paheri are probably better suited to home than to commercial use.

The trees of the few varieties from Martinique, Trinidad, and South America thus far tested lack vigour, while the fruits are either inferior in quality or too small to be promising for general planting. As regards size, flavour, fibre content, and keeping quality, the wild Porto Rican mangoes are less desirable than many imported kinds.

In harvesting mangoes that have not softened on the tree, a stem longer than the fruit stalk should be left to prevent the juice from the base of the fruit from escaping through the fruit stalk and leaving passages for the entrance of infection.

Fruits in orange wrapping paper did not ripen or decay so quickly as those wrapped in oil paper, newspaper, or coconut fibre, or those left in the open air. Fruits packed in coconut fibre ripened earliest. East Indian varieties showed much better keeping qualities than the native kinds.

The mango is one of the most satisfactory ornamental trees for Porto Rico, as variations in habit of growth and colour of foliage make it possible to select from varieties producing fruit of high quality those which best carry out a particular scheme of landscape gardening.

#### VINE GROWING

535 — **Direct Bearers: I. In the Department of the Isère; II. In the Department of the Loire (France).** — I. CAILLE, L. and ROUGIER L. in the *Revue de Viticulture*, Year XXV, Vol XLVIII, No 1230 Paris, March 28, 1918 — II. BLANCARD, *Ibid.*, No 1210, pp. 215-221 April 1, 1918

I. — In a report on his experimental field of direct bearers, M. CAILLE, Professor of Agriculture at Vienne, Isère, states that the vines best suited to that district are: —

a) *Vines with coloured grapes*: — Gaillard No. 2 for earliness and Seibel 41, 47, 1000, 1020, 2007, Couderc 106-46 for satisfactory ripening.

b) *Vines with white grapes*: — Castel 1028, Couderc 272-60, Seibel 880, Bertille Seyve 450.

To these might perhaps be added Prof. C. 221, which is very strong and ripens somewhat late; it should be pruned long. Without Prof. C. 221, this makes 11 varieties of obviously varying value. As a rule they all yield regularly and are worth testing. They are, however, not all equally fertile; Castel 1028, Seibel 2007 and 1020, and Couderc 106-46 appear to give the best crops. At the Vienne experiment field two applications of neutral sub-acetate of copper are given, one before flowering and the other immediately after.

To this information Mr. ROUGIER, Director of the Agricultural Service of the Isère, adds a few remarks applying more especially to the south and east of the department. In places where French vines are exposed to frost in winter the use of winter frost-resistant hybrid direct bearers is essential. Among such hybrids are Seibel Nos. 1, 28, 156, 100, Gaillard 157 (white) and 2 (red), and Couderc 4401. The last is more especially suited to the clay soils of the plains.

II. — The author (Agricultural Engineer, Director of the Agricultural Service of the Loire) mentions the hybrids which would probably prove of value in the Department of the Loire. As a rule these are early plants or those of the first period, though in the warm districts of the Loire some later varieties could be grown. These plants, moreover, give produce free from foxy taint.

A) **RIPARIA HYBRIDS.** — The fruit of some of them is large, and their wine is generally good.\* The bunches are high on the branches, thus requiring the use of wire or props. They are resistant to phylloxera (Riparia

influence), very vigorous and develop their branches with great rapidity. Flowering is very rapid thus protecting them against vine moths and non-setting,

*Black.* — Couderc No. 1 or Pinaud-Couderc, 633 H., Oberlin 595, 604 and 605.

B) RUPESTRIS HYBRIDS. — The most widely used are Rupestris, Lincecumii, Vinifera. They are generally productive and give good wine. They are very resistant to mildew. The bunches are borne low on the branches. They may be pruned low or spur pruned without props, nevertheless it is always preferable to put in stakes.

*Black.* — Couderc 7, 8, 7106, 7120, 4401 (the L. Buffet selection of which has very large fruit) ; Seibel 1000, 2859, 4643.

*White.* — Couderc 117-3, 272-60 ; Seibel 880, 4681.

C) COMPLEX HYBRIDS. — *Black.* — Bertille-Seyve 872, 822.

*White.* — Bertille-Seyve 450 ; Noah (B. S. 450 is a Noah crossed with Seibel 2003).

D) OTHER HYBRIDS. — Gaillard 2 (black), 157 (white) ; Fournié (Riparia-Rupestris-blue Portugais), Poirier 19 637.

536 — **The Red Spruce : Its Growth and Management in the United States.** — MURPHY, L. S., in the *U. S. Department of Agriculture, Bulletin No 544*, p. 100 + Plates I-VII. Washington, October 31, 1917.

FORESTRY

Red spruce (*Picea rubens* Sarg.) is one of the most important woods of the north-east of the United States, where it is found in pure or nearly pure stands. It is used more than any other wood in the manufacture of paper and supplies a large amount of lumber and other material. Of the 116 500 million feet board measure of standing spruce timber in the United States (4 % of the total timber), 48.3 % is composed of red spruce, 30.3 % of the Rocky Mountain or Engelmann spruce, and 21.4 % of the Sitka spruce. These figures concern the districts where this timber is of commercial importance; white spruce, black spruce, Colorado blue spruce and *P. Breweriana* Watts occur also.

The most important by-products of red spruce are the resin, used as chewing gum, and the extract from the tender tips of the branches which forms the basis of spruce beer, a non-alcoholic beverage, formerly very popular, especially amongst sailors, who considered it to be a preventative against scurvy. On account of its lightness, strength, reliability and freedom from hidden defects, spruce wood has recently come into general use in the manufacture of aeroplanes.

Many methods of management have been adopted by the large timber and paper manufacturing companies, who use spruce wood more largely than any other wood. The bulletin under review attempts to determine the methods most suited to various conditions. It is estimated that, under average natural and uniform conditions, 50 to 60 years are necessary for the maximum production of wood used for paper pulp; if judicious thinning is carried out this period may be shortened by 5 to 10 years. For timber production 100 to 120 years either in virgin or selection forests are required.

The bulletin ends with an appendix containing many volume and measurement tables.

- 537 - **Forest Yield of Public Land in Spain** (1). — BERNARD. F., in *Real Sociedad Española de los Amigos del Arbol, Boletín Oficial de la Sociedad*, Year VII, No. 72, pp. 1-2. Madrid, 1917

According to the data obtained for the year 1913-1914, the forests declared of public utility, which depend on the Ministry of the "Fomento", cover in Spain and the neighbouring islands an area of 11 886 349 acres, 29 888 acres less than in the year 1912-1913 due to a rectification of the boundaries. These figures include 609 379 acres (i. e., a little more than 5 %) belonging to the State, 11 261 746 acres belonging to communes, and 15 224 acres belonging to other public bodies.

Of the total area, 1 020 304 acres (i. e., 8 % of the acreage of public forests) are being divided up for cutting and 288 891 acres of mountain land are being regenerated and replanted.

The various kinds of trees found in the forests are distributed as follows:— 5 263 223 acres of full-grown pine, oak and beech; 3 088 860 acres of thicket and 3 534 260 acres of brushwood and pasture land. The income from these forests is estimated at £ 412 247 (*at par*). The principal items are:—

Pasture land . . . . .	£ 192 994
Timber . . . . .	87 516
Resin . . . . .	47 861
Firewood . . . . .	39 437
Cork . . . . .	16 883
Esparto . . . . .	6 499

A profit is also obtained from grazing acorns, fruit, roots, etc. There are great differences in the prices of the various products, less on account of the quality than difficulty of transport. Thus, standing pine costs from 5.98 *d.* to £1.18.0 per cubic metre (1 cubic metre = 35.31 cubic feet), English oak from 3s.1.66*d.* to 18s.5.42*d.*, beech from 5.70*d.* to £1.18.0 (*at par*).

The requirements of industries which utilise various forest products call for increased exploitation of the forests, while, at the same time, the maintenance of livestock and breeding demands improved pasture land.

- 538 - **Timber of British Guiana.** — See No. 497 of this Review.

- 539 - **The Galls of *Tamarix articulata* Vahl.** — TRABUT, L. (Professor of the University of Algiers, Director of the Botanical Service of the General Government of Algeria), in *Bulletin de la Station de Recherches Forestières du Nord de l'Afrique*, Vol. I, Pt. 5, pp. 171-182 + 6 Figs + 2 Plates. Algiers, 1917.

The "takaout" gall of *Tamarix articulata* Vahl, known as "ettl" or "tlaia", was well known to the ancients, except that Dioscorides and later writers confound the gall with the fruit of the tree because the galls usually develop at the expense of the flowers, taking the place of the fruit.

(1) See B. 1912, No. 930. (*Ed.*)

In India the galls of *Tamarix* are used in tanning, dyeing and medicine. In the Sahara, *Tamarix articulata* sometimes forms veritable forests; it is the most important tree the Touaregs have, both by reason of the numbers in which it occurs and its utility.

For a long time the gall of *Tamarix articulata* was believed to be caused by a Lepidopteron (*Pamene pharaonana*), but according to the author it is caused by a mite (*Eriophyes tlaiae* Trab, of the same genus as *E. tamaricis* Trotter).

Most of the commercial galls are flower galls, and smaller and more regular than those of the branches, which may be as large as a nut. The author's observations showed the possibility of forcing the growth of galls on all *Tamarix* which are old enough to flower, thus solving the problem of the production in large quantities of a much valued raw material. In 1883 the Tlemcen tanners paid up to £1.3. 2 ½ per 100 lb.; the present price is 14s. 2 ½ d.

A chemical analysis of the flower galls gave the following results:—

Moisture. . . . .	12.5 %
Extractive matter. . . . .	44.0 %
Tannin. . . . .	55.2 %

The galls form in summer and may be harvested in autumn. The *Tamarix* is easily propagated by cuttings and may be used for fixing sand on the coast. Although it is difficult to estimate the yield in galls it must be heavy considering that infected trees always bear a large quantity, so that a harvest of from 16 to 23 cwt. per acre is not unlikely.

The author recommends experimental plantations of *Tamarix articulata* in soils unsuited to other crops, such as sand and saline steppes, which form a large proportion of the unproductive lands. The *Tamarix* might modify advantageously the flora of such lands by favouring the growth of forage suitable for feeding sheep. Cattle eat the twigs of *Tamarix*.

540—**Forest Fires in the United States in 1915** (1).—PETERS, J. G. (Chief of State Cooperation Forest Service), in *U. S. Department of Agriculture, Office of the Secretary, Circular* No. 69, pp. 6. Washington, January 11, 1917.

The statistics contained in this circular represent the first attempt at an annual estimate of forest fires in the United States. In general the most comprehensive reports were those obtained from States with organised forest-fire protective systems and from the National Forests. Where no protective organisations existed attempts were made to obtain estimates from the civic divisions of the States and from rural mail-carriers. By this means data were obtained from 37 States, representing about 56% of the forest area of the United States. These States may be divided into three groups:—1) those giving data covering the total forest area; 2) those giving data covering 60 to 99 % of this area; 3) those giving data covering less than 60 % of the area.

The figures obtained made it possible to draw up the general classification shown in Table I.

(1) See B. 1912, No. 1312. (Ed.)

TABLE I. — *Forest Fires and their Causes in the United States in 1915.*

Causes	Number	Percentage
Lightning . . . . .	2 298	10
Railway . . . . .	3 548	16
Lumbering . . . . .	728	3
Brush-burning . . . . .	3 545	16
Campers . . . . .	2 347	10
Incendiary . . . . .	1 751	8
Miscellaneous . . . . .	2 384	11
Unknown . . . . .	5 867	26
<i>Total . . . . .</i>	<b>22 468</b>	<b>100</b>

Total area burned . . . . .	3 306 650 acres
Average area burned per fire . . . . .	147 "
Total loss caused by fires . . . . .	\$ 4 009 356
Average loss per fire . . . . .	\$ 179
Average loss per acre . . . . .	\$ 1.20

These data concern 304 864 000 acres, belonging to the States from which reports were obtained. An estimate for the total forest area of the United States gives the following figures : —

Area . . . . .	544 400 000 acres
Number of fires . . . . .	40 000
Area burned . . . . .	6 000 000 acres
Loss . . . . .	\$ 7 000 000

That is to say the area burned represented 1.1 % of the total. Moreover, the loss in young tree growth and the very great damage due to soil deterioration and floods have not been included.

The returns obtained in the United States show that where there is a protective system most of the fires can be controlled before making headway, and that extensive and destructive fires are few as compared with States having no such protective system. This argues strongly in favour of the formation of adequate systems of protection in all States. The figures in Table II show the cost of such a system.

TABLE II. — *Cost of Protection against Forest Fires in the United States in 1915.*

Protected forest area . . . . .	405 550 000 acres
Total expenditure . . . . .	\$ 2 738 999.80
Federal Government expenditure	
On National Forests . . . . .	\$ 2 153 728.17
On State and private lands . . . . .	\$ 71 860.02
Expenditure of States with protective systems	\$ 513.411.61

## LIVE STOCK AND BREEDING.

541 - The Chemical Composition of Lime-Sulphur Animal Dips. — CHAPIN, ROBERT M., in *U. S. Department of Agriculture, Bulletin No. 451*, 16 pp.; Bibliography of 10 Publications. Washington, D. C., December 11, 1916.

HYGIENE

Some of the numerous reactions which determine the composition of lime-sulphur solutions are reversible, the points of equilibrium varying according as the solution is hot or cold, dilute or concentrated, or exposed to the influence of other varying conditions. Under such circumstances the only way in which laboratory studies can be of practical value is by so thoroughly establishing the fundamental principles involved and the effect of varying conditions upon the relative importance of such principles as to afford a sound basis for reasoning.

It appears that when lime and sulphur are boiled with water, ignoring unessential and hypothetical intermediate compounds, the following reactions occur: —

- 1)  $3 \text{ Ca (OH)}_2 + 12 \text{ S} = 2 \text{ Ca S}_5 + \text{Ca S}_2 \text{ O}_3 + 3 \text{ H}_2 \text{ O}$
- 2)  $10 \text{ Ca S}_5 + 3 \text{ Ca (OH)}_2 = 12 \text{ Ca S}_4 + \text{Ca S}_2 \text{ O}_3 + 3 \text{ H}_2 \text{ O}$
- 3)  $\text{Ca S}_4 + \text{S} = \text{Ca S}_5$

Only when substantially all free sulphur has been dissolved will equation 2 become operative or equation 3 fail to hold all polysulphide substantially up to the pentasulphide.

All lime-sulphur solutions are subject to hydrolytic decomposition according to the equation: —

the pressure of the reaction from left to right increasing with rise of temperature. Whether or not hydrogen sulphide can escape, the remaining products on the right-hand side react according to equation 1, giving as final result, in case of  $\text{Ca S}_5$ ,

Thus all solutions are in equilibrium only when they contain a certain excess of hydrogen sulphide, the amount being dependent upon the temperatures and concentrations of the solutions.

Solutions exposed to air are oxidized, as is usually represented by the equation: —

although it is possible that, as propounded by DIVERS and SHIMIDZU, the immediate action is an oxidation of the hydrogen sulphide liberated according to equation 4.

Above a certain concentration of the hot solution, which appears to lie between 3.33 and 3.95 per cent of monosulphur, the following reaction tends to progress from left to right: —

A well-boiled solution, not originally made with an excess of lime, can never under any circumstances possess a plus reaction figure — that is, it cannot contain calcium hydroxide in excess of monosulphur. If original-

ly made with an excess of lime or if not boiled long enough, excess lime is at first present in solution. But if such a preparation be allowed to stand quietly and cool off in the cooking vat, the indications are that the undissolved lime soon settles down, while the small amount of dissolved lime rapidly reacts with polysulphur according to equation 2, so that in this case also, unless the cooled solution is again stirred up with the sediment, a plus reaction figure can never be present in the end. Such a solution will naturally contain a notable amount of tetrasulphide.

As regards the period of boiling, it is not improbable that the time should be increased with increasing concentration. Lime is but slightly soluble in the solution at any stage, and it must probably dissolve before it can react with the sulphur. It would seem, therefore, that a longer time must necessarily be required in a given volume for a large quantity of lime to enter successively into solution and into reaction than for a small quantity.

As regards the effect of the degree of concentration, in addition to the decomposition of thiosulphate which has been noted, the indications are that with increasing concentration the utilisation of both lime and sulphur possibly becomes less nearly complete and also that the polysulphides formed possibly contain a somewhat less proportion of pentasulphide. But the apparent effect might have been produced simply by insufficient boiling, and in any case it is of no material significance in comparison with the practical importance of putting out proprietary preparations in highly concentrated form.

Finished solutions, if stored over sediment which contains free lime, will naturally tend to maintain a plus reaction figure and will undergo changes attributable to the slow progress of reactions 1 and 2. If decanted from sediment and preserved from access of air, only two slight changes are noticeable; firstly, the progress of equation 5 until a certain concentration of hydrogen sulphide is reached, when equilibrium is established according to equation 4; secondly, an apparent slight drop in the thiosulphate figure, for which no explanation is offered, since the phenomenon appeared too quantitatively insignificant to warrant special investigation. Both changes, in fact, are so slight as to be entirely negligible for practical purposes under ordinary conditions.

For the actual preparation of lime-sulphur solutions equations 1, 2, and 3 call for the use of 43.7 parts of available calcium oxide to 100 parts of sulphur. That the laboratory experiments did not precisely check this theoretical ration is attributable solely to the decompositions represented by equations 5 and 6. The decomposition represented by equation 5 is independent of the formula employed and in no way changes the relative proportions of primary ingredients called for; that is, equation 5, following the postulated escape of hydrogen sulphide, produces neither free lime nor free sulphur, and leaves the solution neutral. There remains then only the matter of oxidation to be considered. That is a surface action solely, and considering the enormous advantage in the ratio of volume to surface possessed by even moderate-sized cooling vats over laboratory apparatus, it approaches a negligible factor. Therefore the theoretical ratio becomes

the actual ratio which should be followed in practice, provided only the concentration is not sufficient to allow equation 7 to progress from left to right. The formation of sulphite becomes a significant factor when the formula employs somewhat more than 20 parts of sulphur per 100 volumes of finished solution. For a number of reasons the writer believes that it will be generally inadvisable to try for a much higher degree of concentration in "home-made" solutions. Certainly in such solutions no allowance should be made for the formation of sulphite by increasing the ratio of lime to sulphur, as the extent of the decomposition is too dependent on the degree of concentration and length of boiling after the solution is otherwise complete. Attempts to make more concentrated solutions are attended by greater difficulty in manipulating the thick liquid and in avoiding loss by boiling over, and moreover involve more loss of the finished solution in the wet sludge, especially since the volume of sludge is increased by deposition of calcium sulphite.

Nowhere is there evidence of the existence in cold solutions of more sulphur, either free or combined, than corresponds to the formula  $\text{Ca S}_5$ . On the other hand, a properly prepared home-made solution will contain at most but a small amount of tetrasulphide. It will also contain a very small amount of hydrogen sulphide, some of which may possibly be in the form of calcium hydrosulphide. While rigidly scientific proof is perhaps lacking that the two apparently definite proportions of four atoms and five atoms of sulphur respectively to one atom of calcium may not, in fact, arise from mixtures of lower and higher polysulphides, it is certainly true that all available evidence points to the existence of only these two.

The methods of analysis have proved to be adequate in scope and accuracy as well as practical. Working in the ordinary way with flasks and pipettes the analyst apparently will not recover from a concentrate more than 99 per cent. of the monosulphur, which indicates a recovery of 99.75 per cent. of the polysulphur, or 99.6 per cent of the sulphide sulphur, calculating on pentasulphide only. The loss arises chiefly from oxidation during manipulation of the solutions and may be reduced only by manipulating in an atmosphere of some inert gas.

*Practical applications.* — It is logical to deduce from the data here presented a working formula for the preparation of lime-sulphur solutions. The subject has been dealt with by a number of investigators primarily interested in the preparation of such solutions for horticultural spraying purposes. Some the formulae so developed seem to have given entire satisfaction for the purpose for which they were intended and the dilutions at which the resulting products should be employed under various conditions have become so well established that any change in formula would be of doubtful practical benefit. It is quite otherwise with solutions intended primarily for the purpose of dipping cattle and sheep. The formulae in use are those prescribed by the Bureau of Animal Industry many years ago when uncertainty regarding possible chemical reactions and possible effects of the resulting compounds upon both animals and parasites very properly led to the use of formulae which should be certain and

safe, even if somewhat uneconomical. The formula suggested here is proposed, therefore, solely for use as an animal dip. It may be termed the "8-18-10" formula; that is, 8 pounds of high grade commercial quicklime, 18 pounds fine sulphur (either flowers or flour) with somewhat more than 10 gallons of water, boiled to a volume of 10 gallons at the finish. The time of actual boiling should be one hour. The theoretical ratio between lime and sulphur will be met by this formula if the lime is 98.3 per cent pure, therefore the formula as given is suitable for the preparation of a solution for dipping sheep where any danger of an excess of lime must be avoided. If commercial hydrated (not air-slaked) lime is used the amount should be increased nearly one-third, say to 10.5 pounds. For dipping cattle the formula may be used on the basis of available calcium oxide if the analysis of the lime is known; if this not known the lime may safely be raised to 8.5 pounds, corresponding to 92.5 per cent available calcium oxide, possibly even to 9 pounds. The manipulation of the materials in the actual process of preparation has been described in a recent publication from the Bureau of Animal Industry (IMES, MARION, Sheep Scab. *U. S. Dept. Agr. Farmers' Bull.* 713, 36 pp. Washington, 1916).

The finished solution, drawn off from the sediment, should theoretically contain 18 per cent (grams per 100 cc.) of sulphide sulphur, but will probably contain somewhat less. It is, therefore, suitable for dipping sheep at a dilution of 1 volume of concentrate to 9 or 10 volumes of water, and for cattle at a dilution of 1 volume of concentrate to 7 or 8 volumes of water. But in any case, since baths lose strength during dipping, it is very desirable to keep them at all times under control by means of a "field test" (CHAPIN, ROBERT M. A Field Test for Lime-Sulphur Dipping Baths. *U. S. Dept. Agr. Bull.* 163, 7 pp. Washington, 1915).

The particular advantages of the above formula are, firstly that it closely approaches the theoretical ratio, making allowance for impurities; secondly it is as concentrated a product as can be prepared without conversion of thiosulphate to sulphite; and thirdly, the figures are easily remembered and readily converted into the quantities of ingredients necessary to prepare a batch of any desired size.

In deducing a formula for the preparation of highly concentrated proprietary solutions it is evident that the manufacturer must make a few tests with plenty of sulphur in order to establish the conditions which will uniformly yield the product he desires, analysis of which will then show him by how much he may safely reduce the sulphur to allow for the formation of sulphite.

**542 - The Toxicity of Carotin.** — WELLS, GIDEON H. and HEDENBURG, O. F. (Department of Pathology of the University of Chicago), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 1, pp. 213-116. Baltimore, Md., 1916.

In the course of an investigation of the effects of the bleaching of flour by chlorine gas, it became necessary to ascertain the possible toxicity of the pure pigment matter — carotin (1) — both bleached and unbleached.

(1) Only 1 gm. of colour is contained in 1000 kg. of flour. (*Ed.*)

The purified pigment, chlorinated or not, was dissolved in olive oil, sterilized and injected in guinea pigs intraperitoneally and intradermically. Such large amounts as 0.2 gm. given intraperitoneally or 20 gm. injected intradermically had no effect or caused only a local oedema and inflammation, but no necrosis. Therefore it may be safely concluded that even in relatively very large doses carotin, whether in its natural state or saturated with chlorine, is almost entirely devoid of toxicity.

The studies of PALMER and ECKLES (*Journal of Biological Chemistry*, Vol. XVII, p. 191, 1914) indicate that carotin is almost universally distributed throughout all animal bodies, coming chiefly, if not solely, from the food. The experiments of the authors seem to be sufficient to warrant the assumption that any such quantities as can ever accumulate in the tissues have no harmful effects.

**543 - Studies in Blackleg (Symptomatic Anthrax) Immunization with Special Reference to Blackleg Filtrate.** — EICHORN, A, in *Journal of the American Veterinary Medical Association*, Vol. LII, No. 6, pp. 651-669. Ithaca, N. Y., February, 1918.

Up to the present the most common method of vaccination for immunization against blackleg (symptomatic anthrax) consisted in the injection of attenuated virus prepared in either pellet or powder form.

With this method direct losses from vaccination are known to occur from time to time and insufficient protection following vaccination is also of too common occurrence.

The first investigation on attempts to utilise filtrates of bacterial growths of blackleg cultures for immunization purposes are recorded by FOTH. Japanese investigators have continued the work along the lines developed by FOTH and, according to Prof. NITTA of the Tokio University, the filtrates obtained appear to afford uniform protection, entirely avoiding losses from vaccination.

The experimental work reported in this paper dealing with the preparation, standardization and immunizing properties of blackleg filtrate, fully substantiated these claims, with the following results: —

- 1) Blackleg filtrate is an effective immunizing agent against blackleg.
- 2) Blackleg filtrate confers an active immunity which protects cattle against the disease for as long a period of time as the germ-free extracts (agressins) prepared from the juice of the tissues from affected cattle.
- 3) Since it does not contain the blackleg germ in any form it cannot produce the disease, therefore losses incidental to vaccination with the powder or pellet form are entirely avoided.
- 4) Blackleg filtrate may be prepared in a concentrated form and, when suitably preserved, will retain its potency for an almost indefinite period of time.
- 5) It is essential to subject the blackleg filtrate to the various tests for sterility, both during the filtration and filling processes in order to guard against any possible contamination.

544 - On the Possibility of the Passage of Trypanosomes into Milk (1). — LANFRANCHI, A., in the *Atti della Reale Accademia dei Lincei*, Series V, *Rendiconti*, Vol. XXVII, Pt. I, 1st. Half-Year, pp. 62-67. 1 Diagram. Rome, January 6, 1918.

The author wished to ascertain:— 1) if young animals left at the udder would be infected; 2) if it is possible to ascertain the presence of trypanosomes by the direct examination of the milk; 3) if the milk, on inoculation into the peritoneum, could infect rats and mice.

The results have shown that:— 1) *Trypanosoma Brucei*, T. Evansi, T. Lanfranchi, can pass into the milk of rats; 2) *Trypanosoma Evansi* and T. Lanfranchi can pass into the milk of guinea-pigs; 3) *Trypanosoma Lanfranchi* can pass into the milk of mares; 4) the *Lanfranchi virus* can transmit the infection to new-born guinea-pigs through suckling.

The almost universally-recognised fact that trypanosomes in general do not pass from the mother to the foetus, has again been confirmed.

ANATOMY  
AND  
PHYSIOLOGY :  
GENERALITIES

545 - The Basal Catabolism of Cattle and Other Species. — ARMSBY, HENRY PRENTISS, FRIES, J. AUGUST and BRAMAN, WINFRED WAITT, in *Proceeding of the National Academy of Sciences*, Vol. IV, No. 1, pp. 1-4 Bibliography of 12 Publications. Washington, D. C., January 15, 1918.

The basal catabolism of herbivora and especially of ruminants, unlike that of man or carnivora, cannot well be measured in the fasting state on account of the relatively large amount of feed always present in the alimentary canal of the former species. It may, however, be determined indirectly in the manner described by the authors by measuring the total metabolism upon two different amounts of the same ration and from these data computing the level to which the metabolism would be reduced were all feed withdrawn. For example, a steer receiving two different amounts of the same mixed ration gave the following results:—

	Dry matter eaten daily	Daily heat production
	kg.	calories
Period 2 . . . . .	9.146	16,511
Period 1 . . . . .	4.463	10,905
Difference . . . . .	4.683	5,606
Heat increment per kilogram of dry matter .		1.197

Evidently, out of the total metabolism of 10 905 calories in Period 1,  $1\ 197 \times 4.463 = 5\ 342$  calories may be regarded as the heat production caused by the 4.463 kg. of dry matter eaten, while the remainder, 5 563 calories, is the basal catabolism.

The writers' investigations upon the metabolism of cattle (2) afford

(1) See R., July 1916, No. 767. (Ed.)

(2) ARMSBY and FRIES, U. S. Department of Agriculture, Bureau of Animal Industry, *Bulletin* 128, 1911. — ARMSBY, *ibid.*, *Bulletin* 142, 1912. — ARMSBY and FRIES, *Journal of Agricultural Research*, Washington, Vol. III, p. 435, 1915; Vol. X, p. 599, 1917; Vol. XI, 1917. See also B. January, 1912, No. 149; December, 1912, No. 1646; June, 1915, No. 625. (Ed.)

data for computing in the manner just illustrated the basal catabolism of ten unfattened steers in twenty-seven experiments. In view of the very striking effect of standing in increasing the metabolism of cattle the basal catabolism per 24 hours has been computed separately from the observed rate of heat production during the intervals of lying and standing respectively, and also for 12 hours standing and 12 hours lying per day, assumed as representing average conditions.

As was to be expected, the basal catabolism increased with the size of the animal but with very considerable fluctuations. The graphs of the results indicate an equally close relation of the basal catabolism with the weight and with the two-thirds power of the weight (computed body surface) and this conclusion is confirmed by a comparison of the coefficients of correlation as follows:—

	With live weight	With $\frac{2}{3}$ power of live weight
Basal catabolism, lying 24 hours . . . . .	0.8655 $\pm$ 0.0326	0.9032 $\pm$ 0.0239
Basal catabolism, standing 12 hours . . . .	0.8733 $\pm$ 0.0308	0.8710 $\pm$ 0.0313
Basal catabolism, standing 24 hours . . . .	0.8548 $\pm$ 0.0350	0.8250 $\pm$ 0.0415

Computing the basal catabolism per square metre of body surface as estimated by MOULTON's formulae viz.,

$$\text{For unfattened animals } S = 0.1185 W^{\frac{5}{8}}$$

$$\text{For fattened animals } S = 0.158 W^{\frac{5}{9}}$$

the following results were obtained:—

*Basal Catabolism of Cattle per Square Meter of Body Surface.*

	Lying 24 hours	Standing 12 hours	Standing 24 hours
Mean, calories . . . . .	964.0	1173.0	1365.0
Probable error of mean, calories	$\pm 24.0$	$\pm 21.4$	$\pm 25.7$
Probable error of single result, calories . . . . .	$\pm 124.8$	$\pm 110.9$	$\pm 133.6$
Standard deviation, calories . . . . .	185.1 $\pm$ 17.0	164.5 $\pm$ 15.1	198.0 $\pm$ 18.2
Coefficient of variability . . . . .	0.1920	0.1462	0.1451

A positive correlation of the basal catabolism per square metre of body surface with the live weight was also found as follows:—

*Coefficients of correlation with live weight.*

Basal catabolism per square metre

Lying 24 hours . . . . .	0.5375 $\pm$ 0.0923
Standing 12 hours . . . . .	0.3666 $\pm$ 0.1124
Standing 24 hours . . . . .	0.2405 $\pm$ 0.1223

The results show the marked influence of standing upon the metabolism of cattle, the mean 24 hour basal catabolism lying, standing 12 hours and standing 24 hours being in the proportion of 100 : 121 : 141, the differences largely exceeding the probable errors. Computing, from the results per square metre of surface, the basal catabolism for 12 hours' standing and 12 hours' lying gives as the maintenance requirement for a 1000 pound steer  $5918 \pm 560$  calories.

The results for the basal catabolism of man reported by BENEDICT, EMMES, ROTH and SMITH, and by MEANS are very similar to those obtained by the authors upon cattle with the exception of a much lower variability.

### *Coefficients of Correlation*

	With body weight	With body surface
Total basal catabolism:		
98 men . . . . .	$0.7263 \pm 0.0320$	$0.7747 \pm 0.0272$
75 women . . . . .	$0.7759 \pm 0.0310$	$0.7447 \pm 0.0347$

### *Daily Basal Catabolism of Men and Women per Square Metre of Surface.*

	Men	Women
Mean calories . . . . .	830.0	768.0
Probable error of mean, calories . . . . .	$\pm 4.3$	$\pm 4.9$
Probable error of single results, calories . . . . .	$\pm 42.3$	$\pm 42.8$
Standard deviation, calories . . . . .	$62.7 \pm 3.0$	$63.5 \pm 3.1$
Coefficient of variability . . . . .	0.0755	0.0827

Correcting for the error shown by D. and E. F. DU BOIS to be incident to the use of the MEEH formula, the means for men and women are as follows —

### *Corrected Daily Basal Catabolism of Men and Women per Square Metre of Body Surface.*

	Men	Women
Means, calories . . . . .	935.0	886.0
Probable error of mean . . . . .	$\pm 4.8$	$\pm 5.8$
Probable error of single result . . . . .	$\pm 47.5$	$\pm 49.4$

Including the data obtained by MEISL, STROHMER & LORENZ, TANGL, FINGERLING, KÖHLER & REINHARDT for swine and by ZUNTZ and HÄGERMANN for the horse, the following comparison of species may be made :

*Mean Daily Basal catabolism per Square Meter of Body Surface.*

Men (complete muscular rest) . . . . .	935 ± 5
Women (complete muscular rest). . . . .	886 ± 6
Cattle (lying). . . . .	964 ± 24
Hogs (lying). . . . .	1078 ± ?
Horse (standing quietly) . . . . .	948 ± ?

Considering the nature of the results they show a rather striking degree of uniformity and tend to confirm the conclusions of E. VOIT that the basal catabolism of different species of animals is substantially proportional to their body surface. It may be surmised that the exceptional result with the hog is due to the imperfect data available for computing the body surface of this species.

546 - **Adenine and Guanine in Cow's Milk.** — VOEGTLIN, CARL and SHERWIN, CARL P. (Division of Pharmacology, Hygienic Laboratory, Washington), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 1, pp. 145-149, Bibliography of 3 Publications. Baltimore, Md., January, 1918.

In the course of some work on the isolation of the antineuritic substance present in cow's milk, the authors incidentally discovered that this food contains fair amounts of adenine and guanine. One litre of milk contains at least 5 mgm. of adenine and about 10 mgm. of guanine. These values may be considered as minimum values, as the method of isolation of these amino-purines is by no means quantitative. The question as to whether the purines found in milk are derived from the blood purines or whether they are formed from the breaking down of the nucleic acid in the mammary gland is still left open.

The finding of the writers is of interest in connection with the biochemistry of milk for the following reasons: 1) milk is usually considered to be practically purine-free and has been widely used in metabolism experiments as a purine-free diet; 2) milk was used as a diet in experiments to determine whether or not the animal body can synthesize purines and nucleic acid from purine-free food; 3) under certain conditions the mammary glands may act as an excretory organ for metabolism products, drugs, and poisons.

547 - **The Nature of the Dietary Deficiencies of the Oat Kernel.** — MCCOLLUM, E. V., SIMMONDS, N. and FITZ, W. (Laboratory of Agricultural Chemistry of the University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXIX, No. 2, pp. 341-354 + 9 Diagrams. Baltimore, Md., March, 1917.

FEEDS  
AND FEEDING

In this paper the writers present data showing the supplementary relations between the oat kernel and isolated food factors. The experiments were made with rats. The results may be briefly summarized as follows:—

The oat kernel seems to contain proteins of a poorer quality than either the maize or wheat kernel. 9 per cent of oat proteins serve, when all the other dietary factors are properly adjusted, to induce a small amount of growth at the beginning of the experiment, but cessation of growth always follows after about a month and thereafter the animals remain stationary in weight, or decline.

Casein does not appear to supplement the proteins of the oat kernel in a very satisfactory manner. The addition of 10 per cent of casein to 9 per cent of oat proteins, the other dietary factors being properly adjusted, does not induce growth at the maximum rate as do similar combinations of casein with wheat proteins or with maize proteins. Combinations of gelatin and oat proteins in about equal proportions have uniformly proved vastly superior to the similar casein and oat protein combinations.

The unidentified dietary factor, fat-soluble A, is present in very small amount in the oat kernel. It is not possible to supplement the oat kernel with inorganic salts and purified protein so as to induce growth beyond the 3rd month. The inclusion of butter fat or some other substance which supplies the unknown A prevents failure at this point, just as it does in experiments where the ration consists of purified protein salts, carbohydrate, and an extract which furnishes the dietary factor B.

The whole oat kernel, with the hulls removed in the laboratory by coarse grinding and fanning, will not induce any growth in young rats. A mixture of hulled oats or rolled oats with 5 per cent of butter fat induces very slow increase in body weight for at least 125 days.

The oat kernel, like unpolished rice, wheat, wheat germ, maize kernel, alfalfa leaves, cabbage, and clover leaves, contains a liberal supply of the water-soluble B, the preparations of which induce relief from polyneuritis. The authors found this dietary factor in abundance in all the natural food-stuffs in a fresh condition, so far as they employed them in experimental work.

The addition of any single dietary component as protein, inorganic salts, or fat-soluble A does not supplement the oat kernel so as induce appreciable growth.

The addition of two dietary factors to the oat kernel serves to induce good growth during the first 60 days when one of the additions is a suitable salt mixture. Without modifying the inorganic content of the ration when this is derived solely from the oat kernel, the authors have not seen rats make any marked increase in body weight. When the oat kernel is fed supplemented by but two dietary factors there is always early failure with loss of weight and death following the brief period of growth.

Failure has, in the writers' experience, supervened earlier than when wheat or maize is fed with the addition of two purified food additions. The oat kernel, like the wheat kernel, appears to cause injury to the animals when their diet is of such a character as to lower their vitality. It is not necessary to assume the presence of something toxic in the oat kernel to account for the injury which results from the presence of a high content of oats in a monotonous food mixture taken over a considerable period. Oats produce faeces of a pasty character which makes their elimination difficult, and in all probability tend to debilitate the animal.

This explanation becomes the more plausible when we consider the marked improvement of rats whose rations were identical except that the proteins of the oats were in one case supplemented by 10 per cent of casein and in the other by 9 per cent of gelatin. There can be no doubt that gela-

tin furnishes an amino-acid mixture which makes good the deficiencies of the oat proteins in a much greater degree than does casein. The improved physiological condition of the animals which results from the superior quality of their protein mixture in the former case may render them capable of overcoming the difficulty of elimination of faeces. If this is the real explanation the stunting observed with the oat-casein combinations may be due to the absorption of the products of putrefaction from the intestine.

When the oat kernel is supplemented with casein, a suitable salt mixture and butter fat, growth may proceed to the normal adult size at the normal rate in some animals, but, in general, growth is slower than the normal rate. The authors have been able to secure reproduction with these rations in but a single instance, and the young survived but 1 day.

**548 - Feeding Experiments on the Substitution of Protein by Definite Mixtures of Isolated Amino-Acids.** — MITCHELL, H. H. (Department of Animal Husbandry, University of Illinois, Urbana), in *The Journal of Biological Chemistry*, Vol. XXVI, No. 1, pp. 231-261 2 Tables 5 Diagr. Baltimore, Md. August, 1916.

The writer summarizes as follows the chief results of his researches :

Experiments are reported in this paper in which mice have been kept alive for 70 to 98 days by feeding alternately : — 1) rations containing 4 to 6 per cent of various mixtures of isolated amino-acids, 6 to 4 per cent sucrose, 34 per cent starch, 28 per cent protein-free milk (prepared either according to the procedure of OSBORNE and MENDEL or to a modification of this procedure described in the text), 10 per cent lard, and 18 per cent butter fat, and 2) a ration containing 10 per cent sucrose, with other constituents in the same proportion as in the first mentioned rations. In many of these experiments periods of 15 to 35 days' duration have been observed in which the mice practically maintained their weight.

The alternate feeding of an amino-acid ration and a non-nitrogenous ration (except for the nitrogen present in the protein-free milk) induced a better total consumption of food than feeding with an amino-acid ration alone, and in all other respects led to more successful results. However, it is probable that in no case was the amino-acid intake sufficiently large to assure a fair test of its adequacy.

Amino-acid rations containing no added tyrosine, or no added tyrosine and phenylalanine, did not give appreciably different results from rations containing these amino-acids. However, if tryptophane was absent from an amino-acid ration, the period of survival of mice fed this ration alternately with the non-nitrogenous ration was noticeably shorter than the periods of survival of mice kept on rations containing added tryptophane.

Mice could be kept for much longer periods of time on rations containing mixtures of amino-acids, including tryptophane, fed alternately with the non-nitrogenous basal ration, than when fed the basal ration alone. Furthermore, this difference in survival cannot be accounted for by a difference in energy intake. This fact has been interpreted as meaning that at least some of the amino-acids have specific functions in metabolism aside from that of serving simply as material for the synthesis of body protein. Other

evidence from the literature is cited in support of this view, which is substantially the same as that recently and tentatively put forward by OSBORNE and MENDEL (*Journal of Biological Chemistry*, Vol. XX, p. 377, 1915).

549 — **Fat Assimilation.** — BLOOR, W. R. (Laboratories of Biological Chemistry of the Harvard Medical School, Boston), in *The Journal of Biological Chemistry*, Vol. XXIV, No. 4, pp. 447-460. Baltimore, Md., 1916.

The author has made determinations of total fat; lecithin (phosphatides) and cholesterol in whole blood and plasma (and by calculation in the corpuscles) during a series of fat absorption experiments, carried on with dogs, with results which are believed to justify the conclusions: 1) that the blood corpuscles take up the fat from the plasma and transform it into lecithin; 2) that most if not all of the absorbed fat is so transformed; and therefore 3) lecithin is an intermediate step in the metabolism of the fats.

#### CATTLE

550 — **The "Optimum Age" for Fattening Off Irish Bullocks.** — WILSON, J., in the *Journal of the Department of Agriculture and Technical Instruction for Ireland*, Vol. XVIII, No. 1, pp. 3-6. Dublin, 1918.

The majority of Irish calves are born in spring. For the first couple of weeks they are fed upon whole milk, and then upon meals and separated milk for the rest of the summer. They are then "stored" till they are from 18 to 42 months old, but, in the majority of cases till they are 30 months old. During the first winter of storing they are fed hay, a couple of stones of roots or a couple of pounds of cake, and pasture. During the second winter they depend chiefly on pasture, with some hay or straw, and, in some cases, a few roots. Only pasture is given the third winter though, in very severe weather, a little hay or straw is added. Under these conditions growth is slow and in autumn the bullocks usually require a month's preparatory feeding before being put upon a fattening ration. Their approximate average weight and their selling value (1) per head at different ages are: at birth 70 lb. £2.5s. ; at 6 months, 3 cwt., £4 15s. ; at 12 months, 4 cwt., £6.10s. ; at 24 months, 7  $\frac{1}{4}$  cwt., £11.10s. ; at 36 months, 10 cwt., £15.10s. ; at 42 months, 11  $\frac{1}{4}$  cwt., £17.10s. Therefore the selling value per pound live-weight of the dropped calf falls from 7.7d. to 3.4d. a pound in about 6 months; after this the variation is slight. If the weight of the new born calf is reckoned at 70 lb. and the drop in value at 4  $\frac{1}{2}$ d. a pound, the total loss is 26s. 3d.; a loss which must be wiped out before any profit can be realised. During the rearing period the calf gains about 1  $\frac{1}{2}$  lb. a day, which, with a selling value of 3.4d. a pound, is roughly equivalent to a daily increase of 5d. in money value. If it can be reared at 3d. a day the loss of 26s. 3d. will be discounted in about 5 months. The rearer cannot, therefore, sell a calf profitably till it is 6 months old unless he gets more than 3.4d. a pound for it.

A medium sized fattening bullock puts on about 2 lb. a day, at a cost of about 11d. (i. e., 5  $\frac{1}{2}$ d. a pound), and is sold at 4d. a pound. The loss of 1  $\frac{1}{2}$  lb. a pound is, however, only apparent, being compensated for by the rise in

(1) All prices in this paper are average pre-war prices.

value of every pound of the original lean animal from 3.3*d.* to 4*d.*, but this size animal realises no profit.

From the time the rearer can afford to sell it till the time the fatterer buys it, the Irish bullock is stored, the period of storing lasting from 1 to 3 years. Since the main function of a store bullock is to convert the more or less unmarketable products of the farm into something which can go to market on its own feet, the owner will naturally prefer an animal suited to the fodder produced on the farm and not too advanced in growth, its age being of secondary importance. There is, however, an age at which the bullock can be put up to be fattened to the best advantage; this age is when the difference between the total gain produced by improving the unfattened weight and the outlay upon fattening foodstuffs is at its maximum. This can be determined by estimating the cost of producing a pound of beef with bullocks of different ages. The appended table shows the estimated pre-war costs of producing beef at different ages (page 591).

As grass in Ireland is cheaper than winter foods, the grass fattened bullock costs less to produce. It is seen, however, that, in both cases, the producer's profits begin to decline if the bullock is not fattened off while it is about 2 years old or under. A bullock stored till it is 3½ years old makes no profit, and if such an animal is sold to be fattened, it is clear that if the fatterer makes a profit on it the seller makes a corresponding loss.

**551 - Breeding Hens for Egg Production (1).** — MURPHY, L., in the *Journal of the Department of Agriculture and Technical Instruction for Ireland*, Vol. XVIII, No. 1, pp. 33-48. Dublin, 1918.

The paper under review gives the results of the 5th Irish Laying Competition held, as in previous years, at the Munster Institute, Cork, and the conclusions deduced from them.

The competing breeds included 17 pens of White Wyandottes, 6 of Rhode Island Reds, 5 of White Leghorns, and one each of Black Minorcas, Red Sussex, and Buff Orpingtons. There were, in addition, 4 non-competing pens. Each pen contained 6 pullets.

The dearth of eggs in Ireland in October and November is due to late hatching, heavy breeds hatched in May being useless for winter egg production. The tests showed that with very good laying strains, as, for example, certain families of white Leghorns, late hatching is fairly successful if the feeding and general management during the growing stage are good. The eggs of early hatched pullets are, however, of better size than those of late hatched ones, an important factor when dealing with breeds having a tendency to lay small eggs. Until recently little attention was given to the size of the eggs, though failure to give good sized produce is so serious a fault that it discounts any other merit a strain may have. Good size and large production can be successfully combined but good stock must be used, all hens laying second-grade eggs being rigorously excluded. From the results of these tests it seems that when a pullet has laid a large percentage of small eggs in her first year, but gives good-size eggs about August of

(1) For Report of the 3rd competition see R. May, 1916, No. 542. (*Ed.*)

her first season (*i. e.*, at the beginning of her autumn laying cycle), her female progeny are liable to do the same. It is, therefore, wiser not to use such a hen for breeding, even though her pullet record be far above the average and her eggs in the second year 2 oz. or over. To obtain the best results accurate breeding records and careful selection are essential. So-called "line breeding" cannot be continued successfully over a number of years unless the parentage of every bird in the breeding pens is known.

Too much care cannot be taken in the choice or a cockerel to mate with layers, and special consideration should be given not only to the number, but also to the size of the eggs laid by his dam. The high price paid for such a bird will be amply repaid by the results obtained.

The increase in broodiness in some strains has not yet been definitely explained. In some cases when a non-broody pullet is mated with a cockerel from a non-broody hen, all the progeny will be broody. The most satisfactory explanation is that given by Mr. OSCAR SMART, who suggests that broodiness is due to the presence of two factors, A and B. A pullet inheriting the factors AA or BB will not go broody, but if a bird inheriting AA is crossed with one inheriting BB all the progeny will be broody at some time or other. All that can be advised at present is that a cockerel which has introduced broodiness should not be used again with the same hens.

The food given during the period of the tests included, in decreasing order of the amounts given:—oats, bran and pollard, potatoes, maize meal, wheat, fish meal, dried grains, gluten meal, dried yeast, small quantities of dry mash and concentrates, and greenstuff. Reducing the potatoes to their grain or meal equivalent, 4 lb. of potatoes equal 1 lb. of grain or meal, giving a total of 180  $\frac{1}{4}$  cwt. for the 210 birds, thus 4.31 lbs. of meal were required to produce 1 lb. of eggs. As a large percentage of this meal was unfit for human consumption it showed the hen to be very profitable for the conversion of such food into a rich and easily digested human food. The free use of potatoes was perfectly satisfactory when balanced by a highly concentrated food, such as fish meal. When, as at present, prices are high, it is far better policy to feed a few birds liberally than to keep a large number on little more than a maintenance ration, for, as such birds are very poor for table and useless for egg production, the result is sure to be a loss.

The winning pen (White Wyandottes) laid 1 339 eggs, or an average of 223.2 per hen; the maximum number laid by one hen was 251. The following table gives the general results of the competition compared with those obtained in previous years.

Year	No. of pullets	No. of eggs laid	
		Total	Average per hen
1913 . . . . .	318	38 199	120.1
1914 . . . . .	282	39 216	139.0
1915 . . . . .	264	39 764	150.6
1916 . . . . .	294	49 830	169.5
1917 . . . . .	210	36 660	174.6

552 - The Behaviour of Chickens Fed Rations Restricted to: — I) Cereal Grains; II) Wheat or Maize Kernel. — I. HART, E. B. HALPIN, J. G. and McCOLLUM, V., in *The Journal of Biological Chemistry*, Vol. XXIX, No. 1, pp. 57-67 + 2 Tables + 1 Plate. Baltimore, February, 1917. — II. HART, E. B., HALPIN, J. G., and STERNBOCK, H., *ibid.*, Vol. XXXI, No. 2, pp. 415-420 + 1 Plate, August 1917.

Wheat is generally considered to have a higher food value than other cereals. The numerous experiments carried out on mammals by the authors since 1911 tend to prove the opposite and show almost beyond doubt that wheat contains a slightly toxic material. Moreover, wheat proteins are of inferior quality, and may partly account for the malnutrition observed by the authors when wheat was fed in excessive quantities. The fact that maize kernel proteins are equally inferior for growth but are not otherwise unsuitable for normal nutrition points to the great probability that the lower food value of the wheat kernel is due to one or more toxic substances. The authors, therefore, undertook experiments with chickens to determine: — a) their resistance to an exclusive or restricted diet; b) their food requirements.

I. — Feeding experiments carried out with strong Rhode Island Red hens weighing from 3 to 4 lb., fed exclusively on cereals and their derivatives during 7 to 12 months, showed that chickens started at half the normal weight can grow slowly, maintain themselves, and produce fertile eggs on rations limited to: — 1) maize meal + gluten feed + calcium carbonate, or 2) wheat meal + wheat gluten + calcium carbonate.

These results are in marked contrast to those obtained by the authors with swine and rats, in which these rations led to loss of weight, cessation of oestrus, and, with wheat, to a condition resembling polyneuritis.

The mineral requirement, and probably also that of other normal nutritive factors, is not the same for chickens as for mammals. Moreover, the fowl's capacity to tolerate without fatal results or a modification of diet, the toxic substance contained in wheat, shows its metabolism to differ from that of swine or rats.

When half-grown chickens were used in the experiments no important improvement was obtained in the rate of growth or egg-laying capacity by supplementing the grain with salts, casein, butter fat, or a mixture of the three, as compared with the results obtained with grain + grain protein concentrate + calcium carbonate. The protein content in all cases was about 12 %. The eggs produced on all these rations though fertile were few.

This result, which disagrees with the best practical results in which animal protein concentrates have proved of great value as supplements to a ration of cereal grains for egg production, suggests that either the higher plane of protein intake (20-25 %) obtained in practice by the use of the animal protein concentrates (meat scraps, milk, etc.) would account for this difference, or else these concentrates contain certain factors necessary to a large egg production which are not found in the cereal grains or casein.

II. — The previous experiments were extended to younger chickens weighing from 2 to 3 lb., with the following results: —

Chickens started below half their normal weight can grow slowly and maintain themselves on rations restricted to maize meal, gluten feed, and calcium carbonate. A ration restricted to wheat grain, wheat gluten and calcium carbonate causes death in 3 months. These results agree with those obtained for mammals, especially with regard to the action of wheat grain.

When compared with the results given above, these show a difference in the behaviour of more mature and younger chickens. The former tolerate wheat, but the latter, like adult or young mammals, succumb to a diet containing excessive wheat. There is also a difference in the mineral requirements of growing chickens and growing mammals.

Modifying the wheat grain by the addition of a complex salt mixture, or by this mixture and another change, such as substituting casein for part of the wheat protein, does not improve the dietary properties of wheat for young chickens. Only when butter is added and the salt mixture and casein substituted for part of the wheat protein are tolerance and good health obtained.

These results do not imply that wheat or its derivatives cannot be fed to growing chickens or mammals, but only show their dietary limitations with another species. They also prove that wheat cannot be successfully used as an exclusive diet for young chickens without the introduction of other dietary factors, and show what these factors are.

**553 - Studies on the Physiology of Reproduction in the Domestic Fowl.** — PEARL, RAYMOND (Maine Agricultural Experiment Station, Orono), in *The Journal of Biological Chemistry*, Vol. XXIV, No. 2, pp. 123-135. Baltimore, Md., 1916.

In the preceding paper in this series (1) the author has shown that the injection of the substance or extract of the anterior lobe of the pituitary body into the peritoneal cavity of the domestic fowl failed entirely to activate the completely resting ovary. These negative results seemed to make attempts at administration *per os* worth while. The results may be summarized as follows:—

Feeding the desiccated substance of the anterior lobe of the pituitary body of cattle to hens in laying condition but at a time of year when the rate of fecundity is declining, does not stimulate the ovary to an increased rate of production.

Feeding the same substance to growing pullets does not bring about any earlier activation of the ovary than occurs in normal control pullets not fed this substance.

The anterior lobe of the pituitary body from cattle when fed to growing chicks is accompanied by a distinct retardation in growth in body weight. This confirms for the chick the results which have been obtained with this substance by other investigators (CUSHING, SANDRI, ALDRICH) in mammals.

The feeding of the desiccated substance of corpus luteum brings about a retardation of growth about twice as great in amount as that following pituitary feeding.

(1) See B. August 1915, No. 838. (Ed.)

Neither pituitary substance (anterior lobe) nor corpus luteum substance when fed to laying pullets causes any retardation in the attainment of sexual maturity as indicated by the laying of eggs. The birds so fed begin to lay eggs at the same age, but at a smaller body weight than the normal controls.

## FARM ENGINEERING.

### AGRICULTURAL MACHINERY AND IMPLEMENTS

554 — **State Motoreculture in England and Scotland.** — I. *Mask Lane Express Agricultural Journal*, Vol. CXIX, No. 4505, p. 88. London, January 28, 1918. — II. *The Scottish Journal of Agriculture*, Vol. I, No 1, pp. 61-62. Edinburgh, January, 1918.

I. The President of the Board of Agriculture has stated that the area ploughed by Government tractors from the middle of August to January 12, 1918, was 231 000 acres. On the latter date there were 1 813 tractors working.

II. — The Food Production Department of the Board of Agriculture and Fisheries acquired a large number of tractors, one seventh of which were allotted to the Scottish Board. This quantity, however, was not required, and only 115 new tractors were added to the previous year's total. These were of the following types: — Titan, Overtime, British Universal, Moline, Wallis, Cub Junior, and Burford-Cleveland.

Considerable difficulty was experienced in providing ploughs for these tractors to suit Scottish conditions. The ploughs brought by the Scottish Board were mostly made by Messrs. SELLAR & SON (Scotland) and OLIVER (United States). One SANDERSON & MILL plough and one CASE plough were bought.

Grubbers, cultivators and harrows will also be provided for use with the tractors.

555 — **Agricultural Machinery in Italy.** — ALPE, V., in *L'Industria*, Vol. XXXII, No. 4, pp. 99-100, 4 Figs. Milan, February 28, 1918.

Of late years great progress has been made in Italy in the construction of agricultural machinery.

The writer first describes a turnwrest plough, with an all-metal frame, for hill work, and built entirely in Italy. Its sale price is 1 ½ francs per kg. (instead of ½ a franc—the pre-war price). Large numbers of a plough with the mouldboard carried on front wheels, somewhat like the Belgian plough, are being constructed. Two models can now be delivered, one working at 16, the other at 12 in. deep. They were tested with a draw-bar pull of 60 kg. per sq. millimetre.

The writer also mentions the construction of a seed drill of the American type and of a chop-cutter, both machines much in demand in Italy. Two types of chopcutter are made in Italy: — one with a 12 in. delivery, with round gear wheels, giving 5 different lengths of cut, and with a chain that delivers the forage automatically to the knives; it weighs 175 kg; the other type is simpler, but without an automatic feed. The knives are also of Italian make.

556 — **Energy Required in Cultivation.** — RINGELMANN, MAX, in the *Journal d'Agriculture pratique*, Year LXXXII, Vol. XXXI, No. 4, pp. 66-69, 5 Charts + Tables. Paris, February 21, 1918.

While studying, in 1898, cultivation work in the very fertile soils belonging to the upland silt resting on the tertiary clay of the Coupvray farm, France, the author found that the preparation of the soil for beet after cereals required nearly 8 times more energy than is required in the same soils for winter wheat after beet.

The author calculates that the cultivation of 1 hectare requires, according to the period in the rotation from 7 to 55 million kilogrammetres, which have to be furnished by the farm teams during a time which is always limited (1).

Elsewhere, on tertiary soils where the method of cultivation is different, the author found just over 8 million kilogrammetres for the cultivation of 1 hectare to carry winter wheat after beet, and nearly 39 ½ million kilogrammeters for beets after cereals; the divergences from the figures obtained at Coupvray are mainly due to the machinery employed, as well as to the depth of the ploughing and scarifying.

Ploughing represents the greatest part of this total expenditure of energy the division of which among the different operations is shown in Table I.

TABLE I. — *Repartition of the Total Expenditure of Energy amongst the Various Operations.*

	Breaking-up stubble	Ploughing at 5 to 6 in.	Ploughing	Ploughing at 10 in.	Harrowing	Scarifying	Rolling	Total
	kg.	kg.		kg.	kg.	kg.	kg.	kg.
Preparation of a soil for winter wheat after beet . . . . .	—	680	—	—	130	—	—	810
<i>Idem</i> for beet after cereals	530	—	at 6 in. 830	1 500	460	460	160	3 940
<i>Idem</i> for spring oats. . . .	—	—	from 7 to 8 in. 1 100	—	200	250	80	1 630
Clearing off 3-year clover for a winter cereal . . .	—	—	1 300	—	230	—	80	1 610
Clearing off clover for a winter cereal . . . . .	—	—	1 400	—	240	—	80	1 720

These figures show the average traction in kg. per metre of width worked; to obtain the energy necessary per hectare in kilogrammetres, each average tractive effort must be multiplied by 10 000

(1) These figures would be greater for stronger soils. For the whole work, the energy should be added that is required for carting and spreading manure and fertilisers, sowing, cultivation, harvesting and carting.

For a winter cereal after potatoes the figures are very close to those for winter wheat after beet

Table I shows that ploughing represents, according to the case, 8, 72, 67, 80, and 81 % of the total energy required for the various preparatory operations for these soils. In this way is found the cost of ploughing in comparison with that of other operations. Starting from the fact ascertained on the farm under consideration, that in November a team of 3 good horses ploughed 3.4 ares at 7 to 8 in. deep in a day of 9 hours' actual work, the author deduces the approximate area cultivated per day for the different operations and the number of actual hours of work required for cultivating 1 hectare, as shown in Table II.

TABLE I. — *Area Worked per Day and Time Required per Acre*

	Area worked per day ares	Time required per hectare hours and tenths	
<i>Preparation of a soil for winter wheat after beets</i>			
Ploughing at 5 in	55	16.4	
Harrowing	288	3.1

<i>Total</i>		<b>41.1</b>	<b>41.1</b>

The data of Table II are in agreement with current practice.

557 — **The Agricultural Tractor: Some Factors Governing the Design of a Small Tractor** (1). — CHORLTON, A. E. I., in *Engineering*, Vol. CV, No. 2714, pp. 7-10, Fig. 12, Tables 2. London, January 1, 1918.

The problem of providing mechanical power in the most suitable and efficient form for the purposes of agriculture, is one of no inconsiderable difficulty, the guiding factors being such variables as the size of the farm, the class of land, the nature of crop, road transportation and the financial ones of first cost, annual charges, etc. Owing to lack of precise information the author has had to provide much of the essential data by actual experiments, the results of which are of great value for all those interested in the agricultural tractor.

After having discussed and compared the advantages and disadvantages of a special power implement for each purpose with those of a multi-purpose machine, the author concludes that the financial consideration of the problem brings out the advantages of a multi-purpose machine, but without necessarily excluding special machines. There will always be farms so large or special conditions of such a nature as to allow of the purchase of special machines. The 3 chief uses which, by their requirements, govern the design of the tractor are: — a) Road work, which governs the minimum axle loading; b) Land work, which governs the maximum axle loading; c) Farmstead, which governs the minimum power required.

**ROAD WORK.** — The basic factors are adhesion and resistance. The adhesion of the driving wheels on the road must be sufficient to utilise the power developed by the engine in overcoming the tractive resistance of the load and the tractor combined. There exists a considerable amount of data relating to tractive resistance, but for tractive adhesion on common roads, little can be found. For traction on rails recognised constants have been developed from abundant data. The standard figure of adhesion is 0.25, i. e., one-quarter of the load on the driving axles can be used in drawbar pull. After a detailed consideration of adhesion and resistance the author gives the results of his test in 2 diagrams, which will be of great use for tractor construction.

**WORK ON THE LAND.** — The pressure which worked land will bear without injurious effect on the crops, varies according to the nature of the soil. From the mechanical point of view the limit of pressure is set by the necessity to prevent sinking into the ground, an occurrence which is seldom due to excessive weight. What usually happens is that owing to inadequate gripping power the driving wheels rotate and act as milling cutters, scraping out the soil from underneath. The relative values of weight and spud area are very difficult to allocate so as to be able to make comparisons. For instance, a machine with a 30-cwt. axle loading and short spuds pulls partly by adhesion and partly by grip, the latter being rendered more effective by the weight of the wheel holding the ground down during this action. A lighter tractor with a 15-cwt. axle loading must pull very largely by grip alone and the effectiveness of the grip is modified and reduced by the lighter weight

(1) Paper read before the Institution of Automobile Engineers, London.

behind it, and the greater rolling resistance per ton set up by the spuds. The factors to be determined are, therefore, the proper relation of pressure on the land, the pressure against it, and the action of the rim projection, strake, spud or grouser. In most cases 3 conditions must be met: — *a*) driving axle loading; *b*) pressure against grips or spuds; *c*) effect of rolling resistance. On examining these conditions the author finds that, for light lands, the spud must be increased 4 times, as compared with heavier land. Many useful experiments could be carried out to determine the most efficient form of grip for varying conditions of soil and weight of tractor. On very soft land the wheeled tractor, either by reason of weight or spud pressure, is not suitable, and one of the caterpillar type becomes essential.

**WORK ON THE FARMSTEAD.** — The highest power required is for threshing, which according to the author's diagram, does not exceed 20 HP., though it is usual to allow 25 HP for large machines.

The appended table summarises the results of the author's experiments and shows the basic requirements for a multi-purpose tractor.

	Power required HP.	Driving axle loading Lb.
Road work . . . . .	18—20	4 400
Land work . . . . .	23—25	4 400
Farmstead . . . . .	20—25	Stationary

In considering the engine, the conditions should be taken into account under which it has to run on a farm, the inexpert attention likely to be given to it being an important factor. Generally, while this requires robust construction, it also calls for a low power rating or a considerable reserve of power, and probably the factors of low speed, large cylinder capacity for power required, strength and simplicity of parts are the main ones. The engine *must* operate on paraffin, and it should be able to develop its power without water injection. Such an engine running on paraffin would give an economy of 30 %. It should, however, be quite possible to secure better economies with the ordinary engine than are at present customary. It may be taken that the consumption per acre in practice is about 3 gallons. A 20-HP tractor has probably about 12  $\frac{1}{2}$  brake-HP. Taking 2 hours per acre, this gives 12 pints per hour, or 0.96 pint per brake horse-power. This result is not at all a bad one, and is probably much better than when the tractor is run by an ordinary farm hand in daily work. The consumption might well be reduced to 0.85 pint per brake horse-power, or with a high-compression engine to 0.6 pint or even less.

The author suggests that the horizontal type of engine is to be preferred. The high speed engine reduces the weight of the tractor, but in view of the necessity of giving a reasonably long life under conditions of farm usage, it is debatable if this is a wise policy. The system of cooling chosen — radiator or tank system — depends mostly on local conditions.

The writer deals with the following points: — Frame; Gearing; Steering (there is a general tendency to adopt the double-pivot system for

tractor work) ; Wheels (which tend to be reduced in diameter, probably with a view to reduce weight) ; Land Grips. The caterpillar arrangement, whilst entirely suitable for special conditions on the land, cannot be considered as advisable for road work.

**558 - Improvements of Agricultural Implements in India.** — HENDERSON, G. S., in the *Agricultural Research Institute Punjab, Bulletin* No. 73, pp. 6 + 8 Plates. Calcutta, 1917.

The author describes several implements introduced by him into India and which are mostly modifications of implements in common use in Egyptian Agriculture likely to be useful in irrigated districts. The following are worthy of note : —

The Egyptian plough, provided with hardened steel shares and ridging attachment.

The scraper, for levelling irrigated land.

The threshing machine ; consisting of 3 axles each bearing 6 or 7 iron discs. The axles turn on iron bearings and the whole rests in an angle iron frame. The machine is pulled by a pair of bullocks and will thresh as much as 5 or 6 pairs of bullocks would tread out. The discs are kept sharp by filing. In working the grain is put in a heap on the threshing floor and a thin layer spread out on the circumference of the heap. The machine is pulled round this and the straw kept perfectly turned. Fresh material is gradually placed on the beaten layer until it is all beaten.

The author also describes 2 Archimedian screw water-lifts, as well as a Dutch water wheel. This latter is now used in Egypt, and Dr. PARR, of the United Provinces, gave the machine a trial and reported favourably on it.

**559 - Implements Used for Cultivating Rice in India.** — GILBERT, T., and SALIMATH, S. S., in *Department of Agriculture, Bombay, Bulletin* No 82 of 1916 (Cultivation of Drilled Paddy in South Bombay Presidency), pp. 9 + Fig. 23. Poona, 1917.

This bulletin, which deals with the cultivation of drilled paddy, contains 23 figures drawn to scale of the various native implements used in the South Bombay Presidency.

There is an extraordinary variety of implements in use for the cultivation of drilled rice. They are designed : — 1) to break the soil after harvest ; 2) to level the surface and at the same time to break clods ; 3) to reduce the soil to a fine seed bed ; 4) to sow the seed ; 5) to intercultivate and remove weeds ; 6) to puddle the soil and at the same time to remove weeds.

The different implements, together with their native name are briefly described below : —

- 1) bullock plough ;
- 2) the " kodda " and " kodati " for clod crushing ;
- 3) the " halka " brings clods to the surface ;

(1) The threshers now used in Persia consist of a square wooden frame, carrying 2 wood axles bearing iron discs. The machine described by the author constitutes a notable improvement, and would be very suitable to Persian conditions which do not allow of the use of modern agricultural machinery. (Ed)

- 4) the "kunti" for harrowing;
  - 5) the "doni" for levelling the soil;
  - 6) the "rool", a roller fitted with spikes;
  - 7) a 6 tyred seed drill, sowing 36 to 72 lb. of seed;
  - 8) the "henta" as a brush-barrow, after sowing;
  - 9) the "hutgunti", a 6-tynd hoe drawn by a pair of bullocks;
- in some parts the 2-tynd "yedikunti" is used;
- 10) the "repani" similar to the "hutgunti", but with the cutting edges of its blades rounded;

11) after the fields are flooded, the "ghute" is used for cultivating, levelling the surface, and uprooting shallow rooted weeds;

12) the "baskooti" is a wooden hand rake for collecting the weeds.

The crop is cut with a sickle and laid in rows in the field; it is threshed and handled by means of various native tools and implements.

**560 - The "Acrometer".** — *The Implement and Machinery Review*, Vol. XLIII, No. 515, pp. 1187-1188, Figs. 2. London, March, 1, 1918.

An instrument invented and placed on the market by Mr. W. G. GEORGE, Tunnel Hill, Worcester, England, to measure the acreage covered by tractor ploughs. The "Acrometer" measures from one 9-in furrow up to 6 furrows either 9 in. or 10 in. wide, and can be fitted to any plough in 10 minutes; whilst it will also register the work of other implements, such as mowers, binders, etc., up to 6 ft. wide or over.

The instrument will be very useful for measuring areas in tractor-ploughing tests. It costs £5.

**561 - Double Disc-Harrows for Mechanical Cultivation.** — MANRIN, G., in the *Journal d'Agriculture pratique*, Year LXXXII, Vol. XXXI, No. 3, pp. 50-51, 2 Figs. Paris, February 7, 1918.

Tractors can pass over ploughed land quite safely if they do not exceed a certain weight and if they are followed by a disc-harrow. The double disc-harrow gives excellent results; in the 1917 Noisy le-Grand (France) tests, with a double machine with 32 discs, working a width of 103 in. and a depth of about 3 to 4 in., M. RINGELMANN found that traction on already-hardened ploughed-land varied between 1034 and 1188 lb.; at 3 in. depth the work was well done, while at 4 in. the work was excellent.

The author describes. 1) a double disc-harrow, with 16 in. discs, built by T. PILTER of Paris; the machine is built in 2 models; one with 32 discs; weight, 1 078 lb.; width, 95 in.; the other with 40 discs; weight, 1 254 lb. and 118 in. wide.

2) a double disc harrow, made by the same maker, provided with toothed discs; the 32-disc model weighs 1 276 lb., and covers 95 in.; the 40-disc model weighs 1 342 lb. and covers 118 in. The discs of these 2 models are 18 in. wide.

The machines have steel frames; there are 4 levers, one per row of discs, so as to control the angle as well as the depth and character of the cultivation. In very hard soils, suitable weights can be placed on the frame to give greater grip.

562 — **Harrows with Rotary Spades.** — MANRIN G., in the *Journal d'Agriculture pratique*, Year LXXXII, Vol. XXXI, No. 5, pp. 92-93. Figs. 2. Paris, March 7, 1918.

To break down the soil still further, harrows are used, whose toothed discs are replaced by members similar to stamped spades, called "herse à bèches roulantes, système WASSIS" in Switzerland, where they are much used.

As shown by the appended figure, the spade consists of a pressed steel plate fixed symmetrically on the axle; the successive spades are so mounted that their extremities follow 2 spirals. As with the discs of double disc-harrows, the spades are fixed on 4 shafts inclined towards the line of traction; the inclination of these shafts cannot be altered during the work; the shafts run on bearings fitted with STAUFFER lubricators using thick grease. The spades are scraped by iron rods fixed between 2 consecutive members. A platform is provided on the frame so that weights can be added if the driver's weight does not suffice.

For transport, the seat is removed, and the machine tipped over, when it slides on 2 flat runners.

In another model, the harrow is mounted on a tricycle. By means of a lever the spade-frame can be lifted on the 3 wheels for transport on the road.

These harrows are made by the Société FRITZ MARTI, of Berne, Switzerland. The small model has 28 spades mounted in groups of 7 on each

The WASSIS harrow with rotary spades.

shaft; it works a width of 43 in., and weighs about 400 lb. The large model weighs 462 lb., and has 36 spades mounted in groups of 9; it works a width of 55 in.

In medium soils, a team of 2 horses suffices to draw the small model, while the large one requires 4. The machine can produce a tilth some 3 or 4 in. deep under good conditions.

563 — The “Bucheronne”, a Machine for Felling and Sawing Coppice-Wood. — MATHIS DE GRANDSEILLE, in the supplement to the *Bulletin de la Société des Agriculteurs de France* (Comptes Rendus de l'Assemblée Générale de 1917, 48th Meeting), pp. 51-52. Paris, January, 1918.

M. MATHIS DE GRANDSEILLE, President of the 4th Section (Forestry) of the “Société des Agriculteurs de France”, reports the results obtained by M. PROCHE's machine — the “Bucheronne” — for felling and sawing timber (1), reproduced in the appended figure.

• The “Bucheronne”, for felling and sawing coppice-wood.

(1) On the request of M. MATHIS DE GRANDSEILLE, president of the Forestry Section of the “Société des Agriculteurs de France”, M. PROCHE, the inventor, has communicated the following additional information: —

The “Bucheronne” weighs about 550 lb. with its 3 H.P. electric motor; its speed can be varied and it has a special circular knife-blade whose rounded, bevelled knives are followed by a plane-tooth to clear the cut. The knife blade works in every direction and may be used quite close to the soil. To drive the machine, a 5 H.P. electrogenerating set is needed, furnishing a 220 volt current for the motor of the machine. The generator may be as much as 1600 ft. away.

The machine was tested in Crains forest, Yonne, France, in the presence of several officers of the Forest Inspection Department, the Central War Material Department of Angoulême, the Air Ministry, Woods and Forests, and Patents Office (Engineering section). According to their report, the soil should first be cleared of all shoots of less than 2 ½ in. in diameter. In woods over 30 years old, this is usually unnecessary; for good and continuous working there is needed: 1 driver for the machine, 1 sawyer for the knife-blade, 1 workman to guide the felled tree the right way, and 2 assistants to trim the felled trees and place them in heaps ready for sawing; total: — 5 men. For sawing, the same number of men is needed at the machine. The yield is very satisfactory, especially when compared with that of previous experiments. With the "Bucheronne" 5 men felled 120 trees of 2.7 in. diameter in 1 hour, and the crew of 5 men felled and sawed in 1 day, 741.63 cu. ft. of wood, while the same crew, working with axes, only felled and trimmed 1059.5 cu. ft. in 4 days. With the machine each workman will produce 141.26 cu. ft. per day, while without it he will only produce 35.31 cu. ft. If the coppice is older, the yield will be better. The machine, which is strongly built did very well throughout the trial. The inventor should improve the machine by furnishing greater grip on the soil and by providing a hood so that the knife blade can be inspected during working. It is hoped that the ASTER Co., which has the patent rights over the machine, will improve it.

564 — **The Austin Excavator for Drainage Ditching.** — See No. 506 of this *Review*.

565 — **The Use of Hydrogen for Driving Engines: Tests in Holland.** — Extract from the *Bulletin des Usines de Guerre*, in *Le Génie Civil*, Vol. LXXII, No. 13, p. 224. Paris, March 30, 1918.

Experiments carried out at the Hague with a motor car driven by hydrogen have shown that: —

- 1) a car engine will work quite regularly and perfectly on a mixture of pure hydrogen and air.
- 2) the engine does not require adaption.
- 3) the engine can work smoothly even with a very primitive type of carburettor.
- 4) the experiments that preceded the practical tests did not require a great outlay; a few tubes of hydrogen and the necessary mounting was all that was required.

These tests were carried out as a result of the shortage of petrol for public automobiles in Holland. A 1906 type "Spyker" 10-15 HP motor-taxi was used, which still ran well on petrol and which could still do over 30 miles an hour.

Below the body was placed a tube of hydrogen, 59 in long and provided with a manometer and a pressure-reducing valve. The hydrogen passed under 1 atmosphere pressure in a metallic tube leading to the carburettor. A tap, placed on the gas tube and connected to a pedal, controlled the supply of hydrogen. The air supply was not very well regulated, being done by hand, before starting.

After regulating the entry valves, in spite of the primitive form of the

carburettor, the engine worked quite smoothly and evenly without missing. The number of revolutions was found to be less with hydrogen than with petrol. By igniting at 8 mm. distance from the dead-centre, the maximum number of revolutions was obtained. No traces of naphthaline were found in the exhaust gas, which was found to be pure steam. The engine therefore worked perfectly on hydrogen and air, and that in spite of the casual methods used for adapting the carburettor.

The car started off on the first speed, changing to the second, and after running 15 minutes on the road, returned normally, the engine working perfectly all the time.

The tests and the trial run, which took 30 minutes in all, had required 1 ½ cu. metres of gas, while the pressure had fallen from 160 to 100 atmospheres.

## AGRICULTURAL INDUSTRIES.

567 — **The Passage of Wine over Fresh Lees.** — CARLES, P., in *Bulletin de l'Association des Chimistes de Sucrerie et de Distillerie*, Vol. XXXIV, Nos. 10-12, pp. 334-339. Paris, April-May-June, 1917.

INDUSTRIES  
DEPENDENT  
ON PLANT  
PRODUCTS

When new wine has been allowed to run freely much more wine than dry residue is left in the lees. The wine is retained in this sort of sponge by simple adhesion caused by the large surface, by capillarity, and, finally, because it is held in small cells (as water in starch jelly).

From 100 kg. of lees which have been drained only about 45 kg. of wine may be obtained by pressing. A certain part will, however, resist all pressure; this is the part in the finest capillary tubes, the smallest cells. To remove it the liquid must be mixed with another liquid, which will eject it by capillary force. It is on this principle that is based ROOS's diffusion method, which enables 70 % of wine, as pure as that originally drawn off, to be obtained from drained lees, whereas pressing only yields  $\frac{2}{3}$  of this amount.

If these 70 kg. are removed from the 100 kg. of drained lees, 30 kg. of solids are left in which are found closely mixed: — 1) bi-tartrate of potassium (cream of tartar); 2) tannin; 3) colouring substances; 4) pectic products; 5) substances imparting smell; 6) yeasts; 7) abundant ferric salts combined with 8) various mineral salts.

If, when a proportion of the wine represented by 100 kg. of lees has been drawn off, the new wine in the cask is replaced by an equal volume of old wine, and the contents again drawn off, the liquid obtained is equal in volume to the first, but its quality and composition vary according to the length of time it remained on the lees. If it has only passed over the lees without being left on them, the new element will be that part of the wine

which came in contact with each individual portion of the mass. It will be represented by the 45 kg. of new wine which pressing would easily have extracted, so that the second drawing off will be a mixture of the 45 kg. of new wine + the old wine; the last 45 kg. of old wine will have driven out the other and taken its place.

If contact with the lees is prolonged the influence of the new wine will be felt more because that contained in the capillary tubes will have had time to be replaced. The wine from the cask will contain all the new wine retained in the lees and old wine which for some time has been in contact with their reserve elements. As this reserve is large and usually greater than that which can be dissolved by a normal wine, all badly composed wine poured on this mass will tend to improve, by absorbing that in which it is lacking. Thus a sour wine which disease has rendered deficient in tartaric acid will take up this element in particular, a flat wine will take up flavour, a poor, exhausted wine will take up a provision of tartar.

If, for example, in a series of three casks, one, for some reason or other, has yielded a poor wine, it will be advisable to pass it over the lees of the two others successively, the weaker being used last.

In spite of all the care possible, wines sometimes have a bad flavour, detrimental to their use (flavour of mould, addled eggs, bitterness, fustiness, sourness, etc.). Such wines may often easily be improved merely by passing them over fresh lees, because they are aerated without exposure, and, moreover, in their immediate contact with the yeast they give up the flavours and smells of the disease.

So as to avoid after-taste all the head must be removed from the cask before the operation, because this is always more or less sour and contains the organism known as mother of vinegar.

When a defective wine is so treated, one of the defective elements remains in the lees, and the pressed wine and small wine finally obtained are of a quality inferior to that obtained by ordinary methods. Wines attacked by "casse" cannot benefit by the treatment described unless they have been previously completely cured of the disease.

**568 — The Alcoholic Fermentation of Banana Must** (1). — PERATTI, R., and RIVIERA, V., in *Le Stazioni sperimentali agrarie italiane*, Vol. I., Pt. 9-10, pp. 433-450, 1 Plate, with 9 Figs. Modena, 1917.

The various products of the *Musa sapientum* banana are first enumerated.

Little work has been done on the banana from a microbiological point of view. An important study by Mr. BAILEY (2) shows that the internal part of the pulp is sterile, but that bacteria are present in the internal part of the skin; during the normal ripening process these bacteria may find there favourable conditions of development. Messrs. ROTHENBACH and EBER-

(1) See also *B. Nov.*, 1914, No. 1054. (Ed.)

(2) BAILEY, E. M., Biochemical and Bacteriological Studies on the Banana, *Jour. Amer. Chem. Soc.*, Vol. 34, No. 12, pp. 1700-1730, 1912; *Jour. Biol. Chem.*, Vol. II, No. 2, 1912. (Author).

LEIN (1) show that the formation of the ethers of the banana (isovalerianic isoamylic ether and ethylic ether) does not depend on bacterial action. As regards the utilisation of the banana for fermentation, there is only the paper of M. D'HERELLE (2), who discusses the possibility of using the residue from the preparation of dried bananas and their flour for making fermented drinks. The authors, therefore, considered that a bacteriological study of the banana and the fermentations to which it may be subjected, would be of interest.

The fermented liquid obtained with a must of skinned bananas distinctly showed the characters of alcoholic liquids, but had lost the delicate flavour of the fruit. As this was attributable to the absence of the banana skin the experiment was recommenced, leaving the pulp in the skin.

The must was prepared as follows: the whole fruit was cut into thin slices and passed through a press; the liquid obtained was filtered through linen and diluted with water in the ratio of 1 : 2.5 parts. The residue was digested for 10 hours at 80°C. in  $2\frac{1}{2}$  times its weight of water, and the filtered liquid mixed with the first, so that the final liquid was diluted to  $\frac{1}{5}$ . This must, of a fine dark yellow, was filtered through paper and kept in sterilised flasks.

Part of the must was used for the preparation of a special nutritive gelatine, by the addition of 10 % of commercial gelatine, and for the preparation of a special agar, by the addition of 1.5 % of agar. Another part, removed before sterilisation, was fermented at 28° C. The fermentation started rapidly and was strong; acidification started after 48 hours.

The following bacteria were isolated and grown on the banana gelatine and agar: —

1) a *Saccharomyces*, predominant in the liquid, which the authors called *Sacch. Musae*; 2) a bacterial form, abundant in the liquid (*Bacillus* sp. ?); 3) a variety of *Oospora lactis*; 4) a variety of *Mycoderma*.

The authors describe the first three microorganisms and give in details the results of the study of their nutrition, their growth in various culture media, and their action when isolated, combined in groups of two, or all three together. From this last point of view it was noticed that the action of the *Saccharomyces* is inhibited by the presence of the bacterium, and also, though much less, by the presence of the *Oospora*. The following results were obtained with the banana must: —

Microorganism	Specific gravity at 15° C.	Alcohol per 100 in volume
<i>Saccharomyces Musae</i> . . . . .	0.9978	1.48
<i>Bacillus</i> sp. . . . .	1.0000	—
<i>Oospora lactis</i> var. . . . .	1.0000	—
<i>Sacch.</i> + <i>Bacillus</i> . . . . .	0.9992	0.53
<i>Sacch.</i> + <i>Oospora</i> . . . . .	0.9980	1.34
<i>Oospora</i> + <i>Bacillus</i> . . . . .	1.0000	—
<i>Sacch.</i> + <i>Oospora</i> + <i>Bacillus</i> . . . . .	0.9990	0.67

(1) ROTHIMBERG, F. and EBERLEIN, I., The Occurrence of Esters in Bananas, ref. in *Exp. Stat. Recd.*, Vol. XVII; *Deut. Essigindustrie*, No. 9, pp. 81-82, 1905. (Author).

(2) D'HERELLE, F. H., Utilization of the Surplus Banana Crop, *Bull. Offic. Soc. Agr.*, Vol. 3, No. 3, pp. 241-243, Cuba, 1907. (Author).

In view of the unfavourable influence of the bacillus and *Oospora* the experiments were henceforth only carried out with *Sacch. Musae*. Banana must was prepared with 5.5 lbs. of finely cut fruit and skin digested with twice their weight of water at 55° C, for 2 hours on 3 consecutive days. The liquid was sown with the *Saccharomyces*, after a sample had been taken for an analysis which gave the following results : —

polarisation	before inversion	2.40 %
»	after	2.30 »
Fehling	before	6 »
»	after	61 »

thus showing the absence of saccharose and the presence of glucose and invert sugar, which, calculated as invert sugar, are present in the proportion of 68.66 ‰.

Fermentation was set up in 4 litres of must in a large glass bottle. The determination of the alcohol, made when the strong fermentation had ceased (after 10 days), gave a specific gravity at 15° C. of 0.9979 and 1.41 % of alcohol in volume;  $\frac{1}{8}$  of the sugar had, thus, already changed to alcohol.

Part of the fermented liquid was rapidly filtered through cottonwool, without pressing the solid portion, and the filtrate poured into a bottle which was hermetically closed.

The bottle was opened after about two years, and the contents found to have kept well. The liquid had the pleasant smell of the fruit, was very clear and straw coloured. The taste, however, did not fulfill the promise of the smell. This was due to the dilution of the must, which made the wine rather flavourless and its alcohol content low, while the amount of sugar present was insufficient to compensate for these faults. It is, however, impossible to avoid such a dilution because of the excessive thickness of the undiluted must and its high content in mucilaginous substances. It is practically impossible to prepare an alcoholic drink by the fermentation of natural banana must; it is necessary to add sugar, and, perhaps, to purify the must when the strong fermentation phase is passed. Under these conditions it is possible to obtain successfully from the banana a fermented liquid of good colour, slightly alcoholic and of attractive qualities, amongst which the agreeable smell of the fruit holds first place. The authors intend to carry out further experiments on the subject.

569 — **The Production of Alcohol from Algae.** — KAYSER, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 14, pp. 450-451. Paris, April 17, 1918.

For some time marine algae have been used as a food for man on account of their richness in carbohydrates. Quite recently they have also been used as a substitute for oats in the feeding of horses (1). In bacteriology agar-agar (gelatine) is used as a basis for nutritive media. In this case the gelatine media and the acid solutions must be sterilised separately and mixed after sterilisation so as to prevent the gelatine from changing into sugar.

The author (Lecturer at the National Agricultural Institute) has made

(1) See R. March, 1918, No. 320. (*Ed.*)

an investigation into the amount of fermenting sugars which might be obtained under pressure and by the action of acids.

At the Pasteur Institute the water content of *Laminaria digitata*, previously washed to extract the mineral salts, or unwashed, was reduced by evaporation to 10 %. The algae were then treated with water containing 3, 4, and even 6 % of sulphuric acid for half an hour or an hour at 122° C. The sugary liquid was neutralised to 1 % of acidity, nitrogenous material added in some cases, and sprinkled with brewers' yeast. Fermentation occurred without difficulty, but somewhat better in the flasks containing nitrogenous matter. An average of 6 litres of alcohol per 100 lb. of dry algae was obtained.

It is probable that larger quantities could be obtained commercially, when higher pressure is possible. The author is of opinion that the solid liquid residue could subsequently be used for the extraction of mineral matter and potash, thus serving a double purpose.

570 — **Sorghum or Dari, a New Substitute for Malt Used in Brewing.** — RAUX, J., in *Brasserie et Malterie*, Year VII, No. 24, pp. 372-375. Lyons, March 5, 1918.

For several months brewers have been offered as a new substitute for malt, sorghum or dari, also called "dura" and "Guinea millet". Owing to the high price of rice and maize, used as substitutes in brewing, and their present use, particularly for bread-making, it was suggested that sorghum, which is cheaper, might be used in their stead. It is offered either as a meal or as whole grains; sometimes the grain is not decorticated and the yield in extract is then low (about 10 %).

The moisture content is from 12 to 15 %. If too damp the sorghum quickly goes bad turning sour and takes on an abnormal odour.

The yield in extract — 64 to 70 % — is much below that given by maize, and especially by rice. In maize it depends on the extent of cleaning. Sorghum is delivered at the brewery without any special treatment, but it would be easy to treat it in such a way as to remove part of the fats, which amount to 3 to 5 %, *i. e.*, little less than those contained in crude maize. In sorghum, as in maize these substances hinder the solution of the starch, thus accounting for a yield in extract below that which might be expected from the proportion of starch it contains (62 to 66 %).

Sorghum fat also has the disadvantage of going rancid fairly quickly. Care must, therefore, be taken to store the grain in good condition and to use nothing with any rancid smell, as this might be transmitted to the beer.

Most of the samples contain a fairly large amount of total protein; this would account for the rapid spoiling of over-damp grain. Most of this protein, however, is insoluble and, as in all crude grain, does not pass into the must and can have no influence on the keeping quality of the beer.

Sorghum is used in the same way as maize and rice, *i. e.*, it is added during the first mashing or to the copper. It may be advantageously used in brewing. The only difficulty is that of filtering, which is attributed to the use of excessively fine meal, which must not exceed a certain degree of fineness. From the point of view of filtering, treatment during boiling is advantageous as it allows all the starch to be dissolved by dividing the cellulose of the grain into the smallest possible particles.

571 - **Microscopical Studies on Tomato Products** (1). — HOWARD, BURTON J., in collaboration with STEPHENSON, CHARLES H., in *United States Department of Agriculture Bulletin* No. 581, pp. 24, 5 Fig., 12 Tables. Washington, October 6, 1917

During the past few years the Bureau of Chemistry has conducted a very comprehensive investigation to establish a basis for judging tomato products. Experiments were conducted in the bureau laboratory and also in factories, a large number of which were visited. Out of the mass of data thus collected, it was felt that the scientific facts underlying the relationship between microorganisms and the rot and decay of tomato products should be of value to manufacturers and food control officials at the present time. The results bearing upon the relation of the physical condition of the stock from which tomato products are made to the number of microorganisms present in tomato products are therefore given in this bulletin.

A great many tests at factories were made by noting the general condition of the stock and then examining microscopically samples of the finished products. The criteria published in 1911 in the Bureau of Chemistry Circular 68, for the guidance of manufacturers, were reached largely by such experiments.

Tomato products promptly made from stock judged acceptable by visual inspection never showed high counts of microorganisms. Similarly, products made from stock obviously not good or from stock improperly handled usually showed high counts. It may therefore be assumed that high counts of organisms in such products indicate unmistakably that the stock used was in bad condition or was handled in an insanitary manner during manufacture.

It was found that tomato pulp stored in barrels usually gave high microscopical counts; hence it would seem inadvisable to use barrels for storing the product.

Field work performed during the past three seasons has proved that with proper equipment and factory management there is no reason for stock ready for the cyclone to contain over 1 per cent of decayed material.

In factories where the stock is properly handled the mould count is of greater importance than the counts of the other organisms in judging the condition of the raw stock. High counts of yeasts and spores, and bacteria are more frequently an indication of secondary than of primary spoilage. A low mould, yeast and spore or bacterial count does not necessarily indicate sound stock, but a high count in any of these organisms always indicates bad stock or improper handling.

It was found that, of the samples made in the laboratory, none with less than 5.5 per cent of rot gave a mould count of more than 50 per cent of microscopical fields. In the case of the factory samples the mould count rose sharply from 0 to  $\frac{1}{2}$  per cent of rot. Beyond  $\frac{1}{2}$  per cent the rate of rise gradually decreases, until after 20 per cent of rot the rate of increase is slow. A mould count of 40 may be obtained in samples having any amount of rot between 2.2 and 100 per cent.

(1) See also R., September 1917, No. 856. (Fdl)

A yeast and spore count of 20 per  $\frac{1}{80}$  cm. represents about 1 per cent of decay. From this point the rate of increase is slow.

A bacterial count below 15 000 000 per cc. indicates little as to the amount of decay. Beyond this point, however, up to 20 per cent of rot the rate of increase is about 20 000 000 for each per cent. of rot.

An investigation of the manufacture of tomato sauces and pastes in Italy showed that Italian products should be equal to American products made under similar conditions. The mould count for the concentrated products was found to be about the same as that for pulp, and the yeast spore and bacterial counts to be proportional to the degree of concentration. Sauces and pastes made from objectionable material run particularly high in yeasts, spores and bacteria. High counts on this class of products, then, indicate bad stock or insanitary handling.

572 - **The Importance of Bacterial Action in Indigo Manufacture.** — HUTCHINSON, C. M. (Imperial Agricultural Bacteriologist, Pusa), pp. 11. Calcutta 1917.

As the result of investigations carried out in the Imperial Laboratory during 1916 in conjunction with the Indigo Research Chemist, it has become apparent that the yield of indigo from a given weight of indigo plant depends upon the intervention of bacteria during the steeping process. The account of the work done on this subject is intended to give some idea of the manner in which this fact has been ascertained, the extent to which it is probable that bacterial action affects yield, and the possible ways of making use of this new piece of information so as to successfully modify existing factory practice. It is remarkable that so far as published records are concerned, no previous work on these lines has apparently been done in India, as the obviously bacterial nature of the fermentation process going on in the steeping vat would naturally suggest investigation into the action of such bacteria upon the plant and upon the important part of it which goes into solution in the water.

The chief conclusions reached in the present study are as follows:—

- 1) The yield of indigo depends largely upon bacterial action.
- 2) Some kinds of bacteria operate beneficially, others detrimentally. In the absence of the former class in sufficient numbers there will be a reduction in yield.
- 3) It should be possible to ensure the presence of the beneficial kinds by artificial inoculation.
- 4) It is necessary to bring the bacteria normally present on the walls of the steeping vat into closer contact with the indigo plant in the vat, by altering the shape of the latter so as to reduce the ratio of cubic content to wall area.
- 5) It will probably be found beneficial to modify the character of the wall surface so as to promote more extensive and permanent growth of the beneficial bacteria.

573 - **The Use of *Imperata cylindrica* in Paper Making; Experiments in Italy.** — VIGNOLO-LUTATI, FERDINANDO, in *Annali della R. Accademia d'Agricoltura di Torino*, Vol. LVIII, 1915, pp. 68-76. Turin, 1916.

Since 1913 (*L'Industria chimica*, Nos. 2 and 13, Turin, 1913), the author, attached to the Chemical Laboratory of Commercial Products at the

Royal Institute of Commerce of Turin, has carried out laboratory experiments and industrial investigations into the utilisation of *Imperata cylindrica* as raw material in paper-making. In his laboratory experiments he treated the leaves by the soda method; in the industrial experiments the calcium bisulphite method was used. The results obtained in the laboratory experiments led to the conclusion that:— 1) under normal pressure the cellulose (which is easily bleached by the ordinary methods) may be extracted from *I. cylindrica* without difficulty in quantities amounting to 40 % of air-dried raw material; 2) the fibre of *Imperata*, *Stipa* and *Lygeum* are very similar. From the results obtained in the industrial investigations it may be concluded that:— 1) the cellulose of *I. cylindrica* is very similar to that of esparto grass; 2) the yield of bleached cellulose may amount to 38 %; 3) no greater consumption of chemicals is required to reduce to paper pulp the cellulose of *Imperata* than to reduce that of esparto.

In the industrial experiments the soda method was tested with the following results:—

The best conditions for obtaining an easily bleached pulp are realised by using the autoclave under a pressure of from 2 to 3 atmospheres and caustic soda in quantities not less than 10 % of the air-dried raw material. An excess of soda facilitates bleaching but reduces the pulp yield. The yield is higher with low pressure (1 to 2 atmospheres) and prolonged boiling than with greater pressure and shorter boiling. The crude fibre obtained with 10 to 15 % caustic soda contains a high proportion of slimy substances which are largely removed by prolonged washing. By the use of 10.6 % of soda and 6 hours' boiling under a pressure of 3 atmospheres, 37 % of crude fibre is obtained. If this is treated with 15 % calcium chloride (containing 33 % free chlorine), a satisfactory white fibre is obtained. If a larger quantity (15.9 %) of caustic soda is used under the same conditions of boiling and pressure, the yield is slightly less, and, when treated with 12.4 % of calcium chloride, a perfectly white fibre is obtained. The yield of bleached fibre is thereby raised to about 35 %, but if normal pressure is used the yield is from 39 to 40 %.

The stems (70-80 cm. long, 3-4 mm. in diameter at the lower internodes and about 2 mm. at the upper internodes; water content about 11 % when air-dried), stripped of their nodes, chopped and crushed, then treated by the methods used for the leaves, give about 45 % of bleached cellulose.

According to HACHEL there are 3 varieties of *I. cylindrica*:—

- 1) a) var. *genuina* sub-var. *europaea*, growing on the sandy shores of rivers and the sea throughout the Mediterranean district, and even as far as the Sahara and Caspian Sea;
- b) var. *genuina* sub-var. *Thunbergii*, of central and southern Africa;
- 2) var. *condensata*, of Chili;
- 3) var. *Koenigii*, of East Africa and southern and eastern Asia.

In his experiments the author used *I. cylindrica* var. *genuina* sub-var. *europaea*. In certain districts varieties of *Imperata* have been of great service in fixing moving sands and in fighting the desert. For this reason when these plants are to be used in such districts for paper-pulp they should be cut and not uprooted, so as not to injure growth.

In Italy *I. cylindrica* grows mostly on the southern Tyrrhenian coast, on the Ionian coast, and in the islands. In Calabria it is often found as a weed, infesting the olive-orchards in particular. In this last case harvesting and using it would not only improve olive growing, but would also form a source of income.

574 - Dairy Inspection in the United States. — BAILEY W. H., in the *Journal of the American Veterinary Medical Association*, [Vol. LII, No. 6, pp. 686-692. Ithaca, N. Y., February, 1918.

In this address delivered at the 54th Annual Meeting of the American Veterinary Medical Association, the following points were discussed: 1) Healthy Cattle; 2) The Importance of Clean Milking Methods, Cooling, Transportation and Distribution Methods; 3) Pasteurization.

The following points were emphasized concerning the value of close correlation of dairy and milk inspection: —

a) Milk produced under filthy conditions may possess a low bacterial count if it is instantly and constantly cooled to 50° F. or below.

b) Milk produced under sanitary conditions may possess a high bacterial count at the time of distribution, if it has not been cooled and maintained at proper temperature.

c) A high scoring dairy may, at times, produce a badly contaminated milk, while a dairy scoring very low may produce clean milk.

d) Thus careful inspection of gross conditions and the rating of their value in terms of per cent. on the government score card, together with milk inspection, particularly bacterial analysis, will enable any health department to judge its milk supply correctly.

The establishment of a government milk hygiene service for the control and regulation of milk production throughout the United States is advocated.

575 - The Daily per Capita Consumption of Milk in the United States (Connecticut). — JUDKINS, H. F., *Journal of Dairy Science*, Vol. I, No. 3, pp. 246-249. Baltimore, September, 1917.

While it is difficult to compile any accurate figures on the daily per capita consumption of milk, it is generally conceded that the average for the United States is about 0.6 of a pint. This is a little more than a glass a day. That this is too small an amount is beyond question considering that from the standpoint of protein, which is especially needed by the growing child, or from the standpoint of total energy as utilized by the adult, much more food value is obtainable from milk for a given sum of money than can be purchased in any comparable food.

The following table recently prepared by the United States Department of Agriculture illustrates this point: —

Protein.	Energy.
1 quart of milk is equal to:	1 quart of milk is equal to:
7 ounces of sirloin steak	11 ounces of sirloin steak
6 ounces of round steak	12 ounces of round steak
4.3 eggs	8 ½ eggs
8.5 ounces of fowl	10.7 ounces of fowl.

INDUSTRIES  
DEPENDING  
ON ANIMAL  
PRODUCTS

Were it not for the infant the per capita consumption would be much less than it is. According to Vermont Bulletin 195 one sixth of the milk produced by 22 000 000 cows is used as a food for infants and young children. It has been figured that an infant consumes 530 quarts of milk during the first year of its life.

In order to study the per capita consumption of milk first hand data were tabulated from families living in Storrs to whom the Connecticut Agricultural College retails daily about 90 quarts and hence accurate records were available.

The families were divided into three groups : —

#### GROUP I.

*Families with one or more children under three years.*

	Number of days	Number of pints	Average daily consumption	Number in family	Average per capita (pints)
Total . . . . .	1 019	5 679	55.46	39	—
Average . . . . .	101.9	567.9	5.546	3.9	1.42

#### GROUP II.

*Families with children three to twelve years.*

Total . . . . .	586	1 780	18.02	24	—
Average . . . . .	97.6	296.6	3.003	4	0.75

#### GROUP III.

*Families with no children.*

Total . . . . .	873	1 517	19.72	2.3	—
Average . . . . .	76.09	135.1	1.79	2.0	0.895
Average per 27 families . . . . .	—	—	3.45	3.22	1.07

The per capita consumption of milk on 17 farms where it was produced resulted in 1.30 pints daily with considerable variation in different families.

576 - **Chemical Changes in the Souring of Milk.** — VAN SLYKE, LUCIUS L. and BOSWORTH, ALFRED W. (Chemical Laboratory of the New York Agricultural Experiment Station, Geneva), in *The Journal of Biological Chemistry*, Vol. XXIV, No. 3. pp. 191-202. Baltimore, Md., 1916.

Fresh milk was analyzed for its soluble and insoluble constituents, a porous porcelain filter being used to make separation. Another portion of the same milk was inoculated with a culture containing *Bacterium lactis acidii* and *Bacterium lactis aerogenes*. At the end of 60 hours determinations were made of the soluble and insoluble portions. About 22 per cent of the milk-sugar was changed by the lactic acid bacteria, 88.5 per cent of the amount changed being converted into lactic acid. Citric acid completely disappeared.

The insoluble inorganic constituents of the fresh milk were made soluble by the lactic acid. Albumin of sour milk passed through the

porcelain filter completely. Calcium caseinate was changed into free protein and precipitated, the calcium forming lactate.

To study the rate and extent of chemical change under given conditions, fresh, pasteurized, separated skim-milk was inoculated with a pure culture of *Bacterium lactis acidii* and kept at 32.2° C. Samples were taken for analysis at intervals during 96 hours. Most of the change in milk-sugar occurred between the 10th and 24th hours. When the milk contained 0.7 per cent of lactic acid, the bacterial activity was much reduced. The acidity increased most rapidly during the first 24 hours, the rate of increase diminishing after that. The increased acidity of the serum was due to increase of lactic acid. In the insoluble portion of the milk the free casein is the acid constituent. Calcium combined as  $\text{CaHPO}_4$  goes into solution completely in 13  $\frac{1}{2}$  hours. Calcium combined as caseinate was acted upon more slowly, complete solution requiring about 24 hours. The amount of albumin nitrogen in the serum increased with increase of acidity; all the albumin of the milk appears in the serum in 14 hours.

577 - Studies on Goat's Milk. — I. The Casein of Goat's Milk: II. The Soluble and Insoluble Compounds of Goat's Milk. — BOSWORTH, ALFRED W. and VAN SLYKE, LUCIUS L., in *The Journal of Biological Chemistry*, Vol. XX, 3, pp. 173-175; 177-185. Baltimore, Md., 1916.

I. — On the basis of the analytical results obtained in the study of the compounds formed by casein of goat's milk with bases, taken together with the amount of phosphorus and sulphur found in such casein, the molecular weight is 8 888 and the valency of the protein molecule in basic caseinates is 8.

II. — Goat's milk contains two general classes of compounds, those in true solution and those in suspension or colloidal solution. These two portions can be separated for study by filtering milk through a porous earthenware filter like the PASTEUR-CHAMBERLAND filtering tube.

Serum prepared from fresh milk of goats is nearly transparent, with a faint greenish-yellow tinge and slight opalescence. The following constituents are in true solution: sugar, potassium, sodium, chlorine. The following are partly in solution and partly in suspension or colloidal solution: albumin, inorganic phosphates, calcium, magnesium, citrates. The following are entirely in suspension or colloidal solution: fat, casein.

The insoluble portion of milk, freshly prepared and moist, is grayish to greenish-white in colour, of a glistening appearance, and of gelatinous consistency. When shaken with water, it goes into suspension, forming a mixture having the opaque, white appearance of milk. Such a suspension is neutral to phenolphthalein. When purified, the insoluble portion consists of neutral calcium caseinate ( $\text{Casein Ca}_4$ ), di- and tri-calcium and magnesium phosphates.

The insoluble portion, suspended in water and treated with neutral potassium oxalate, reacts alkaline to phenolphthalein, indicating the presence of tri-calcium phosphate. This is shown also by a quantitative comparison of the amount of bases and acids.

The acidity of the serum is considerably greater than that shown by the milk after treatment with neutral calcium oxalate. This is accounted for by the presence of di-calcium phosphate.

The following arrangement is tentatively suggested as representing the forms in which the constituents of goat's milk may be present : —

	per cent
Fat . . . . .	3.80
Proteins, combined with calcium . . . . .	3.10
Milk sugar . . . . .	4.50
Salts : . . . . .	0.94
Di-calcium phosphate . . . . .	0.092 per cent.
Tri-calcium phosphate . . . . .	0.062
Di-magnesium phosphate . . . . .	0.068
Tri-magnesium phosphate . . . . .	0.024
Mono-potassium phosphate . . . . .	0.073
Potassium citrate . . . . .	0.250
Potassium chloride . . . . .	0.160
Calcium chloride . . . . .	0.115
Sodium chloride . . . . .	0.095
Total solids . . . . .	12.34

#### 578 — A Comparison of the Composition of Cow's Milk, Goat's Milk, and Human Milk.

— BOSWORTH, ALFRED W. and VAN SLYKE, LUCIUS I. (Chemical Laboratory of the New York State Agricultural Experiment Station, Geneva), in *The Journal of Biological Chemistry*, Vol. XXIV, No. 3, pp. 187-189. Baltimore, Md., 1916.

The authors have published statements attempting to indicate the individual forms or compounds in which the salts exist in cow's milk (1), goat's milk (2) and human milk (3). It is a matter of interest to bring these results together in order to see in what respects the three kinds of milk differ. In the appended table the figures which have a special interest are those relating to the salts, and we notice the following points in relation to these compounds.

**PHOSPHATES.** *Cow's Milk.* — The insoluble phosphate is di-calcium phosphate; tri-calcium, di- and tri-magnesium phosphates do not appear to be present. The soluble phosphates are mono-magnesium and di-potassium which constitute about two-thirds of the total phosphates.

*Goat's Milk.* — This differs from cow's milk 1) in containing tri-calcium, di- and tri-magnesium and mono-potassium phosphates, and 2) in containing no mono-magnesium or di-potassium phosphates.

*Human milk.* — This differs noticeably from both cow's milk and goat's milk in containing no insoluble phosphates, but only the soluble compounds; mono-magnesium and mono-potassium phosphates. The phosphates in human milk are much less in amount than in cow's or goat's milk.

**CITRATES.** All three milks contain potassium citrate, while cow's milk and human milk contain sodium citrate also.

**CHLORIDES.** Chlorides are present in goat's milk in much larger amounts

(1) See B. May 1915, No. 548. (2) See No. 577 of this Review. — (3) See: *The Journal of Biological Chemistry*, Vol. XX, pp. 707-709, 1915. (Ed.)

than in cow's milk or human milk; the amount in cow's milk is considerably larger than in human milk. In cow's milk and human milk the chloride appears to be calcium chloride, while in goat's milk potassium and sodium chloride are also present.

**TOTAL SALTS.** The total amount of salts in human milk is about one-third that of cow's milk or goat's milk. The number of different salts appears to be greatest in goat's milk and least in human milk.

*Compounds in Cow's Milk, Goat's Milk, and Human Milk.*

579 - **Pasteurization of Cream.** — LARSEN, C., FULLER, J. M., JONES, V. R., GREGORY, H. and TOLSTRUP, M., in *Agricultural Experiment Station, South Dakota State College of Agriculture and Mechanic Arts, Dairy Husbandry Department, Bulletin No. 171*, pp. 529-548 9 Tables. Huron, S. D., November, 1916.

Some European countries have required for some time that all butter be made from pasteurized cream. In the United States about  $\frac{2}{3}$  of the butter is now made from pasteurized cream, and pasteurization of cream for butter making is constantly increasing.

The chief purposes of the writers' experiments were:— 1) to ascertain the efficiency of the coil cream vat for pasteurization of cream; 2) to determine the effect of different temperatures of cream pasteurization upon: a) germ content of cream; b) chemical composition of cream; c) size and condition of butterfat globules in cream; d) keeping qualities and acidity of butter manufactured.

The equipment consisted in a 150 gallon coil cream vat, a 20 HP return tubular boiler and a 15 HP engine which ran the coil in the cream vat. The cream was of uniform good quality and contained 30 per cent butterfat. When the steam pressure reached 73 lb., the coil in the vat was started and run 10 minutes at the speed of 42 to 45 revolutions per minute. After thus mixing the cream, samples were taken for chemical and bacterio-

logical analysis and for measurement of fat globules. The temperatures of pasteurization were as follows: — in one series of experiments the cream was heated to 140° F for 25 minutes; in a second series to 160° F for 10 minutes; in a third series it was heated to 180° F and cooled immediately. Subsequently the cream was cooled to ripening temperature, or about 75° F; after cooling samples were again taken for chemical and bacteriological analysis and for measurement of fat globules; 8 to 12 % of starter was added, and each lot of cream ripened as nearly as possible to the same acidity. The percentage of acid developed in the cream varied from 0.45 to 0.55. After ripening, which required from 2 to 6 hours, the cream was cooled to a few degrees below churning temperature (52° to 56° F.), held from 1 to 2 hours and then churned. A sample of butter from each churning was placed in cold storage (at about 40° F); the acidity and score of the butter was determined when the butter was fresh and at the end of 1, 2 and 3 months.

The results may be summarized as follows: —

It was found that in pasteurization of cream at different temperatures namely, 140° F. for 25 minutes, 160° F. for 10 minutes and 180° F., with immediate cooling, the temperature of 160° F. for 10 minutes was the most effective in destroying total micro-organisms. Pasteurization of cream at 160° or 180° F. proved more efficient in killing moulds and non-acid forming organisms than pasteurization at 140° F.

The only noticeable change in composition of cream due to pasteurization was a slight decrease in percentage of water, and a consequent increase in percentage of total solids.

There was a slight decrease in acidity of the cream after pasteurization at temperatures of 140° and 160° F. Cream pasteurized at 180° F. showed on the average less decrease in percentage of acid. This is probably due to the fact that the decrease in acidity by volatilization of acids just about offsets the increase in acidity through evaporation of water from the cream.

Numerous microscopical examinations of fat globules in raw and pasteurized cream show that at the higher temperature (160° and 180° F.) the fat globules tend to coalesce or unite. This is probably due to the higher heat, together with the greater agitation of the cream by the coil.

In no instance was it noticed that the high pasteurization temperatures unfavourably affected the body of the butter.

Butter made from cream pasteurized at 180° F. retained its keeping qualities the best.

The different temperatures of pasteurization did not have any important effect on the chemical composition of the butter.

580 - **Concerning Rancidity of Butter.** — GUTHRIE, E. S. (Department of Dairy Industry, Cornell University), in *Journal of Dairy Science*, Vol. I, No. 3, pp. 218-233. Baltimore, September, 1917.

The plan of research of the investigations, concerning rancidity of butter, reported in this paper, was outlined as follows: — Is rancidity due to chemical, cow enzymic, or biological changes? On account of lack of time to study all the factors, the first two changes were the only ones investigated.

So long as most of the previous investigators thought that oxidation

was the main consideration in the development of rancidity, the chemical changes were studied with special reference to the iodine number.

The chemical changes in butter were found to be very slight when biological agencies were held in check. These changes did not cause rancidity. The enzymic development caused very little variation in the iodine number, and it produced no rancidity.

The exposure of butter and butter fat to high temperatures, light and air, did not cause a marked change in the iodine number, and this exposure did not cause rancidity. Rancidity of butter as defined by butter dealers and expert butter judges is rarely found. The average persons thinks of the strong flavour of butter as rancid.

A bibliography on the subject is appended.

581 - **Indole and Scatole in Cheese.** — NELSON, V. E. (Laboratory of Agricultural Chemistry of the University of Wisconsin, Madison), in *The Journal of Biological Chemistry* Vol. XXIV, No. 4, pp. 533-536. Baltimore, Md. 1916.

In attempting to isolate certain amines and other decomposition products resulting from the action of various microorganisms upon amino-acids found in cheese, the author observed that Limburger and "Handkäse" contain a considerable amount of indole and that the former also contains an appreciable quantity of phenolic bodies. This led to a study of other varieties of both soft and hard cheese, to determine whether they contained such substances as indole, scatole and phenol.

The method of procedure was to macerate about 400 gm. of cheese with water, place the mixture in a 5 litre flask, and distil with steam. To the distillate were applied tests for the detection of indole, scatole, phenol and ammonia. The results were as follows: —

Indole and phenol were found to be present in Limburger cheese. Scatole was not found in Limburger cheese. Indole is present in *Handkäse*. It is doubtful if scatole and phenol are to be found in this type of cheese. A trace of indole is present in Camembert cheese. Scatole and phenol are absent in this type of cheese. Cheddar, Swiss, *Gammalost*, brick, and Roquefort do not contain any indole, scatole, or phenolic bodies.

The amount of indole in a Limburger cheese naturally varies, depending upon how far the ripening process has gone. A young cheese may contain such a small amount that a quantitative estimation is impossible, while a good ripe Limburger cheese may contain as much as one part in 52 800 parts of cheese.

Lactic and bulgaricus forms of organisms when grown upon media containing tryptophane produced no indole or scatole. As growing organisms upon pure amino-acids is more difficult than upon proteins it may be necessary to add a little peptone or milk to the culture and until further work has done upon this phase it will be impossible to say that these organisms do not produce these putrefactive substances.

The liquefying coccus isolated from a Cheddar cheese appears to produce traces of indole from tryptophane.

582 - Cheese Mites. — EALES, NELLIE B., in *The Journal of the Board of Agriculture*, Vol. XXIV, No. 10, pp. 1087-1096. London, January, 1918.

The experiments described were carried out at the Zoology Department of University College, Reading, as a result of the great damage done by mites to cheeses in England. Four species of mites attack cheese: — 1) *Carboglyphus anonymus* (in Cheddar); 2) *Tyto'lyphus siro* (in Stilton and Cheddar); 3) *T. longior* (*id.*); 4) *Aleurobius farinae* (*id.*).

The mites, their life history, and the experiments made on cheese infection are described, and methods of prevention and remedies given.

*Methods of prevention.* — 1) Perfect cleanliness of the rooms in which the cheeses are kept, and of all utensils and shelves used, the stopping up of cracks and crevices, etc.

2) Netting of windows and double doors.

8) Thorough disinfection of the rooms between the Stilton seasons; the whole room, especially all corners, window ledges, crevices, shelves and their supports, etc. should be washed with a 5 % carbolic acid solution.

4) It would be advisable to use short, movable shelves, preferably of glass, with iron supports and to have concrete floors with gutters for drainage.

*Remedies.* — 1) Filling the cheese room with steam vapour, and dipping the cheeses in hot water or formalin are useless as remedies.

2) Brushing the attacked cheeses daily and removing the mite dust considerably reduce the damage.

3) Fumigate the room with carbon bi-sulphide in the proportion of 1 lb. of bisulphide to every 500 cubic feet of space during August or September; there should be at least two fumigations, the second 12 or 14 days after the first, a third after the same interval is advisable. Painting the surface of the cheeses with bisulphide is the only way of freeing them entirely from mites; three paintings should be applied.

TRADE

583 - The Handling and Precooling of Florida Lettuce and Celery (1). — RAMSEY, H. J. and MARKELL, E. L., in the *U. S. Department of Agriculture, Bulletin No. 60*, pp. 28 + 11 Tables + 19 Figs. Washington, December 21, 1917.

In Florida the cultivation of lettuce and celery, now being grown over 4 000 acres, an area which is constantly increasing, brings into the growers about 1 500 000 dollars annually. As rot frequently causes serious loss, not only in the field, but also in apparently sound produce during transit, the Office of Horticultural and Pomological Investigations of the Bureau of Plant Industry of the U. S. Department of Agriculture undertook a series of investigations into the best commercial methods for reducing the losses which occur from the time the produce leaves the field till it is delivered to the consumer.

The experiments on lettuce were carried out in 1913-1915 near Palmetto, Manatee County, one of the largest lettuce-producing centres of Florida, those on celery at Palmetto and Manatee, chiefly during the spring of 1915. The rotting of lettuce during transport was found to be due prin-

(1) See R. Jan., 1918, No. 100. (*Ed.*).

cipally to lettuce drop (*Sclerotinia Libertiana*), a fungus which seems to enter the lettuce through the lower leaves.

The lettuce was cut just above the lowest 3 or 4 leaves, and all diseased leaves removed; such lettuce decayed much less during transit than that cut by the ordinary method. Produce in cars pre-cooled at the shipping point to 40°F. decayed much less during the journey than that in cars that had not been pre-cooled. Lettuce cut as described and packed in pre-cooled cars reached its destination in almost perfect condition and sold much better than that treated by the usual methods.

Celery is often injured in transit because it is packed too closely in the car to permit of proper circulation of the air and rapid cooling. Temperature records taken during transit in pre-cooled cars iced at the station and non-precooled cars kept iced throughout the journey, showed that non pre-cooled cars required about 4 days to reach as low an average temperature as that maintained by pre-cooled cars from the start. During the whole journey from Florida to the destination (New York) the temperature in the top row of cases never exceeded that in the lowest row by more than 5 or 6° in the pre-cooled cars, whereas in the non pre-cooled cars it amounted to 18° F. for a considerable time.

The cost of the pre-cooling and initial icing of a car of celery was less than that of full refrigeration throughout the journey. In hot weather it may be necessary to renew the ice once during transit, but this is not likely to raise the expense above that usually incurred for full refrigeration.

Pre-cooled celery reached the market in uniformly fresh condition, with the leaves of the top row almost as green as those of the lowest rows. The leaves in the top rows of non-pre-cooled celery were very yellow, decreasing the value of the whole load.

It appears that, during the latter part of the Florida celery-shipping season, the produce might be sold at a better price if stored for a short time. Pre-cooled celery was successfully stored during 4 weeks with very little decay, whereas non pre-cooled celery stored during the same time decayed considerably. Celery from the lower rows of a non pre-cooled car can be stored for a short time, but, during warm weather, that on the top row should be sold as soon as it reaches the market.

## PLANT DISEASES

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

584 — **Observations on the Damage Done to Trees by Tarring the Streets of Milan, Italy** (1). — BRIZI, U., in *Reale Istituto Lombardo di Scienze e Lettere, Rendiconti*, Series 2, Vol. L, Pt. 12-13, pp. 568-591. Milan, 1917.

As had already been noticed in France, England, and even in Italy, the author observed that tarring roads causes the death of the plants near them. Many of the observations made at Milan agree with those previously made, as regards both trees and plants in beds bordering on the tarred roads.

The most sensitive plants are *Æsculus Hippocastanum* and *Æsc. carnea* (= *Æsc. glabra*) the leaves of which, at the beginning of summer, turn rusty at the edge and curl up slightly, while their surface is covered with numerous small spots, which, at first, are yellow and as if covered with a thin layer of shining varnish. The leaf then curls up more and more, dries, and is easily torn and carried away by the wind.

Other conditions being equal *Platanus orientalis* is more resistant. In late summer the leaves, particularly the youngest and those of the lowest branches, are sprinkled with yellowish spots, which later turn into small, brownish, confluent marks with a shiny surface. The leaf is rarely completely covered with these spots, and, for that reason, does not often dry up altogether and fall.

Very sensitive are *Forsythia viridissima*, *Fagus laciniata* (= *F. sylvatica*) *Lagerstræmia indica*, *Taxus baccata*, *Spiræa solstitialis* (?), *Cornus*, *Deutzia*,

(1) See B. Dec., 1910, p. 391; B. Jan., 1911, Nos. 281 and 282; B. Feb., 1911, No. 592; B. May, 1911, No. 1522; B. July, 1911, No. 2271; B. Nov.-Dec., 1911, No. 3227; B. June, 1912, No. 967; B. Feb., 1913, No. 184; B. May, 1913, No. 522. (Ed.)

*Magnolia grandiflora*, etc., and, of the herbaceous plants, *Lamium*, *Stellaria*, etc. Field grasses are more resistant.

The injury is caused almost exclusively by the very fine dust raised by the passage of motor cars along the tarred roads. This dust settles slowly and is most abundant on low plants and the lowest branches of trees, and less abundant on high branches. This was confirmed by a set of experiments on both herbaceous and woody plants (*Chrysanthemum*, *Primula sinensis*, *Cineraria*, *Dahlia variabilis*, *Fuchsia*, *Canna indica*, *Pelargonium zonale*, *Hordeum vulgare*, *Lolium*, *Festuca*, *Aloë margaritifera* (= *Haworthia margaritifera*), *Echeveria metallica* (= *Cotyledon gibbiflora*), *Crassula*, *Nephrodium*, *Pteris*, *Hydrangea*, *Forsythia viridissima*, *Syringa vulgaris*, *Spiraea solstitialis* (?), *Æsculus*, *Fagus purpurea*, *Tilia*, *Ulmus effusa*, *Acer Pseudoplatanus*, *A. Negundo* (= *Negundo aceroides*), *Phoenix*, *Trachycarpus*, *Kentia*, *Laurus nobilis*, *Thuya*, *Cupressus*, *Araucaria*, *Platanus orientalis*).

The harmful action of the dust is due, if not exclusively, at least largely, to the action of the vapours given off by the small particles of tar it contains when it is strongly heated by the sun. No other explanation can be given of the fact, observed in nature, and absolutely clear and indisputable in the experimental tests, that on the same plants, covered with the same amount of dust of the same quality, marked and serious lesions occur only in the parts reached by the sun and are more intense and rapid in growth in proportion as the period of insolation is prolonged, and, consequently, the temperature is higher. Plants exposed in the shade, or not reached directly by the sun, never suffer perceptible injury. The soluble compounds contained in the particles of tar cannot be considered to be direct causes of the injury, chiefly because these particles are insoluble, and, secondly, because even if some injurious substances could be dissolved by rain, this would not explain why the lesions only appear in the parts exposed to the sun. On the other hand, rain, though only light is favourable, because it washes the leaves free from dust.

The best remedy lies in a rational, regular and abundant watering of the tarred roads, which would remove the dust, especially when it accumulates after long droughts. It is probable that the slight damage hitherto observed in England is due, not only to the use of a better quality tar — it is not the crude tar from the gas-works as in France and Italy, but a special refined tar — but to the fact that all the tarred roads on which there is much traffic are not only watered daily, but are well washed by powerful streams of water which prevent the dust from accumulating. Care should also be taken to choose for shaded roads trees or plants little subject to the action of tar.

To avoid serious injury when the boiling tar is applied the operation should be carried out by preference during the period of vegetative rest, or before the plants begin to grow, *i. e.*, at the beginning of spring, never in the middle of summer. By these means and by copious periodical watering the damage may be considerably reduced, but doubtless the only way to avoid it altogether is to replace tarring by another method of coating roads. At Milan it was observed that the use of asphalt or "San Valentino bitumen" gives rise to none of the damage to plant life caused by tar.

## DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

## GENERAL

585 — **Rusts and Smuts Collected in New Mexico in 1916.** — STANDLEY, PAUL C., in *Mycologia*, Vol. X, No. 1, pp. 34-42. Lancaster, Pa., January, 1918.

The list contains about 60 species of rusts and 5 species of smuts, collected chiefly by the author in August and September, 1916, at Ute Park, Colfax County, in the extreme north of New Mexico, at an altitude of about 2 350 metres. Many of the species are new to the State, several others were found on hosts hitherto unreported for New Mexico. The rusts were determined by Dr. J. C. ARTHUR, the smuts by Mr. H. R. Rosen.

Among the rusts are *Coleosporium ribicola* (Cooke and Ellis) Arthur (*Peridermium ribicola* Long), very abundant on *Ribes aureum* Pursh., *R. inebrians* Lindl. and *Grossularia inermis* (Rydb.). Cov. and Britt, all new hosts for the State. The fungus was also found at Ute Park on a leaf of *R. Wolfii* Rothr. In the North American flora this rust is reported neither on *G. inermis* nor on *R. Wolfii*. LONG reported its aecidial stage on *Pinus edulis* Engelm., from the Sandia Mountains. He also reported the coleosporial stage on *R. mescalegium* Coville, in the Santa Fe National Forest; the host was probably rather *R. inebrians*, because according to the author, *R. mescalegium* is confined to the south of the State. LONG also noted the coleosporial stage in Albuquerque on *R. longifolium* (*longiflorum* ?), a name which should doubtless be corrected to *R. aureum*; *R. longiflorum* is not known to occur in New Mexico.

Among the smuts are mentioned *Ustilago Hordei* (Pers.) Kell. and Swingle on cultivated *Hordeum trifurcatum* Jacq., and *U. levis* abundant on cultivated oats.

586 — **Brazilian Fungi** (1). — RANGEL, E., in *Archivos do Jardim Botânico do Rio de Janeiro*, Vol. II, pp. 69-71 + 3 Plates. Rio de Janeiro, 1918.

The list includes :—

- 1) *Puccinia grumixamae* Rangel n. sp., on living leaves of *Eugenia brasiliensis*, in the Botanical Garden of Rio de Janeiro;
- 2) *P. cambucae* Puttemans; the host of this fungus described previously is *Marlierea edulis*, not *Myrciaria plicato-costata*;
- 3) *S. Simasii* Rangel n. sp., on leaves, petioles and twigs of *Breweria Burchellii*, at Icarahy, near Niteroy;
- 4) *P. paulensis* Rangel n. sp., on leaves and twigs of *Capsicum annuum*, at S. Paolo;
- 5) *Laestadia cambucae* Rangel; the host of this fungus is *Marlierea edulis*, not *Myrciaria plicato-costata*;
- 6) *Septoria Miconiae* Rangel n. sp., on living leaves of *Miconia* sp., at Niteroy;

(1) See *B.* Jan., 1912, No. 11; *B.* June, 1913, pp. 876-879; *B.* Oct., 1913, No. 1216; *B.* Dec. 1913, No. 1401; *B.* Jan., 1914, No. 78; *B.* Aug., 1915, Nos. 859 and 861; *R.* Apr., 1918, No. 493. (Ed).

7) *Cercospora Genipae* Rangel, n. sp., on living leaves of *Genipa* sp. (*G. americana*?) at Rio de Janeiro; .

8) *Helminthosporium Manihotis* Rangel, n. sp., on living leaves of *Manihot Aypi*, at S. João Nepomuceno (Minas Geraes);

In 1915 the author described a new genus of hyphomycetes, which he called *Velloziella*; so as to avoid confusion with the similarly named genus of Scrofulariaceae, he has changed the name of the genus he formed to *Mycovellosiella*.

A description of the species new to science is given in Latin.

587 - **Fungi of the Philippine Islands.** — YATES, H. S., in *The Philippine Journal of Science, Section C., Botany*, Vol. XII, No. 6, pp. 361-380 Manila, 1917.

This paper gives a list of 78 species of fungi collected during recent years in various districts of the Philippines. Many are new to science and, in this case, are accompanied by a description in Latin.

It is interesting to note that the genera *Meliola* and *Asterina* are particularly numerous. This may be explained in part by the fact that representatives of these two genera are mostly not very remarkable forms which may have escaped previous investigators. In the Philippines the *Meliola* genus includes a larger number of known species than any other genus of Ascomycetes, second place in this respect being held by the genus *Asterina*. The list given by the author includes 21 species of *Meliola*, 17 of which are new to science, and 10 species of *Asterina*, 6 of which are new.

Among the various fungi enumerated are:—

- 1) *Meliola catubigensis* n. sp., on leaves of *Loranthus*;
- 2) *Asterina colliculosa* Speg., on leaves of *Eugenia Jambolana*;
- 3) *Actinodothis Piperis* Syd., on leaves of *Piper retrofractum* and *Piper* sp.; a fungus very common in the Philippines; in some places practically all the *Piper* plants are attacked;
- 4) *Cercospora personata* Syd., on leaves of *Arachis hypogaea* (1);
- 5) *Hadronema orbiculare* Syd., very common on living leaves of *Quercus* sp.; it is one of the few fungi which have only been reported from Japan and the Philippines.

588 - **Plants Resistant to Diseases, Pests and Adverse Meteorological Conditions.** — See No. 519 of this Review.

589 - **Mineral Anticryptogamic Compounds Produced in Spain.** — See No. 509 of this Review.

590 - **Comparison of the Effects of Copper Mixtures and Acid Mixtures on Mildew of the Vine.** — CAPUS, J., in *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. IV, No. 2, pp. 86-90, Paris, 1918.

In 1917 the author undertook experiments in the experiment field of Cadillac (Gironde) and the laboratory of the Plant Pathology Station of the Department of Gironde, on the comparative effects of the following mixtures:—

RESISTANT  
PLANTS  
  
MEANS  
OF PREVENTION  
AND CONTROL

(1) See R. March, 1918, No. 350 (Ed.)

a) basic Bordeaux mixture, according to the formula of MILLARDET and GAYON, with 2 % copper sulphate ;

b) acid Bordeaux mixture prepared by the PICKERING and SICARD method, with the same quantity of copper sulphate ;

c) basic Bordeaux mixture, prepared by PICKERING'S method, i. e., with lime water and 2 % copper sulphate ;

d) acid Burgundy mixture, prepared by FONZES-DIACON'S method ;

e) 2 % neutral Burgundy mixture.

The results obtained showed the acid and basic mixtures to be equally efficacious against mildew of the vine, but that for a period exceeding 20 days and during heavy rains, basic mixtures retain their efficacy better than acid ones.

DISEASES  
OF VARIOUS  
CROPS

592 - *Pseudomonas Tritici* n. sp., Injurious to Wheat in the Punjab. — HUTCHINSON, C. M., in *Memoirs of the Department of Agriculture in India, Bacteriological Series*, Vol. 1, No. 7, pp. 160-175 + 4 Plates. Calcutta, October, 1917.

A bacterial disease of wheat, called locally "Tannan" or "Tandu", has long been known in the Punjab. Its principal characteristics are very similar to those described by RATHAY (1) and O'GARA (2) for *Dactylis glomerata* and *Agropyron Smithii* respectively.

The inflorescences and part of the stem are covered with a bright primrose yellow slime or gum, forming adherent, sticky layers between the glumes and between the stem and sheath. This slime is composed of masses of bacteria, and the outer, exposed parts become dry, hard and flaky, and, at the same time, turn a deeper yellow. A frequent characteristic of the disease, due to obstruction of the growth of the plant by the sticky bacterial masses, is the distortion of the stem immediately below the head.

Although the disease has appeared in the same district (Montgomery) of the Punjab every year since 1908, with the sole exception of 1915, and is said to have been known there many years earlier, it does not appear to be of serious importance at present as it only attacks a very small percentage of plants, and only those in soil rendered infertile by bad cultivation and bad drainage.

The occurrence of the disease must, however, be carefully and continually observed to prevent an eventual increase of parasitic activity and a wider distribution of the pathogenic agent, although the disease seems at present to be limited by natural causes — dry air and high soil temperature — to the only part of India in which it is as yet known. As these causes vary only in abnormal seasons, it seems that, in the Punjab, the disease would only form a serious obstacle to wheat-growing if the irrigation water were applied unjudiciously, or if a new variety of wheat, more subject to attack by the parasite, were introduced. The damage might also increase if the bacterium were to acquire higher parasitic power or resistance to adverse climatic conditions.

(1) See R. Nov., 1917, No. 1093. — (2) See R. Feb., 1916, No. 212. (Ed.)

The disease may be spread either by bacteria persisting in the soil or by those carried on the grain or chaff of the plant; this should be remembered when using seed wheat from infected districts.

The causal bacterium is described in detail under the name of *Pseudomonas Tritici* n. sp. It is probable, as in similar cases, that eelworms play an important part in spreading or accentuating the disease.

In the inoculation experiments at Pusa bacterial growth on the wheat could only be obtained under a bell-jar, which ensured sufficiently moist air and the formation of dew on the plant. The rapid growth of the wheat, however, not only made it impossible to observe the full effect of the parasite, but appeared to prevent the characteristic distortion of the stem observed in the Punjab fields.

No positive results were obtained with inoculation of other Gramineae, but considerable bacterial growth was obtained on living onion bulbs. Onions were chosen because of the many points of resemblance in the morphological, cultural, and physiological characters of the wheat bacillus and *Ps. Hyacinthi* Wakker. The onion is the plant most closely resembling the hyacinth obtainable in the plains of East India.

In view of the relatively small percentage of wheat attacked by the disease, the only methods of control which need be emphasised for this as for other bacterial diseases of plants are good drainage and careful cultivation.

593 — **Bacterial Blight of Barley.** — JONES, L. R., JOHNSON, A. G. and REDDY, C. S., in the *Journal of Agricultural Research*, Vol. XI, No. 12, pp. 625-643 + 2 Figs. + 4 Plates. Washington, D. C., December, 17, 1917.

This paper describes a bacterial disease of barley (*Hordeum* spp.) which was first observed in 1912 doing considerable damage to two-row Montana barley (*H. distichon*), and later on common six-row varieties (*H. vulgare*), at Madison, Wis. Since then it has appeared each year in the same district and has also been reported from other parts of the United States.

The disease principally attacks the leaves, where it forms small water-soaked areas, which enlarge later into translucent yellowish or brownish blotches or stripes. Similar lesions may also appear on the glumes.

A bacterial exudate may appear on the lesions in the form of tiny, clouded drops, which harden into yellowish resinous granules or form a grayish flaky, surface film. This exudate and translucency of the infected parts distinguish the bacterial blight from diseases caused by *Helminthosporium*. The disease is somewhat similar to those caused by *Aplanobacter Rathayii* E. F. S., *A. Agropyri* O'Gara, and *Pseudomonas Avenae* Manns, but is nevertheless distinct from each of them.

The primary lesions may appear very early on the young plants, and the secondary lesions when the plants are from 8 to 10 inches high. Later the disease develops with increasing rapidity.

The disease is very widespread, from the Mississippi Valley to the Pacific coast. It attacks the two row (*H. distichon*), common six-row (*H. vulgare*), and erect six-row (*H. hexastichon*) barleys. The varieties of these three groups are not all equally susceptible to infection; some appear to be

naturally immune, but nothing definite can be stated till further work on the subject has been carried out

The pathogenic agent is present in great numbers in the invaded tissues and the exudate. It is a monotrichic bacterium, yellow in culture, which the authors believe to be new to science and describe under the name of *Bacterium translucens*. Not only has it been isolated from infected tissues and the exudate, but also from dry leaves, kept throughout the winter, and from grain 2 years old.

Inoculation experiments have shown that the disease may easily be reproduced in barley by spraying with water containing the bacterium in suspension. Negative results were obtained by inoculations of oats, rye, wheat, spelt, emmer, einkorn and timothy. The bacterium enters the host through the stomates and intracellular spaces

Although the bacterium may hibernate in infected leaves there is no doubt that diseased grain is the principal factor in spreading the parasite and the seat of spring infection. The most efficacious means of control known at present consist in avoiding infected seed and in doubtful cases, disinfecting it.

594 - **Diseases of Cabbage in the United States.** — HARTER, L. L. and JONES, L. R., in the *United States Department of Agriculture, Farmers' Bulletin* 925, 1 p. 30 + 13 Figs. Washington, D. C., January, 1918.

After observations on the spread of diseases of cabbages and other cultivated Cruciferae and the methods of controlling them, the author describes the most important of these diseases, nearly all of which are caused by vegetable parasites. They are:—

1) Clubroot (clubfoot, finger and toe), caused by *Plasmodiophora Brassicae* Wor.;

2) root-knot (*Heterodera radiculicola* [Greef] Müll.);

3) black-rot (brown-rot, stem-rot, dry-rot) caused by *Bacterium campestris* (Pammel) Erw. Sm.;

4) yellows (yellow-sides, wilt, dry-rot), caused by *Fusarium conglutinans* Wollenw.;

5) black-leg (foot-rot, wilt), a disease caused by *Phoma lingam* (Tode) Desmar.;

6) soft-rot, caused by soft-rot bacteria, of which *Bacillus carotovorus* Jones is a typical example;

7) root-rot (wilt), a disease of non-bacterial origin caused by asphyxia of the plant due to stagnant water;

8) malnutrition, a disease due to excess of chemical fertilisers and a deficiency of humus in the soil;

9) downy mildew (*Peronospora parasitica* [Pers.] De By.);

10) white-rust (*Albugo candida* [Pers.] Ktz. = *Cystopus candidus* [Pers.] Lev.);

11) drop (*Sclerotinia Libertiana* Fuck.);

12) spot disease of cauliflower, a new disease caused by a bacterium which appears to attack only *Brassica oleracea* and *B. oleracea* f. *Botrytis*;

13) black leaf-spot (black mould); the most common form of thi-

disease is caused by *Alternaria Brassicae* (Berk.) Sass., but other related fungi may cause similar leaf-spotting, and yet others may contribute to moulding the plants in storage deposits ;

14) powdery mildew (*Erysiphe Polygoni* D. C.) ;

15) damping-off, a disease which chiefly attacks young plants in seed-beds, and which may be caused by several species of fungi.

**595 - *Pseudomonas seminum* n. sp., a Bacterium Injurious to Peas, in England.**

— CAYLEY, DOROTHY M., in *The Journal of Agricultural Science*, Vol. VIII, Pt. 4, pp. 461-479 + Plates IV-VII. Cambridge, 1917.

Crops of *Pisum sativum* grown near the John Innes Horticultural Institution, Merton, Surrey, are badly damaged by a bacteriosis which, having appeared in a particularly serious form from 1910 to 1912, was found later in other districts in the south of England. The same disease was found in 1915 on peas from Sleaford, Lincoln. An examination of samples from various districts showed that this bacteriosis tends to spread more and more.

The author proposes to call the bacterium, which has not yet been described, *Pseudomonas seminum*, and gives details of its morphology and biology.

The chief characteristic of the disease is that it occurs within the seed, discolouring the centre of each cotyledon. External examination does not show if the seed is diseased or not. The bacteria cannot penetrate the ripe tissues, so that infection, found only in the lesions of the very young tissues, takes place long before it is shown by discolouration of the tissues.

The bacteria is found in all parts of the plant except the vessels, in which it has never been observed. It has been isolated from the interior of both the dry and fresh seed, from the stem and the pod. It has never been seen to pass the micropyle although, in one case, it was found in the space between the cotyledons and the young embryo.

All varieties of table peas seem more or less subject to the disease. The most resistant variety is Sutton's Improved Petit Pois, which when sown in infected soil, produced 49 to 50 % of sound plants, the seeds of which, sown in the same soil the following year, produced 50 % of sound plants. The Duke of Albany and Nec Plus Ultra varieties are very subject to the disease, the number of healthy plants in the first variety was, at the most, 14 to 15 %, and cultivation of the second at Merton for Mendelian experiments had to be stopped because of its great susceptibility. Tall, early varieties are much less attacked than late ones ; this appears to be due to their less succulent vegetative apparatus, and their more rapid growth, which allows them to become sufficiently mature before external conditions determine a rapid development of the bacteria.

The author examined many varieties of early peas grown at Wisley in 1915. All the plants were nearly ripe. One variety only showed the typical discolouration of the cotyledons, although, judging by the external appearance, there were many doubtful cases. A row of Duke of Albany grown in an adjacent plot, but in a much more advanced stage of develop-

ment showed the typical discoloured area in the centre of the cotyledons. Infection was more marked at Merton than at Wisley, where it was probably introduced by seed.

Of the dwarf, succulent early varieties, Chelsea Gem and Little Marvel, and, of the later types, Nec Plus Ultra and Duke of Albany, are especially subject to the disease.

The bacteriosis does not stop germination, but, in serious cases, it delays the growth of the plant by killing the whole main stem and preventing the development of lateral shoots.

So far no means of controlling the disease are known. As precautions may be recommended crop rotation, early seed, drainage, a sufficiency of lime in the soil, elimination of seed from diseased plants. Infected plants and their props should be burnt as soon as the harvest is gathered. Partial sterilisation is of no use, and involves too much work and excessive expense. Special care should be taken to clean thoroughly all tools used in infected soil so that the disease may not be spread by them.

596 - *Verticillium albo-atrum* a Hyphomycete Causing "Vissnes Juka" (Wilt) of Cucumber in Sweden. — LINDFORS THORE, in *Kungl. Landbruks Akademiens Handlingar och Tidskrift*, Year LVII, Nos. 7-8, pp. 627-636 + 3 Figs. Stockholm, 1917.

In 1916, in a field of cucumbers at Ballersta, Södermanland, plants which were sound and strong till the end of July, were attacked by wilt, of which the majority died. A microscopical examination of the infested material showed the existence within the stem tissues of masses of mycelium which more or less completely closed up the vessels, thus preventing the passage of the water from the roots. While the host lives the parasitic mycelium is restricted to the vascular bundles, and only invades the surrounding tissues after the death of the plant.

In cultures made from infested material 3 fungi were identified: — 1) *Verticillium albo-atrum*; 2) *Ascochyta Cucumis*; 3) *Fusarium nivium* (?) in one case only and even then it was not possible to isolate it.

The following results were obtained from infection experiments, in which *Fusarium sclerotioides* and *F. redolens* var. *angustius* were used in place of the allied *Fusarium* species which could not be isolated from the material:—

1) *Ascochyta Cucumis* produces in the cucumber spots on the leaf, but no wilt;

2) *Fusarium sclerotioides* and *F. redolens* var. *angustius*, do not cause wilt, but, in certain cases, may give rise to a kind of stem-rot;

3) *Verticillium albo-atrum* is the only and the real specific agent of wilt; its hyphae easily enter the living tissues of both mature and young plants, and develop in large number in the vessels, which they stop up more or less completely.

Up to the present, apart from Ballersta, the disease has been reported from the districts of Stockholm, Nyköping, Västmanland and Örebro. Though the damage done is slight the possibility of further, more extensive infection, calls for a study of the methods of control.

The author suggests, in the first place, the uprooting and destruction of diseased plants, care being taken to remove all the soil with which such plants may have been in contact. Dead plants left in the field rapidly become seats of infection. In infected districts neither cucumbers nor potatoes should be grown for several years. The soil should be disinfected. The author believes that for this purpose good results could be obtained with formalin; tests with 2 % potassium permanganate solutions had no effect.

597 - On "Verde-secco" of Fruit Trees in Apulia, Italy. — VIVARELLI, I., in *La Propaganda Agricola*, Series 2, Year X, No. 5, pp. 51-55. Bari, March 15, 1918.

In Apulia the name "verde-secco" is given to a serious disease by which many woody plants (almond, olive, apricot, myrobalan, and peach trees, etc.) pass with great rapidity from a state of normal and flourishing development to a very grave disorder followed by death. First the leaves dry up, then the smallest twigs, then the branches, and, finally, the trunk itself.

Field observations and experiments carried out by the author in different parts of Apulia (Andria, Canosa, Barletta, Casamassima, Trani, Molfetta), showed no plant or insect parasites in the epigeal part of the plant, but proved the root system of all, or nearly all the plants killed by "verde-secco" to be attacked by a rot caused by *Rosellinia necatrix*. The disease is favoured by certain conditions, such as heavy and impermeable soil, prolonged stagnation of rain water, badly executed plantation, the custom of digging, at the foot of the plant, a central hole to receive water instead of a circular ditch in proportion to the foliage, the re-planting of trees in the place of those recently killed by the rot.

According to the author, a plant the root system of which is seriously affected by the rot, has difficulty in maintaining the balance necessary to the complex working of its vegetative organs, and when by a sudden, high rise in temperature, especially during fine days, transpiration is considerable, it cannot counterbalance it by an equal intensity of root absorption and dies. By allowing the plant to develop its root system well and to keep it healthy the damage described above would certainly be avoided.

598 - *Monilia* sp., the Cause of a Specific Gummosis of the Apricot Tree, in Italy. — PEGLION, V., in *Rendiconti della Reale Accademia dei Lincei, Classe di Scienze fisiche, matematiche e naturali*, Series V, 1st. Half-Year 1917, Vol. XXVI, Pt. 12, pp. 637-641. Rome, 1917.

In Emilia apricot growing is seriously threatened by a form of gummosis, which, already noted incidentally by BEIJERINCK and ERIKSSON, had been reported by FAES as very injurious to apricot trees in Valais, Switzerland, and by CHIFFLOT and MASSONNAT to those of the Rhone district (1).

The disease is caused by a conidial form (*Monilia*) of a *Sclerotinia* which, according to the author, would correspond to *Scl. laxa* if the differential characters observed by ADERHOLD and RUHLAND were sufficient to distin-

(1) See *B.* Oct., 1915, No. 1098. (Ed.)

guish this parasite from *ScL cinerea*. The most significant character is the absolute restriction of parasitism to the apricot tree, which is also observed in the Emilian orchards.

The first signs of infection occur during flowering; some of the flowers fade and dry up, but do not drop. Later, when the leafy shoots are longer, the wilt suddenly attacks, from one day to another, the buds corresponding to these flowers. Above the point of insertion of these buds, sometimes at a distance of a few nodes, especially during rainy seasons, a gummy stream of transparent drops is noticed flowing from the cracks of the bark and forming lumps more or less large in size. A more considerable gummosis is observed on the adult branches and even on the trunk corresponding to a faded adventitious floral bud. The infection of the growing fruit is very limited; most frequently fruit is infected which has grown in contact with a mummified flower spotted with gum.

The rapid spread of infection which may occur seems to correspond to an early and rather long flowering period during which insects, by visiting infected flowers, carry conidia of *Monilia* and spread disease by visiting sound flowers.

This disease must be controlled by systematically destroying the parasite's hibernation quarters. It is not sufficient to burn the mummified fruit, which may easily be found and collected in winter; it is against the blisters formed by the fungus hibernating under the remains of flowers, on the twigs killed by the disease, and the fragments of bark covering the cankers of the adult branches and trunk that measures must be taken. It is easily suppressed by careful pruning when vegetation starts and the localised injuries on the tree can be seen without difficulty, so that the tree may be cured before the winter period of rest. The cankers heal normally, and infection in them is limited to the more or less fragmentary remains of bark, which may easily be removed by superficial scraping.

**599 - Treatment of *Fusicladium pirinum* var. *Eriobotryae*, Injurious to the Japanese Medlar Tree.** - SAVASTANO, L., in *R. Stazione sperimentale di Agrumicoltura e Frutticoltura in Acreale, Bollettino*, No. 29, pp. 6 + 2 Figs. Achade, 1917.

In the east of Sicily a disease called "brusone" by the author, who has observed it for 8 years, is developing with increasing virulence on the branches, leaves and fruit of the Japanese medlar tree (*Eriobotrya japonica*). It is caused by *Fusicladium pirinum* (Iib.) Fuck. var. *Eriobotryae* Scal.

On the medlars is observed a small, blackish spot, which gradually increases. The attack of the parasite may begin in December and continue till February or March.

If the fruit is attacked during the first stage of its development it becomes deformed, and shrivels, the spot grows, and the fruit dries up and becomes mummified. If attacked during ripening, this stage remains imperfect. The infected branches are twisted, stunted, spotted with black, and with irregular, shrunken leaves; they fade and dry up from year to

Those trees which have the largest and sweetest fruit are most subject to attack by the fungus.

The author's experiments on winter treatment showed the efficaciousness of spraying with lime-sulphur mixture made according to the formula of the "Stazione di Agricoltura" (lime, 2 lb.; sulphur, 4 lb., water, 2 gall.). The mixture should be applied in 12 % strength, at the most 14 %, in December, when all the flowers have fallen, and in January.

The trees to be treated should be pruned in August, during the resting period, so as to remove the branches, in which the parasite passes the summer, and to give strength to the tree. The pruned branches should be burnt at once. It would be well to undertake experiments to prove whether 6 % sprayings in summer to destroy the parasite in the branches would be advisable.

**600—The Tumours of the Cluster Pine (*Pinus Pinaster*), in France.** — DE FREN OV, J., in *Comptes rendus des séances de l'Académie des Sciences*, Vol. CLXVI, No. 8, pp. 355-356 Paris, February 25, 1918.

The cluster pines of the Arcachon forests have many tumours on their stems and roots. On the one year stems the tumours are cankerous and exude abundant resin which flows down the stem. The old tumours may close and form lumps appearing as knots, more or less resinous on the surface.

After describing the structure of the tumours, the author draws attention to the masses of bacteria found in the diseased tissues. A very fine mycelium, which often lives on the surface of the resin exuded, may enter the cankerous tissues by the parts rendered resinous by the bacteria. This mycelium, however, is only an adventitious organism.

The author isolated the bacteria observed in the infected tissues. After 3 days at 12° C. when the tumours were one year old, and after 5 days when the tumours were older, cultures made with the tissues of the stem tumours develop very dense, greyish colonies, forming a slight veil over the surface of the agar, which they liquefy. The mycelium from the resin often grows in tubes at the end of 8 days, forming whitish colonies, quite distinct from those of the bacteria. At the end of 8 days cultures made with the tissues of the root tumours develop white colonies which become very dense and thick and grow on, or just below, the surface, without liquefying the agar.

Under the microscope the bacterial colonies from the stem appear to be composed of bacteria resembling those observed in the stem tumours. The colonies from the roots are composed of much larger bacteria than those from the stem and resemble those of the root tumours.

The stem and root tumours of *Pinus Pinaster* appear to be due to two different bacteria, the characters of which the author will publish later. The bacterial tumours of the stem of the cluster pine differ from those of the Aleppo pine which have long been known.

601 — *Phyllactinia suffulta*, an Ascomycete Injurious to Common Oak, in Spain.

— ROBREDO, L. H., in *El Cultivador Moderno*, Year VIII, No. 3, p. 12. Barcelona, 1918.

For some time *Phyllactinia suffulta* has been spreading in the plantations of common oak in Galicia, depreciating the value of the tree for the various uses to which it is put.

As a preventative measure, to lessen the intensity of the disease during the following year, it is advisable to burn the infected fallen leaves in autumn, an operation which must be carried out simultaneously in all the neighbouring oak plantations. Sulphur treatment should also be carried out when the young shoots are about 4 inches long. This treatment should be carried out in dry weather and repeated 20 days or a month later if the white spots of the disease continue to appear on the leaves. The treatment costs about 2*d.* for an average sized tree and 4 ½ *d.* for a large tree.

Observations and experiments show that trees which are not pruned are not attacked by the fungus, that those pruned a little, are attacked slightly, and that those which are excessively pruned are badly attacked. *Quercus palustris* and *Q. rubra* var. *americana* are the varieties most resistant to the fungus.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

### GENERAL

- 602 — Biological Observations on some Coleoptera of the Department of Hérault, France (1). — LICHTENSTEIN, J. L., in the *Bulletin de la Société entomologique de France*, No. 4, pp. 91-95. Paris, 1918.

Special mention should be made of :—

*Anthaxia aurulenta* Fabr. — An insect found on the elm, and, according to CAILLOL, especially on the small trunks of young, dead elms. Nevertheless in April the author found several specimens of this *Anthaxia*, which seems very rare in the Department of Hérault, on young branches of *Salix alba*.

*A. manca* L. — Common on the elm and also known to occur on certain other trees, has not previously been reported on *Rhamnus Alaternus* (barren privet) on the branches of which the author found it in June and July.

*Scobicia chevrieri* Villa. — Not rare on branches of fig trees, this insect is also a host of branches of vine and barren privet.

*Stromatium fulvum* Villers. — The author received from the province of Constantine, Algeria, branches of cork-oak containing larvae of this species which, in the Department of Hérault, develop on young elm. He obtained adult insects after 5 to 6 years (according to MAYET the larval state may last for 15 years.) In some bits of branch, about 5 inches long, several larvae had developed, hollowing wide galleries throughout the sap-wood, which were so filled with excreta that they were almost as hard as the wood. Although this insect is common in cork-oak forests, it does little damage.

*Exocentrus punctipennis* Muls. — In Languedoc its larvae are found under the bark of white willow and elm.

(1) See R. March, 1918, No. 366. (Ed.)

*Hylesinus vittatus* Fabr. and *Scolytus multistriatus* Marsh. — These two insects of young elms also attack branches of *Rhamnus Alaternus* L., hollowing their galleries under the bark, where *Sc. multistriatus* is attacked by two braconidae—a species of *Ecphyllus* which will be described shortly, and *Dendrosoter protuberans*. *Hyl. vittatus* continually bears on its sides numerous mites not yet determined.

*Rhytidoderes plicatus* Oliv. — According to BEDEL this insect lives at the foot of *Reseda lutea*. It also seems to attack Cruciferae; the author found one eating a leaf of *Diplotaxis tenuifolia* in April, and another on cultivated cabbage.

*Derolomus chamaeropsis* Fabr. — Abundant on specimens of *Chamaerops humilis*, cultivated at Montpellier, particularly in the Botanical Garden. According to PERRIS the egg is doubtless laid in the ovaries, but the author has only observed this insect on the male flowers of the palm.

*Choerorhinus squalidus* Fairm. — PERRIS reported it on elm and the fig-tree. The author found it in small numbers on the dead part of a fig-tree trunk which had been invaded by ants (*remasiogaster scutellaris*); this insect is, however, by no means myrmecophagous; when it established itself in the trunk the ants had already left it.

*Eremotes punctatulus* Boh. — Dead ash wood, in which the author found larvae, pupae and adults, may serve as food to this insect which has already been observed on several species of trees.

*Mononychus punctum-album* Herbst. — It is very common at Montpellier on *Iris Pseudacorus* and *I. foetidissima*; the author knows, in rather dry soil, several of the latter, the fruit of which are eaten by the insect each year. He found large numbers of the *Mononychus* on different cultivated varieties of *I. germanica* and *I. florentina*.

603 — *Perezia legeri* n. sp., a Protozoan Parasite of the Larvae of the Large White Cabbage Moth (*Pieris brassicae*) (1). — PAILLOT, A. in *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXI, No. 4, pp. 187-189 + 1 Fig. Paris 1918.

This paper describes a new microsporidion temporarily placed in the genus *Perezia* under the name of *P. legeri* n. sp.

It is found especially in the adipose tissue of the larva of *Pieris brassicae* and in some of the giant cells of its blood. In the rather rare cases of generalised infection the spores of the protozoon are found in all the tissues of the larva of the insect.

604 — *Leptocoris varicornis*, a Weevil Injurious to Rice in Assam. — Report of the Agricultural Department, Assam, for the Year ending the 30th June, 1917, pp. 5. Shallog, 1917.

At Jaintia Perganas and the Karimgary farm in Sylhet, *Leptocoris varicornis* (rice bug) has done considerable damage to rice. The early varieties suffered most. The results of the experimental harvest showed the loss to amount to 90 % of the normal yield.

605 — Experiments on the Disinfection of Dwarf Beans Infested with *Acanthoscelides obtectus* and *Spermophagus subfasciatus*. — PANTANELLI, E., in *Le Stazioni sperimentali agrarie italiane*, Vol. I., Pt. 11-12, pp. 591-609. Modena, 1917.

Part of a consignment of dwarf beans imported from Brazil in May,

MEANS  
OF PREVENTION  
AND CONTROL

INSECTS, ETC.  
INJURIOUS  
TO VARIOUS  
CROPS

(1) *Sec R.*, May 1918, No. 37<sup>a</sup>. (Ed.)

1917, on arrival in Italy, was found to be already slightly infested with *Acanthoscelides obtectus* (1), and much more seriously by another weevil *Spermophagus subfasciatus* (= *Sperm. musculus*), peculiar to South America and hitherto met with only once in Europe (Paris), where it did not increase.

The author undertook experiments on the disinfection of the seed and the store-houses. He ascertained that to cause the certain death of the adult insects in the seeds, each hundredweight of dried beans should be treated for 48 hours with fumes given off by either 50 gm. of carbon bisulphide, by about 50 cc. of carbon tetrachloride (= 81.54 gm.) or by 0.5 gm. of potassium cyanide. The germinating power of the seeds is more affected by the bisulphide than by the tetrachloride, but is not affected at all by the potassium cyanide.

The store-houses may be satisfactorily disinfected by spraying with an emulsion of tar oil.

Among the preparations tested the author recommends "lysol", made by Schülke and Mayr, "cresosol" made by the Society for the distillation of tar (Società Distillerie Catrame), "creselion" made by Carlo Erba, and "creoline" prepared by G. Pearson.

Experiments made in October on *Ac. obtectus* and *Sperm. sub-fasciatus* at temperatures of from 12 to 15° C., showed that, to kill completely adult insects within the seeds the following proportions are needed:—

creoline . . . . .	7	volumes in	100	volumes of water
creselion . . . . .	6	"	"	"
cresosol . . . . .	5	"	"	"
lysol . . . . .	4	"	"	"

**606 — Observations on *Acanthoscelides obtectus* (Bean Weevil), in Italy. —**

RAZZAUTI, A., in *Bollettino del Laboratorio di Zoologia generale e agraria della R. Scuola superiore d'Agricoltura in Portici*, Vol. XII, pp. 94-122 + 16 Figs. Portici, 1917.

Very little work has been done on the presence of *Acanthoscelides obtectus* Say ("tonchio del fagiuolo") and the damage it does to runner and dwarf beans, although this insect has been known in the country for about 20 years. The present investigations were, therefore, undertaken in an attempt to learn more about the "bean weevil"

A list of the synonyms of the insect is followed by a morphological and biological description. According to some workers the insect is a native of Persia or Armenia, according to others of Northern America, and is so widely distributed geographically that it may almost be considered cosmopolitan. SHARP reports it from the following districts: — North America to the east of the Rocky Mountains, Mexico, Guatemala, Nicaragua, the Antilles, and the Argentine (Buenos-Aires). It is also found in Australia, the Azores Islands and the Canary Islands. In Europe, according to the author, *A. obtectus* is known in England, France and Italy. BERTOLINI reports it from the Alpes Maritimes and the Mediterranean district; MINÁ PALUMBO reports it from Genoa, Naples and from Sicily (Palermo, Castelbuono). According to informa-

(1) See No. 605 of this Review. (Ed.)

tion received by the author, I. UGIONI found it in 1913 in the Valtournanche valleys and SILVESTRI at Acerra (Caserta) and Lower Nocera (Salerno), where it did great damage to dwarf beans. In Tuscany the weevil is well known in the provinces of Florence, Leghorn, Lucca and Pisa, and the other provinces are not free. The large province of Pisa is particularly badly infested.

In the larval stage the insects prefer the seed of the numerous varieties of dwarf bean (*Phaseolus vulgaris*), and scarlet runner (*Ph. multiflorus*). In Tuscany the larger white varieties suffer most ("fagioli pisani", or "fagioli di S. Michele" or "premi") as well as elongated beans ("pinoli" or "piroli"); but the small varieties ("tondini") are less attacked.

In the absence of dwarf beans, however, the weevil may attack cow-pea (*Dolichos melanophthalmus*), bean (*Vicia Faba*), common vetch (*Vicia sativa*), white lupin (*Lupinus albus*), chickling-vetch (*Lathyrus sativus*), and garden pea (*Pisum sativum*). The author observed in artificial breeding that in exceptional cases the insect will adapt itself to maize.

A single bean seed may be attacked by 25 larvae in one generation, and the generations succeed each other very rapidly. The cotyledons become a mass of debris of no value as food. Even when infestation is slight the beans suffer heavily. It frequently happens that the beans cannot be sold and have to be thrown away or given to animals. In the province of Pisa and other districts the damage has been so heavy that some farmers have had to give up growing dwarf beans.

From a point of view of reproduction even, beans attacked by the weevil cannot be used as seed. An experiment carried out by the author in the spring of 1917 with dwarf beans gave the following results:—

Condition of dwarf beans		Number of beans sown	Number of beans germinated	Percentage of germination
Not attacked by		50	42	84 %
	1 generation . . . . .	50	22	44 "
	2 generations . . . . .	50	24	48 "
	3 " . . . . .	50	10	20 "
	4 " . . . . .	50	3	6 "
	5 " . . . . .	50	0	0 "
Percentage of unattacked beans which germinated . . . . .				84 %
Percentage of beans attacked by the weevil which germinated . . .				23.6 %
Percentage of beans attacked by the weevil which were destroyed .				76.4 %

Moreover, plants from seed attacked by the insect are much less resistant and subject to disease, besides giving a much lower yield of inferior quality.

*A. obtectus* has an efficacious enemy in the mite *Pediculoides ventricosus* (Newp.), but, to the author's knowledge, it has in Italy no natural enemy among the insects. The mite mostly attacks the newly-hatched

larvae, but may also attack adult larvae and pupae, although their surroundings make this more difficult. The eggs themselves are sought for by the mite, which eats their contents. It must, however, be pointed out that if the action of this *Pediculoides* is really useful, it may, during the transport and handling of infested seed, attach itself to the skin of those who manipulate the beans and cause more or less serious pathological troubles.

The artificial method of control most widely recommended in America is based on the use of bisulphide of carbon fumigations when the adults of the first and second generations appear, in the same manner and proportions as those required for wheat or other cereals. Another method, which the author found much more preferable for dwarf beans grown for food, is to put the beans attacked in an oven or drying room at a temperature of about 60°C.

607 - *Hypothenemus ritchiei* n. sp., a New Scolytid Injurious to Dried Sweet Potatoes in Jamaica. — SAMPSON, WINN, in the *Bulletin of Entomological Research*, Vol. VIII, Pt. 3-4, p. 295. London, February, 1918.

The paper gives a morphological description of the scolytid *Hypothenemus ritchiei* n. sp., found by Mr. A. H. RITCHIE, Government Entomologist for Jamaica.

The beetle causes serious damage to dried sweet potato chips. It is not yet known whether it attacks other products.

608 - A New Weevil Pest of Sweet Potatoes in Jamaica. — MARSHALL, GUY, A. K., in the *Bulletin of Entomological Research*, Vol. VIII, Pt. 3-4, pp. 269-272 + 1 Fig. London, February, 1918.

The Imperial Bureau of Entomology recently received from Mr. A. H. RITCHIE, Government Entomologist in Jamaica, specimens of a weevil which had caused serious injury to tubers of sweet potato. The insect, which belongs to the sub-family *Cryptorhynchinae* is a species new to science and is described under the name of *Palaeopus costicollis*.

According to Mr. RITCHIE the damage done by this weevil to sweet potatoes is similar to that done by *Euscepes batatae* Waterh., common in the West Indies and known there as "scarabee". As these two insects may easily be confused by untrained observers, Mr. RITCHIE considers it very probable that damage attributed to *E. batatae* has been caused by *P. costicollis*.

The author found in the British Museum two other specimens of the genus *Palaeopus*, one from St. Vincent and the other from Grenada. They are specifically distinct from the Jamaican species and from each other, and, as their habits are probably similar to those of *P. costicollis*, the author describes them in his paper under the names of *P. grenadensis* n. sp. (weevil from Grenada), and *P. subgranulatus* n. sp. (weevil from St. Vincent).

609 - Insect Parasites of the Cacao Tree and other Cultivated Plants in São Thomé. — DE SCABRA, A. F., in *Mémoires publiés par la Société portugaise des Sciences naturelles*, Vol. III, Pt. 1, pp. 1-28 + 24 Figs. + 1 Plate. Lisbon, 1917.

With the help of material obtained from various parts of São Thomé the author has collected in his paper a series of observations on the insect

parasites of cultivated plants in the island. The study pays particular attention to scale insects.

I. — A morphological description is given of a coccid which, with due reservation, the author identifies as *Aspidiotus trilobitiformis* Green. This species shows preference for cacao leaves, and is found ranged with great regularity along the main veins; the females are relatively rare on the upper surface, whereas, on the lower surface, the males are very rare.

According to information supplied by the director of the Perserverança farm, the damage caused by the insect is of less importance than that caused by certain cryptogamic diseases. The effect is first seen at the ends of the branches, which gradually dry up, so that, in two or three months, the plant loses all its leaves. Sometimes cutting the branches attacked prevents the development of the parasite, but this is not always the case and infestation spreads with great rapidity. The cut branches should be destroyed immediately near the tree.

The bailif of the Bindá farm states that trees from four to six years old suffer most. The attacks of the coccid assume great importance on the Uba Budo farm; production there is almost nil.

Spraying with petroleum emulsion and other insecticides has been attempted, but its practical use is very difficult on account of the thick vegetation of the island which sometimes makes access to the plants impossible. Good results are hoped for from the propagation of fungoid parasites of the scale; experiments on this subject have already been made.

II. — The coccid *Lecanium viride* has been reported in the island, from specimens received from Peserverança farm, as a serious parasite of coffee; it is accompanied by its greatest natural enemy, *Cephalosporium Lecanii* Zimm. As this latter is fairly common in São Thomé, the author believes that, considering the very favourable climate, it would be easy to propagate it on a large scale. Experiments in the cultivation of this fungus have already been made in the island. The presence of this *Cephalosporium* may explain why a coffee plantation on the Perseverança farm which was severely attacked by the coccid in October, 1916, did not suffer serious damage. The fungus may be best disseminated by the method used in Ceylon, by which leaves bearing coccids attacked by the parasite are introduced into the plantations where *Cephalosporium* is non-existent or very rare; these leaves may be pinned on to those of plants to be protected against the attacks of the insect.

III. — A third note is confined to *Aspidiotus articulatus* Morgan and *Asp. palmarum* Morgan and Cockerell, neither of which occur in large numbers in the island but live at the expense of many wild and cultivated plants (coffee, *Ficus* sp.?, *Carica Papaya*). One of the wild plants particularly attacked by *Asp. articulatus* is an orchid, locally called "herba pega pega", which has been identified as *Megaclinium falcatum*.

*Asp. palmarum* is very abundant on the Uba Budo and Perseverança farms on *C. Papaya* and on *Ficus* sp.?. It is also found on many other native plants, but rarely on the cacao tree.

IV. — *Lecanium nigrum* Nictner is another parasite of coffee in the island, and is also very common on the large leaves of *Ficus* sp.? (Perceverança farm). The young larvae in particular are attacked by a fungus. The dimensions, shape and colour of this species vary; on the leaves attacked by it the author found a large number of specimens of *Asp. trilobiformis* and *Diaspis* sp.

V. — Among the most abundant parasites of coffee at São Thomé is the coccid *Orthezia insignis* (Douglas), which also attacks other plants. The author received from the Perceverança farm leaves completely covered with this insect which, according to the reports received, attacks in a general way the young buds, branches and stem, but seems to prefer the terminal bud of the plant. The coccid is found both on the upper and lower side of the leaf; sometimes it is found round the edge of the leaf. The branches attacked by the scale which were sent to the author for examination were found to be almost covered with a fungus (*Capnodium Coffeae* ?) the importance of which in São Thomé may be compared with that of *Capn. Citri* in Europe; the damage done when it attacks the young buds is well known. *O. insignis*, then, is a parasite dangerous, not only on account of the damage it does itself, but also because its secretions may form a favourable medium for the development of the fungus.

VI. — White ants are considered very injurious, especially in old cacao plantations. In a climate such as that of the island consideration must be given not only to the consequences to the plant itself of the galleries made by the ants, but also to the fact that the open galleries in the trunks, roots, or even the soil, prepare the way for numerous cryptogamic diseases.

Through the research of Prof. E. SILVESTRI six species of white ants are known in São Thomé, and seven in Princes' Island. The first specimens sent from São Thomé and examined by the author belonged to *Neoterme gestri* F. Silvestri, known locally as "Salalé"; numerous specimens of this species were sent from Binda in June, 1916. Another variety from the same locality, of which only very few specimens were received belonged to the s. sp. *theobromae* Dens. of *Microcerotermes parvus* Hav. It is known in the island by the name of "formiga branca". *N. gestri* is one of the greatest pests of the cacao plantations at Uba Budo. The infested plants are said to revive if cut at the base so long as they are not attacked by disease. At S. João dos Angolares, *N. gestri* also attacks old plantations, entering the trunks by badly closed pruning cuts.

In August, 1916, the author received the first notice of damage done by *N. gestris* as being of great importance in the occurrence of cryptogamic diseases. The old plants suffered most, especially those with broken branches which had not been carefully treated with protective substances. According to the author the insect always enters the trunks in the upper part, but the nests are always underground. The bailif of the Binda farm also observed that the insect enters the trunk in the upper part and shows a tendency to descend, never to ascend the branches. This observation may be of value in controlling the pest.

610 — **The Most Common Deformities Caused by Animals on Fruit Trees in Sicily.** — DE-STEFANI, T., in *Annali della R. Stazione di Agrumicoltura e Frutticoltura, Acireale*, Vol. IV, pp. 147-170 + 1 Plate. Acireale, 1917.

The aim of the paper under review is to draw attention to the numerous and complex deformities of animal origin of which horticulturists ignore the cause. Insects and other invertebrates (arachnida, worms) are the causes of these deformities. They belong chiefly to the hemiptera, and, more especially, to the aphids, and, in decreasing order of importance, to the diptera, with the family of *Cecidomyiidae*, the lepidoptera, with 4 representatives, the coleoptera, with 2, the hymenoptera and neuroptera, with only one representative. The greater part of the species causing deformities on fruit trees, however, belong to the arachnida, especially the mites, which form the family of *Eriophyidae* and certain species of nematodes, belonging to the family of anguillulidae.

In order to draw up a guide by which tree growers may recognise deformities caused by animals, the author gives a brief morphological descriptions of such injuries most common in Sicily, together with an indication of the specific agent.

611 — ***Olethreutes variegana*, a Microlepidopteron Injurious to Fruit Trees, in Italy.** — SARRA, A., in the *Bollettino del Laboratorio di Zoologia generale e agraria della R. Scuola superiore d'Agricoltura in Portici*, Vol. XII, pp. 175-187. Portici, 1918.

The species described exists in central and southern Europe, Livonia, Finland, Sweden, and Asia Minor. A morphological description is given of the egg, larva, and pupa, followed by the biology of the perfect insect and the larva.

In the districts of Santeramo Colle (Apulia) and Matera (Basilicata), the larva lives on the common medlar, almond, mahaleb cherry, plum, apricot, and apple trees. The author found it from March 15 to April 30. Medlar and plum trees are attacked the most. Other host-plants are: *Prunus avium* L., *P. Cerasus* L., *P. insititia* L., *Pyrus communis* L.

The parts of the medlar which suffer most are the leaves, the floral buds, and the small fruit, which is covered with holes or entirely destroyed. On the plum, apple, apricot and mahaleb cherry trees, only the leaves are attacked. The leaves of the almond are attacked, and sometimes, though rarely, the young fruit, which is pierced and filled with the remains of the seed involucre. Experiments have shown that a larva fed on almond leaves will eat almost two whole ones in three days so that it may do a fair amount of damage to a medium sized tree. In the company of other tortricids, however, and especially if low trees, such as the medlar, are attacked, the injury done by *O. variegana* may be very serious.

According to the author the insect is controlled by five parasitic hymenoptera — the chalcid *Copidosoma* sp., the braconid *Accogaster quadridentatus* Wesm., *Apanteles longicaudis* Wesm., *Macrocentrus thoracicus* Nees, and the ichneumonid *Pristomerus vulnerator* (Pauz.) Curtis.

The chalcidid lays an egg in that of *O. variegana*; the author noticed that 4 % of the larvae of the microlepidopteron contained parasites.

*A. quadridentatus* lays its egg in the larva of the tortricid, and was found in 20 % of them. *Ap. longicaudis* also lays an egg in the larva of *O. varie-*

*gana*, being found in 6 %. The larva of *M. thoracicus* is an endophagous parasite of the larva of the microlepidopteron; the specimens of the braconid examined by the author represented 1 % of the larvae of *O. variegana*. *Pr. vulnerator*, the larva of which is also an endophagous parasite of that of the tortricid, was observed in 4 % of the latter.

When it is easy to collect the larvae the natural method of controlling *O. variegana* is to be recommended, and should be carried out in April. The larvae are enclosed and bred in boxes placed in the open, and covered with a wire netting with a mesh not exceeding 2 mm., so that the parasites may pass, but not the adult microlepidoptera. When artificial control is necessary spraying with 1 % lead arsenate paste or ½ % lead arsenate powder may be recommended.

612 — **The Campaign against the Codlin Moth (*Carpocapsa pomonella*) in Cyprus, in 1917.**— *The Cyprus Agricultural Journal*, Vol. XIII, Pt. 1, p. 13. Nicosia, 1918.

In accordance with His Excellency's Order of April 25, 1917, a campaign was started in 1917 in Cyprus, against the codlin moth, which, for some time, had caused much injury to apple, pear, quince and walnut trees. The area of operations included some 26 villages in the Pitsillia of which Agros was the centre.

The treatments applied were:— a) lime-dressing; b) daily collection and destruction of fallen fruit; c) bandaging the trunks with grass or cloth bands.

The application of grass bands was not very successful. As many as 80 000 trees were lime dressed.

613 — **Strong Lime-Sulphur Spraying against *Chrysomphalus dictyospermi*, a Coccid Injurious to Citrus.**— SAVASTANO, L., in *R. Stazione sperimentale di Agrumicoltura e Frutticoltura in Acireale*, Bollettino No. 30, pp. 3. Acireale, 1917.

Without modifying in any way the formula of the lime-sulphur mixture used by the "R. Stazione di Agrumicoltura e Frutticoltura" of Acireale (lime, 2 lb.; sulphur, 4 lb.; water, 2 gall.) attempts were made to ascertain whether it were possible to increase the insecticidal power of the dilute mixture, i. e., the percentage, in order to obtain a greater and more rapid effect against the scale *Chrysomphalus dictyospermi* ("bianca-rossa" of citrus).

The results obtained from the various experiments carried out under the supervision of the author may be summarised as follows:—

- 1) The trees may be sprayed in September and at the beginning of October with a 10 % mixture, density 1.25, to obtain better results;
- 2) 10 % must not be exceeded as the plant may be scorched;
- 3) the spraying must be even and very fine but not very abundant, as, if so, even in percentages below 10, it may cause scorching;
- 4) the percentage may be raised to 12 % when the *Chrysomphalus* attack is severe, and when the fruits are few, completely infected, and valueless.

Strong treatment is advantageous in the case of bad attacks or when spraying at the correct time has been neglected. Orange trees — the fruit of which would lose all value if scorched — should, however, only be treated if infection is so serious that it is the tree itself which must be saved. As a general rule it may be said that only lemon trees should be so

treated ; the fruit which is thrown out might be used for obtaining essence or citrate, as lemons when slightly scorched are in no way spoilt for the extraction of these two products.

614 — Observations on *Coeliodes ruber*, a Coleopteron Injurious to Hazel Trees in Italy. — SILVESTRI, F., in *Bollettino del Laboratorio di Zoologia generale e agraria della R. Scuola superiore d'Agricoltura in Portici*, Vol. XII, pp. 155-174 + 14 Figs. Portici, 1917.

Before 1904 the damage done to hazel trees by the coleopteron *Coeliodes ruber* (Marsh) had not been studied. In that year TROTTER drew attention to the injury done to the male inflorescences of the tree by the larvae of this insect. The question was not taken up again till 1914, when great loss of nuts was reported at Vico di Palma, Campania (province of Caserta) though the attacks of *C. ruber*. The author, therefore, undertook a study of the insect, and, during the last three years, continued his studies not only in the Nola district, but also in the Avellino district.

After giving a detailed morphological and biological description of the insect the author points out that *C. ruber*, which is only known to attack hazel trees, is shown by the catalogues of coleoptera to exist throughout Europe. In Italy the author found it frequently in the districts of Avellino and Nola, as well as round Naples, he has also seen specimens from Capri and found a few in Sicily (S. Piero Patti).

The adults attack the leaves, piercing holes in the blade or in the petiole. They also attack the buds by hollowing a hole in the axis, a few centimetres from the point, the nuts, by piercing the shell and part of the kernel, which they eat, the catkins, by piercing them and eating some of the flowers ; they may also attack the floral and leaf buds. The attacks result in the drying up of the pierced leaves, buds and young nuts, and the destruction of some of the flowers of the catkin. The larvae also destroy some of the male flowers.

The most serious damage caused by the adults and larvae would appear to be that done to the petiole and the axis of the buds. In reality, however, if this damage is compared with the number of insects found in three years and the number of leaves and buds on a plant, it may be considered negligible. This also applies to the damage to the catkin, for, since the catkin is not entirely destroyed, there remains a plentiful supply of pollen. If, contrary to the author's observation, the greater part of the catkins were destroyed, atrophy of the female flowers through lack of fertilisation, such as TROTTER feared, might be expected.

The worst damage by *C. ruber* observed by the author and complained of by growers from 1914 to 1917, is that done to the young nuts which, if pierced by the insect once only, immediately dry up. Such injury has been frequently observed in the Nola district, where the S. Giovanni, an early variety, the fruit of which, at the end of May, is already 5 mm. long and 7 mm. broad is the most common variety of hazel.

In field observations the author frequently saw spiders of the family *Thomisidae*, *Xisticus lanio* C. Koch, capture adult *Coeliodes* for food. Others also probably attack the insect, but, judging by the number of *C. ruber* on the trees, their action does not appear to be very efficacious.

From 1914 to 1917 the author observed numerous eggs, larvae and

pupae of *C. ruber*, but only noticed one parasitic hymenopteron (fam. *Ichneumonidae*) which laid its eggs in the larvae which was later eaten by the insect hatched from the egg while it was underground in the cell in which its metamorphosis should have taken place. The author calls the new hymenopteron *Thersilochus coeliodicola*.

The only efficacious and practical artificial method of control is the collection of the adult insects during the first fortnight in May. This should be done in the morning by means of a cloth stretched under the plant, the branches of which are shaken by hand or with hooked sticks. By this means are destroyed at the same time many nut weevils (*Balaninus nucum* [L.]), another curculionid which occurs on hazel trees at the same period and often does great damage by attacking the nuts. If *C. ruber* is not collected in May it should be collected at the end of September or the beginning of October.

615—*Coleophora fuscadinella*, a Microlepidopteron Injurious to Birch and other Trees in Sweden. — KEMMER, N. A., in *Kungl. Landbruks Akademien Handlingar och Tidskrift*, Year LVII, No. 7-8, pp. 637-660 + 30 Figs. + Bibliography of 15 Publications. Stockholm, 1917.

In 1914 the conditions in Sweden were very favourable to the development of *Coleophora fuscadinella* Zell. ("Björksäckmalen") the numerous larvae of which, in 1915 and 1916, caused considerable damage to birch trees by attacking their foliage. Other trees besides birch were attacked — pear trees, apple trees, *Sorbus Aucuparia*, oaks, etc. — with such violence that at times the whole tree, or a greater part of it, dried up.

The districts which suffered most were those of Östergötland, Jonköping, Kronoberg, and Kalmar, whereas in the Malmöhus district the attacks were very limited, probably because there are few birch trees there. More or less wide-spread attacks were also reported from the districts of Älfsborg (Vänersborg), Örebro (Bofors), Sörmlands (Stenstorp), Kopparberg (Falun), and Norrbotten (Luleå). Copulation and oviposition occur towards the end of June and the beginning of July. The larvae hatch after about a fortnight and live on the leaves, eating the tissues. They hibernate on the branches of the host (near the buds) in a shelter made of bits of leaf joined by silky threads. Hibernation ends in May, and it is in this month and in June that the adult larva, before pupating, does the greatest damage.

In 1917 the pest was decreasing rapidly, certainly largely on account of the many natural enemies of the insect which have been reported in various parts of Sweden. Amongst them are:—*Hemiteles* sp. ♂; *Itoplectis maculator* F. ♂ and ♀; *Glypta* sp. ♂; *Phobocampa* sp. ♂; *Agathis varipes* Th.; *Apanteles sodalis* (?) Hall.; *Apanteles* sp.; *Pezomachus instabilis* Först.; *Angitia* sp.; *Apanteles corvinus* Reinh.; *A. xanthostigmus* Hal.; *A. mesoxanthus* Ruschka n. sp.; *Microdus mediator* Nees; *Habrocytus radialis* Thoms.; *Dibrachys boncheanus* Ratz.; *Elasmus viridiceps* Th.; *Cirrospilus pictus* Nees; *Miotropis sulcicrista* Th.; *Chrysocharis elongata* Th.; *Geniocercus charoba* (Walk). Kurdjium.

*A. mesoxanthus* n. sp. was reported from Lamhult (Kronoberg) and from Luleå.

616 - The Nutritive Value of Yeast, Polished Rice and White Bread as Determined by Experiments on Man. — FUNK, CASIMIR, LYLE W. G. and MC CASKEY, DONALD, in cooperation with CASPE, JOSEPH and POKLOP, JOSEPH, in *The Journal of Biological Chemistry*. Vol. XXVII, No. 1, pp. 173-191, Bibliography of 23 publications, Baltimore, Md., 1916.

RURAL  
HYGIENE

Concerning the problem of a protein minimum, there are two distinct theories: ABDERHALDEN and his school claim that, as the composition of the body, and especially of the blood proteins, is so different from food proteins, the best protein minimum can be obtained by feeding proteins of the same species; on the contrary, HINDHEDE was able to show that, when using potatoes as practically the only food, 1 gm. of the absorbed potato nitrogen is equivalent to 1 gm. of body nitrogen. One cause of discrepancy of opinion on this question is that the importance of vitamins in metabolism has been overlooked in most recent experiments. There must be a fixed ratio between the vitamine content and the carbohydrate: if this ratio is destroyed, disordered nutrition of the tissue cell occurs (1).

Considering that heretofore the vitamins in foods have been disregarded in all nutrition experiments on man, the writers have performed on four normal men the experiments here described, in order to determine primarily the food value of a vitamine-free diet as compared with one containing vitamins. The results are summarized as follows:—

Yeast cannot very well be recommended as a sole protein source, as a large part of the yeast nitrogen apparently has no food value. It is badly assimilated and occasions a rise of uric acid figures in the blood. The

(1) In a recent paper of ABDERHALDEN, FODOR and RÖSE (*Archiv gesammter Physiologie* Vol. CLX, p. 511, 1915) we find a comparative study of the food value of potatoes as compared with whole bread and white bread. The protein minimum was lowest in the case of potatoes (4.5 gm. nitrogen), higher with whole meal bread (7.6 gm. nitrogen), and still higher with white bread (9 gm. nitrogen). a possible reason being that the white bread was deficient in vitamins.

amount of nitrogen which would be fully adequate in the form of potatoes was proved to be insufficient with yeast. This also applies to the experiments with white bread and white rice. The writers were unable to get a positive nitrogen balance by the addition of vitamine.

In this field of nutrition research the authors' studies have by no means enabled them to pronounce a verdict that yeast possesses no value in dietetics.

Problems of personal idiosyncrasy as to the taste of foods, methods of administration suitable for the particular individual, questions of amino-acid synthesis after the yeast protein and purine bases have entered the organism, are all complex factors which must be taken into consideration.

**617 - The Digestion of Aleurone Cells Incorporated in 85 % Bread; Experiments Made in France.** — LAPICQUE, L. and LEGENDRE, A., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXI, No. 5, pp. 217-220. Paris, March 9, 1918.

The envelope which encloses the wheat seed, the fragments of which, more or less mixed with flour form the bran, contains on its inner surface the layer of aleurone cells. The authors' experiments confirm the fact, shown first by POGGIALE, then by AIMÉ GIRARD that the eminently digestible and nutritive contents of these cells are protected from the action of the digestive ferments by the cellulose walls. The authors found aleurone cells in the faeces of men and dogs after the ingestion of wheat which had been roughly ground, chopped, or rolled after having been softened by soaking. The authors believe this fact should be extended to certain herbivorous animals, as it was also observed in the guinea-pig and rabbit.

This resistance to digestive ferments is, however, clearly connected with the integrity of the walls. Baking does not affect the result, but, nevertheless, by rupturing the walls mechanically it is possible to render the nutritive substances accessible to the action of the digestive juices. In bran of the first milling which does not pass a No. 70 sieve, the walls of the layer of aleurone cells are intact, and the aleurone thus resists baking and digestion. If, however, the bran is re-milled so that most of it passes through a No. 100 sieve, the walls of the aleurone cells retained by a No. 200 sieve are still intact, but nearly all of these break during baking, and, after digestion, only the empty walls are found in the faeces, the contents having been digested, as the authors proved experimentally. It is for this reason that in bread made with 85 % flour, the bran of which is mixed with fine flour and re-milled (as decreed in France at the present time) without any systematic preparation, the greater part of the aleurone cells is digested, thus increasing the total food value of the bread by 1 to 2 %.

**618 - Physiological and Pharmacological Studies on Coal Tar Colours. Experiments with Fat-Soluble Dyes.** — SALANT, WILLIAM and BENGIS, ROBERT (Pharmacological Laboratory of the Bureau of Chemistry, U. S. Department of Agriculture, Washington), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 2, pp. 403-427, Bibliography of 20 publications. Baltimore, Md., 1916.

Although synthetic dyes have played an important part in the study of biology and medicine, the behaviour of many of these compounds in the body is still imperfectly understood and the action of some of them is

entirely unknown. Owing to their extensive employment in numerous industries, and especially in the preparation of foods, this lack of satisfactory information frequently proved to be a matter of serious import as questions regarding their effect on health were often raised, but no definite answer could be given in the present state of our knowledge.

The recognition of the need of a more intimate acquaintance with the reactions produced in the body by these compounds formed the starting point of these investigations.

The present report embraces the results of experiments with fat-soluble dyes. The following compounds were employed, the commercial names most commonly used and their numbers in SCHULTZ's tables are given at the right: —

Benzeneazo- $\beta$ -naphthyl-amine . . . . .	Yellow A. B. **	Benzeneazodimethylaniline Butter Yellow 32*
Tolueneazo- $\beta$ -naphthyl-amine . . . . .	Yellow O.B. **	Benzeneazophenol . . . . Oil Yellow
Benzeneazobenzeneazo- $\beta$ -naphthol . . . . .	Sudan III 223*	Benzeneazoresorcinol . . . Sudan G. 351*
Benzeneazo- $\beta$ -naphthol . . . . .	Sudan I 36*	Aminoazobenzene . . . . Spirit Yellow 31*

\* SCHULTZ, *Farbstofftabellen*, Berlin, 1914.

\*\* HELLER and MERTZ

Rabbits were mainly used as subjects of the experiments, but observations with some dyes were also made on a few cats and on rats. The results are summarized as follows:—

Oil-soluble and water-insoluble dyes administered to different animals were eliminated in the urine and in the bile. Elimination in the urine was usually inhibited in poisoning with zinc or oil of chenopodium.

Two of the compounds of benzeneazophenol and benzeneazoresorcinol, which were isolated from the urine of rabbits, proved to be conjugated with glucuronic acid.

Most of the dyes were deposited in the adipose tissues; staining of the nervous tissue, the kidney, and muscle was also observed in some experiments.

Ten to 15 hours after intravenous injection of 25 mgm. per kilo of benzeneazoresorcinol, the dye was still present in the blood.

The toxicity of the different dyes was not pronounced even when larger doses were administered.

620 — Report on the Agricultural Control Stations of Holland for the Year 1916-1917.

— Communication from the Dutch Minister for Agriculture, in *Verslagen en Mededeelingen van de Directie van den Landbouw*, 1917, No. 4, pp. 88 + Tables. The Hague, 1917.

By Royal Decree of September 6, 1915, the Royal Agricultural Stations of Holland ("Rykslandbouwproefstations") were divided into 2 classes: experiment stations and control stations. The experiment stations are at Groningen and Hoorn; their reports are published regularly under the title

EXPERIMENTAL  
AND  
ANALYTICAL  
WORK.

of "*Verlagen der landbouwkundige onderzoekingen van de Rykslandbouw-proefstations*". The bulletin under review contains the reports, for the year 1916-1917, of the following control stations: — *Wageningen*, control of live stock feeding stuffs; *Maastricht*, control of manures; *Goes*, control of remedies against fungi, etc.; *Wageningen*, seed control.

**WAGENINGEN STATION FOR THE CONTROL OF FEEDING STUFFS.** — From June 1, 1916 to June 1, 1917, 2467 samples were controlled by making 9895 analyses. The report of this station records a certain number of cases of falsification, chiefly with regard to compound or concentrated food stuffs, the majority of which are made up of products of absolutely no feeding value for live stock, but which are nevertheless sold at excessive prices; this is why, whenever it is possible to obtain simple feeding stuffs, their purchase should be advised in preference to that of any compound feed.

**MAASTRICHT CONTROL STATION.** — From June 1, 1916 to June 1, 1917, 10027 samples of manures were controlled, 15983 analyses being made. As with the preceding station, numerous cases of falsification were detected; this station also advises farmers who wish to buy artificial manures, in spite of the high price, to require that the nitrogen should be present in either ammoniacal or nitric form and that the phosphoric acid and potassium should be water soluble. On account of the lack of homogeneity of large stocks of fertiliser the station advises the taking of several samples and it distributes a circular free of charge showing how the samples are best taken.

**GOES CONTROL STATION.** — From October 1, 1916 to June 1, 1917, 2079 samples were examined, including 86 anticyptogamic substances and remedies against parasites, 1468 agricultural products, 243 soil and 58 water samples, 129 dairy products and 32 miscellaneous samples.

**WAGENINGEN SEED CONTROL STATION.** — From June 1, 1916 to June 1, 1917, 3783 samples were controlled, thus giving an increase of 35% on the previous year's number. Owing to present conditions, the quality of the seeds was very variable. Regional agricultural committees usually judge crops on the spot, calling "seed suitable for sowing" ("voor den zaai geschikt zaad") those that fulfil the required conditions and are suitable for cultivation; those judged in this way by the official district agricultural agent or a representative chosen by him are called "first quality seeds". Judging on the spot is too uncertain and can only give doubtful results; for this reason it is now well understood that accurate and rigorous control is more than ever necessary at the present moment.

## CROPS AND CULTIVATION.

### AGRICULTURAL METEOROLOGY

621 — **Method for Calculating the Length of the Growing Season at any Period of the Year and in any Locality.** — REED, G. W., in the *Monthly Weather Review*, Vol. XLIV, No. 9, pp 509-512. Washington, 1916.

To calculate the length of the growing season, it is customary to count the number of days elapsed between the average date of the last destructive spring frost and that of the first killing autumn frost, but, in accepting these average dates as they are the agriculturist would run great risk.

To shed light on the question, the data may be examined that have been collected at the Keokuk Station (Iowa, U. S. A.) where it was found that the average date of the last killing spring frost was April 15, that of the first killing autumn frost was October 15, while the average length of the season without frosts (growing season) was 183 days.

On analysing the statistics collected annually from 1872 to 1914, it will be noted that, out of 43 years, 20 had spring frosts after April 15, so that the degree of safety with regard to frost would be only 53 % in relation to the average date. On the other hand the statistics for the whole of the United States tend in general to confirm the fact that crops suffer from spring frosts every two years (50 % security) and at a date after the average one of the last killing frost.

As for killing autumn frosts, they appeared in 21 years out of 43 before October 15, so that the degree of security, in relation to the average date, varies round 50 %.

Out of the 20 years without killing spring frosts after April 15, there were 8 with autumn frosts before October 15, so that only 12 years of the entire period, or 28 %, really had 183 days without killing frosts, counting from the average date of the last killing spring frost.

To avoid risk of frosts, the farmer should sow or plant at a date sufficiently late so as to be sufficiently safe from spring frosts, but not so late as to prevent ripening before there is risk of autumn frosts. Thus, as has been already seen, the knowledge of the average length of the frostless season alone does not suffice, nor does it correspond to the desired aim.

The article under consideration gives data from which can be calculated the probably available growing season (*i. e.* without frosts) includey between a spring period and an autumn period where the degree of security from frosts is very high, in order to forecast a good harvest. The symbols used are as follows:—

$s$  = date of the last killing spring frost in any one of the years under consideration.

$a$  = date of the first killing autumn frost in any one of the years under consideration.

$l$  = number of days elapsed between  $s$  and  $a$ .

$A_s$  = average date of the last spring frost.

$A_a$  = average date of the first autumn frost

$A_l$  = average number of frost-free days

$A'_p$  = an arbitrary number near to  $A_p$ ;  $d_s$  = difference between  $s$  and  $A'_s$ .

$A'_a$  = an arbitrary number near to  $A_a$ ;  $d_a$  = difference between  $a$  and  $A'_a$ .

$A'_l$  = an arbitrary number near to  $A_l$ ;  $d_l$  = difference between  $l$  and  $A'_l$ .

$n$  = number of days of observation.

$\sigma_s, \sigma_a, \sigma_l$  = average differences from  $s, a$ , and  $l$ .

$\Sigma d_s, \Sigma d_a, \Sigma d_l, \Sigma d_s^2, \Sigma d_a^2, \Sigma d_l^2$  = algebraic sums of  $d_s, d_a, d_l, d_s^2, d_a^2, d_l^2$ .

of "*Verslagen der landbouwkundige onderzoekingen van de Rykslandbouwproefstations*". The bulletin under review contains the reports, for the year 1916-1917, of the following control stations: -- *Wageningen*, control of live stock feeding stuffs; *Maastricht*, control of manures; *Goes*, control of remedies against fungi, etc.; *Wageningen*, seed control.

**WAGENINGEN STATION FOR THE CONTROL OF FEEDING STUFFS.** — From June 1, 1916 to June 1, 1917, 2467 samples were controlled by making 9895 analyses. The report of this station records a certain number of cases of falsification, chiefly with regard to compound or concentrated food stuffs, the majority of which are made up of products of absolutely no feeding value for live stock, but which are nevertheless sold at excessive prices; this is why, whenever it is possible to obtain simple feeding stuffs, their purchase should be advised in preference to that of any compound feed.

Judging on the spot is too uncertain and can only give doubtful results; for this reason it is now well understood that accurate and rigorous control is more than ever necessary at the present moment.

## CROPS AND CULTIVATION.

AGRICULTURAL  
METEOROLOGY

621 — **Method for Calculating the Length of the Growing Season at any Period of the Year and in any Locality.** — REED, G. W., in the *Monthly Weather Review*, Vol. XLIV, No. 9, pp. 509-512. Washington, 1916.

To calculate the length of the growing season, it is customary to count the number of days elapsed between the average date of the last destructive spring frost and that of the first killing autumn frost, but, in accepting these average dates as they are the agriculturist would run great risk.

To shed light on the question, the data may be examined that have been collected at the Keokuk Station (Iowa, U. S. A.) where it was found that the average date of the last killing spring frost was April 15, that of the first killing autumn frost was October 15, while the average length of the season without frosts (growing season) was 183 days.

On analysing the statistics collected annually from 1872 to 1914, it will be noted that, out of 43 years, 20 had spring frosts after April 15, so that the degree of safety with regard to frost would be only 53 % in relation to the average date. On the other hand the statistics for the whole of the United States tend in general to confirm the fact that crops suffer from spring frosts every two years (50 % security) and at a date after the average one of the last killing frost.

As for killing autumn frosts, they appeared in 21 years out of 43 before October 15, so that the degree of security, in relation to the average date, varies round 50 %.

Out of the 20 years without killing spring frosts after April 15, there were 8 with autumn frosts before October 15, so that only 12 years of the entire period, or 28 %, really had 183 days without killing frosts, counting from the average date of the last killing spring frost.

To avoid risk of frosts, the farmer should sow or plant at a date sufficiently late so as to be sufficiently safe from spring frosts, but not so late as to prevent ripening before there is risk of autumn frosts. Thus, as has been already seen, the knowledge of the average length of the frostless season alone does not suffice, nor does it correspond to the desired aim.

The article under consideration gives data from which can be calculated the probably available growing season (*i. e.* without frosts) includey between a spring period and an autumn period where the degree of security from frosts is very high, in order to forecast a good harvest. The symbols used are as follows :—

$s$  = date of the last killing spring frost in any one of the years under consideration.

$a$  = date of the first killing autumn frost in any one of the years under consideration.

$l$  = number of days elapsed between  $p$  and  $a$ .

$A_s$  = average date of the last spring frost.

$A_a$  = average date of the first autumn frost

$A_l$  = average number of frost-free days

$A'_p$  = an arbitrary number near to  $A_p$ ;  $\bar{d}_s$  = difference between  $s$  and  $A'_s$ .

$A'_a$  = an arbitrary number near to  $A_a$ ;  $\bar{d}_a$  = difference between  $a$  and  $A'_a$ .

$A'_l$  = an arbitrary number near to  $A_l$ ;  $\bar{d}_l$  = difference between  $l$  and  $A'_l$ .

$n$  = number of days of observation.

$\sigma_p \sigma_a \sigma_l$  = average differences from  $s$ ,  $a$ , and  $l$ .

$\Sigma d_s, \Sigma d_a, \Sigma d_l, \Sigma d_s^2, \Sigma d_a^2, \Sigma d_l^2$  = algebraic sums of  $d_s, d_a, d_l, d_s^2, d_a^2, d_l^2$ .

In Table I are reproduced figures, quoted from those obtained at Keokuk for the first and last quinquennial periods of 1872 to 1914.

TABLE I. — *Data on Spring and Autumn Frosts at Keokuk*

Year	Last spring frost			Last autumn frost			$d_s, d_a$	Frostless season		
	$s$	$d_s$	$d_s^2$	$a$	$d_a$	$d_a^2$		$l$	$d_l$	$d_l^2$
1872 . . . .	April 16	+ 1	1	October 6	— 9	81	— 9	173	— 10	100
1873 . . . .	" 25	+ 10	100	" 6	— 9	81	— 90	164	— 19	361
1874 . . . .	" 23	+ 8	64	" 23	+ 8	64	+ 64	183	0	—
1875 . . . .	May 2	+ 17	289	September 18	— 27	729	— 459	139	— 44	1 936
1876 . . . .	April 2	— 13	169	October 7	— 8	64	+ 104	188	+ 55	25
. . . . .										
1910 . . . .	April 25	+ 10	100	October 22	+ 7	49	+ 70	180	— 3	9
1911 . . . .	" 9	— 6	36	" 22	+ 7	49	— 42	196	+ 13	169
1912 . . . .	" 3	— 12	144	" 23	+ 8	64	— 96	203	+ 20	400
1913 . . . .	" 13	— 2	4	September 22	— 23	529	+ 46	162	— 21	441
1914 . . . .	" 10	— 3	9	October 27	+ 12	144	— 36	198	+ 15	225
Sums . . .	—	— 30	5 904	—	+ 5	— 6 487	— 1 111	—	+ 85	14 612
Means . . .	April 15	—	—	October 15	—	—	—	183	—	—

The formula :  $\sigma = \sqrt{\frac{\sum d^2}{n} - \left(\frac{\sum d}{n}\right)^2}$  is used for calculating the standard deviation  $\sigma$ . On substituting the values given in Table I for the symbols, we have, for  $\sigma_s$ ,  $\sigma_a$ , and  $\sigma_l$ :

$$\sigma_s = \sqrt{\frac{5904}{43} - 0.49} = 11.7 \text{ days}, \quad \sigma_a = \sqrt{\frac{6487}{43}}; \quad 0.01 = 12.3 \text{ days};$$

$$\sigma_l = \sqrt{\frac{14612}{43} - 0.66} = 18.4 \text{ days}.$$

Once the standard deviation is known, it is easy to find the probability of frost or the degree of safety for any time, by the aid of Table II, based on the theory of probabilities.

TABLE II. — *Determination of the dates corresponding to the various probabilities of frost and to the various degrees of security.*

Probability of frost	Degree of safety	Calculation of the dates	
		Spring	Autumn
50 %	50 %	$A_s$	$A_a$
40	60	$A_s + 0.25 \sigma_s$	$A_a - 0.25 \sigma_a$
30	70	$A_s + 0.52 \sigma_s$	$A_a - 0.52 \sigma_a$
25	75	$A_s + 0.67 \sigma_s$	$A_a - 0.67 \sigma_a$
20	80	$A_s + 0.84 \sigma_s$	$A_a - 0.84 \sigma_a$
10	90	$A_s + 1.28 \sigma_s$	$A_a - 1.28 \sigma_a$

Thus, multiplying 0.52 by 11.7 ( $\sigma_s$ ) and adding the product (nearly 6) to the date April 15 ( $A_s$ ), the date April 21 is obtained, when the probability [621]

of frost is reduced to 30 %, while it is 50 % on April 15. For the autumn a similar calculation is made, but the product obtained is *subtracted* from  $A_s$ .

The degree of safety for a given period as regards frost is obtained by multiplying the degree of safety for the beginning of the period by the degree of safety for the end of the period. Thus, for example, on April 15 and October 15 the degree of safety is 50 %; for the period April 15 - October 15 the degree of safety would be  $0.50 \times 0.50 = 0.25$ , or 25 %, *i. e.*, very close to the value obtained on counting the cases directly.

The agriculturist would run great risks, if he only based his calculations on the average length of the frost-free period. In fact, as is shown in Table II, the degree of 70 % of safety is obtained: in spring, 0.52  $\sigma_s$  days *after* the average date of the last killing frost; in autumn, 0.52  $\sigma_s$  days *before* the average date of the first killing frost — that is, April 21 and October 8 respectively. For the period of 170 days included between these two dates, the degree of security is about 50 % ( $0.70 \times 0.70 = 0.49 = 49$  %). The risk would still be great.

For a crop to succeed, there must be a degree of safety of at least 80 %, that is, there must be at least 4 good years out of 5. In this case, the degree of safety at the beginning and end of the frost-free period must be 90 % ( $0.90 \times 0.90 = 0.81 = 81$  %). In the case of Keokuk, by calculating the value of  $A_s + 1.28 \sigma_s$  and  $A_e - 1.28 \sigma_e$ , the two dates April 30 and October 1, are obtained which have the degree of 90 % safety; this means that, in that locality, the degree of safety is 90 % for the 153-day period included between April 30 and October 1; in other words, as far as risk of frosts is concerned, any crop may be sown and harvested successfully.

622 — **The Relation of Weather to the Amount of Cotton Ginned during Certain Phases of the Harvest.** — KINCER, J. B., in the *Monthly Weather Review*, Vol. XLV, No 1, pp. 6-10, 2 Figs. Washington, 1917.

During the cotton harvest, the U. S. Bureau of Census, Department of Commerce, issues periodical reports as to the cotton ginned during the following harvest periods:— September 1 and 25; October 18; November 1 and 14; December 1 and 13; January 1 and 16.

In order to resolve the question of the influence of weather on the amounts of cotton ginned during these periods, a series of researches was carried out in the cotton belt; the present article discusses the results thus obtained.

The growth of cotton has strictly geographical limitations, established largely by temperature conditions, as the plant requires a mean summer temperature of about 78° F and an average frostless season of about 200 days. The higher the temperature is during the active growing season, principally in May and June, the earlier will be maturity, and the bigger the crop.

For example, Table I gives the data obtained for the State of Oklahoma for the period 1905-1915, as regards the influence of temperature on yield. Column II shows the number of bales, of 500 lb. each, ginned up to October 18, to the nearest thousand bales; thus the first number, 179, shows that, out

of 1000 bales total yield, 179 were obtained up to October 18; this number is 112 less than the average 291. Column III shows the variations from the average. Columns IV, V, VI and VII show the variations from the normal temperature for the period May to August, while Column VIII shows the variations in temperature calculated for the whole period. Column III and Column VIII correspond almost perfectly; when the average temperature of the period May-August is below the normal, the cotton ginned during the first period of the harvest (up to October 18) is below the average and vice-versa.

TABLE I. — *Relations of the temperatures of the period May-August and the cotton ginned during the first period of the harvest in Oklahoma.*

I Years.	II Bales ginned up to October 18.	III Departure from average yield	Temperature departure from normal, in °F				VIII Average daily departure from the normal temperature, May-August in °F
			IV May	V June	VI July	VII August	
1905 . .	179	— 112	+ 0.2	+ 1.8	— 2.8	— 0.1	— 0.9
1906 . .	199	— 92	— 0.1	— 1.4	— 4.2	— 3.1	— 8.8
1907 . .	240	— 51	— 0.8	— 1.4	+ 0.2	+ 2.0	— 6.0
1908 . .	133	— 158	— 0.6	— 1.0	— 2.5	— 0.9	— 5.0
1909 . .	329	+ 38	+ 1.5	+ 0.9	+ 3.3	+ 3.3	+ 6.0
1910 . .	422	+ 131	— 2.2	+ 0.5	+ 2.7	+ 0.1	+ 1.1
1911 . .	397	+ 106	+ 4.0	+ 8.3	+ 0.3	— 0.6	+ 11.4
1912 . .	398	+ 107	+ 3.6	— 2.2	+ 2.9	— 1.2	+ 3.7
1913 . .	391	+ 100	+ 2.8	+ 0.2	+ 3.7	+ 4.8	+ 11.5
1914 . .	451	+ 160	— 0.6	+ 5.4	+ 4.6	— 1.0	+ 8.4
1915 . .	66	— 225	— 1.7	— 2.0	— 2.1	— 7.0	— 12.8
Mean	291						

Data are also given for the States of North Carolina, South Carolina, Georgia, Alabama, Mississippi, Texas and Arkansas.

In Oklahoma, close to the northern limit of cotton, all the negative oscillations, even in very advanced stages of development (July-August), have considerable influence on the plant, whose critical period for temperature covers the whole period May-August, whence the positive correlation between the figures of Columns III and VIII. But when going south, temperatures below the normal, especially in July and August, are always relatively high and cannot affect the normal growth of the cotton plant, so that the critical time for temperature tends to be limited to May and June. Thus, in Georgia, South Carolina and Alabama, the departures from the normal yield during the first period of the harvest correspond exactly to the departures from the normal temperature during the period May-June. On the contrary, the correlation is much less relatively to the whole period from May to August, on account of the great heat.

The increased maturity due to positive variations in temperature in

May and June is accompanied by an increased yield during the early part of the harvest and, on the contrary, by a decrease during the latter part. Table II gives the data for Georgia. In that State, to the south of Oklahoma, the harvest begins much earlier than in the latter State, the first period ending on September 1, instead of October 18. The variations in yield, which are usually positive and occur during the first and second periods of the harvest (up to September 25), correspond to positive variations in temperature, as do the variations, usually negative, during the following periods (after September 25), and vice-versa.

TABLE II. — *Departures from the average yield during various ginning periods ; average daily temperature departures from the normal during May and June in Alabama.*

Year	Departures from the average yield, in percentages ginned						Average daily departure from the normal temperature during May-June
	Up to September 1	From Sept. 1 to 25	From Sep. 25 to Oct. 18	From Oct. 18 to Nov. 1	From Nov. 1 to Nov. 14	From Nov. 14 to Oct. 1	
1914	+ 1.2	+ 2.1	- 6.4	- 0.5	+ 1.1	- 0.8	+ 3.5
1911	+ 1.0	+ 1.5	- 0.2	- 2.4	- 2.8	- 0.6	- 1.3
1905	+ 2.9	+ 6.8	- 1.2	- 1.3	- 2.1	- 1.9	- 3.9
1915	+ 3.1	+ 8.9	- 4.5	- 2.2	+ 0.9	- 2.1	- 0.4
1908	- 0.5	+ 1.6	+ 2.2	- 1.5	- 1.0	—	- 1.9
1906	- 2.3	- 5.4	- 2.5	+ 2.3	+ 1.7	+ 3.2	- 4.8
1913	- 0.7	- 5.3	+ 6.0	- 1.9	- 0.7	+ 1.5	+ 4.3
1912	- 1.9	- 8.0	+ 0.4	+ 2.5	+ 2.2	+ 3.9	- 1.6
1909	+ 1.9	+ 2.2	+ 2.8	- 0.4	- 0.5	- 2.8	- 1.3
1907	- 1.9	- 4.6	+ 0.4	+ 2.3	+ 0.1	- 1.9	+ 5.3
1910	- 2.7	- 2.0	+ 1.8	+ 3.0	+ 0.9	+ 1.5	+ 2.9

Another weather factor, of less importance than that of temperature, but worth consideration, is that of the number of fair days ; the more there are, other conditions being equal, the greater will be the yield during the corresponding periods. As regards this point, Table III gives the figures obtained in Alabama for the period from September 25 to October 18 ; it will be seen from the almost completely identical figures of columns II and IV, that the correlation between the two groups reaches the maximum ; the positive or negative departures in the number of clear days correspond to similar departures in the yield.

The planters and cotton brokers attach considerable importance to the reports of the Bureau of the Census regarding the amounts of cotton obtained in the first or first two periods of the harvest, as the value of cotton depends largely on the amount grown. A forecast of the size of the cotton crop, based on the ginning reports, has a much greater value when consideration is given to the influencing weather reports, as has been pointed out, than when the reports alone are considered.

TABLE III. — *Relation between the cotton ginned and the number of clear days for the period from September 25-October 18, in Alabama.*

I	II	III	IV	V
Year	Amount ginned in % of the total yield	Departure from average yield	Fair days, in percent of the total number of days	Departure percentages of clear days
1905. . . .	25.5	— 1.6	78 %	— 5
1906. . . .	19.9	— 7.2	65	— 18
1907. . . .	25.1	— 2.0	78	— 1
1908. . . .	28.4	+ 1.3	83	+ 8
1909. . . .	31.2	+ 4.1	87	+ 8

1912. . . .	30.1	+ 3.0	70	— 1
1913. . . .	34.6	+ 7.5	91	+ 8
1914. . . .	24.2	— 2.9	65	— 14
1915. . . .	23.9	— 3.2	70	— 3
<i>Means</i>	<b>27.1</b>	—	<b>77</b>	—

For example, if temperatures during the critical months of growth are high and the weather be favourable for picking during the first period, it may be taken that the yield during that period will be high, while the final yield will be much less than that apparently indicated by the actual amount ginned to that date.

On the other hand, if the temperature is low during the growing period (retarded maturity) while rainy days retard the harvest at the beginning, the yield of the first period will be low, but as the successive yields will be high, the total yield will be higher than that calculated on the basis of statistics for the first period.

Again, when the temperature is high during the growing period and there are rainy days at the beginning of harvest, or, on the contrary, if the temperature is low during the growing period, with clear days at harvest time, there will be, in these 2 cases, two groups of phenomena tending to neutralise each other and the statistics for the first crop will allow a forecast of the final yield to be made with greater accuracy without the need of making corrections for early or late maturity.

To obtain a good forecast of the final crop (total yield of all the periods of harvest), by using the meteorological and statistical data for a single period, the author proposes the use of the equation: —  $X = \frac{a}{bc}$  where  $X$  is the approximate total crop;  $a$ , the number of bales ginned during the period;  $b$ , the percentage of the total crop ginned on the average (for a series of years) for each fair day of the period; and  $c$ , the number of fair days during the particular period.

To gain an idea of the accuracy of the information obtained by using this formula, it will be seen from Table IV that the figures of columns VI and

VII closely approximate; the error being never greater than 5 %, and averaging about 2.5 per cent.

TABLE IV. = *Forecast of the total yield of ginned cotton in Georgia, based on statistics for the crop-period September 1 to November 14, using the formula  $X = \frac{a}{bc}$ .*

623 — *Researches on Certain "Soil Sicknesses" in the Netherlands.* — SÖLMGEN, N. L., KNETEMANN, A. and WIERINGA, K. T. (Royal Agricultural Experiment Station of Groningen), in *Verslagen van Landbouwkundige Onderzoekingen der Rykslandbouwproefstations*, No. XXI, pp. 121-165 + 2 Photos, 4 Tables, 6 Fig. The Hague, 1917.

The recent appearance of various "soil sicknesses" in Holland, Germany and Denmark has lead the authors to undertake the researches described below. These sicknesses are shown by a loss in fertility of the soil, cereal crops being particularly affected. The first case, which appeared in 1905, was called "haverziekte" (oat disease) by SjöLLEMA and HUDIG, who attributed it to an excess of bases in the soil; it corresponds to the "Dörrfleckenkrankheit" described in Germany in 1914 by KRÜGER and WIMMER. Since then, fearing to make the soil too alkaline, dressings of lime have been given more and more rarely in certain localities, with the result that, in 1913 and 1914, another soil sickness appeared at Hooghalen, which HUDIG called "Hooghalensche ziekte" (Hooghalen disease). This disease chiefly affects cereals, but beets and potatoes also suffer from it. As a strongly alkaline manuring does away with the sickness and as a strongly acid manuring can, on the contrary, cause the sickness in healthy soil, it is attributed, inversely to the preceding one, to excessive soil acidity.

I. — PREVIOUS RESEARCHES. — To explain the origin of the disease,

SOIL PHYSICS,  
CHEMISTRY  
AND  
MICROBIOLOGY

other experimenters, especially ABERSON, have thought that other factors were responsible : — 1) the hydrogen-ion concentration of the soil ; but researches have shown that the differences found between its values in healthy and sick soils are too small to have any influence ; 2) excess of nitrites, due to *Bacillus nitrosus*, which actively transforms nitrates into nitrites ; in fact, a minimum amount of nitrites, only a few milligrams per kilo, suffices to stop the growth of plants and even kill them.

The present report includes the authors' researches on the acidity of the soil and its influence on vegetation ; the intervention of the microbiological factors will be dealt with in a further paper.

*Properties of Humus.* — The numerous researches on the properties of humus (1) have resulted in a great diversity of opinion as regards the physical and chemical properties of this complex compound. There are 2 chief opinions : — according to SPRENGEL, MULDER, KISSLING, TACKE and SVEN ODEN the fundamental properties of humus are due to the presence of acid radicals ; while according to VAN BEMMELEN and BAUMANN, they are due to its colloidal nature.

II. — DETERMINATION OF THE CONTENT OF FREE AND COMBINED HUMIC ACID AND THE LIME REQUIREMENT. — A) WITH THE HELP OF CULTURES OF AZOTOBACTER. — 1) The authors adopted the method used by CHRISTENSEN (State Laboratory at Copenhagen) (2) in order to ascertain the soil reaction as regards the cultivation of cereals, so as to be able to control soil sicknesses in this way. Having found that *Azotobacter* was not present in soils receiving no lime, he conceived the idea of growing that organism on various soils, as an index of their acidity or basicity. He proceeded as follows : —

In 2 Erlenmeyer flasks are placed 50 cc. of distilled water, 2 % of mannite, 0.2 % of bipotassium phosphate and 5 gm. of soil ; the mixture is inoculated with the bacterium and incubated at 26° C. One flask receives a piece of chalk and serves as a control. According to whether the culture grows or not in the flask without chalk, the soil in that flask is called basic or acid.

By using this method the authors found that soil causing the oat disease did not favour the growth of the bacterium, while soils affected with Hooghalen disease, on the contrary, did, so that this microbiological method is very efficacious for ascertaining the soil reaction.

2) To determine the amount of lime required to render a hyperacid soil healthy the bacterium was again used, by adding increasing amounts of lime. The use of two species : *Azotobacter Vinelandii* and *A. chroococcum*, the former able to grow at a slightly higher degree of acidity than the latter, easily allowed of the estimation of the limit of the quantity of lime required, which is that which suffices for the growth of the first species, while it is insufficient for the second. The quantities found in

(1) See also R., January 1918, No. 8. (Ed.)

(2) See R., 1916, No. 843 and R., 1917, No. 996. (Ed.)

this way agree quite well with those obtained with the diffusion method and the probability of error is reduced to  $\pm 1784$  lb. per acre.

B) BY THE AID OF A DIFFUSION METHOD ON AGAR PLATES STAINED BY INDICATORS. — The authors made use of a diffusion method based on the fact that acids and bases, even when difficultly soluble, diffuse in a hydrogel.

If a series of small cavities are made by means of a bent, nickel spatula in a layer of agar coloured by an indicator, taking care not to pierce the layer, acids or alkalis placed in these cavities develop a surrounding zone of acid or alkaline diffusion in the agar, shown by the indicator. The sensitiveness of agar coloured by litmus is very great; a N/1000 solution of acid or alkali gives a very distinct effect; that of a N/5000 solution is still perceptible.

1) *Determination of the free humic acid content, expressed in mgm. of  $\text{CaCO}_3$  per 10 gm. of dry soil.* — This is done in a similar way to the previous one by adding increasing quantities (5 mgm. a time) of  $\text{CaCO}_3$  to the specimens. After heating for 3 hours at  $100^\circ \text{C}$ . to drive off the  $\text{CO}_2$  so as to avoid error, small samples are taken and placed in the cavities in the agar plate. Humic acid gives a red zone of diffusion,  $\text{CaCO}_3$  or  $\text{CaH}_2(\text{CO}_3)_2$  a blue zone, and calcium humate a neutral zone. The accuracy with which the free humic acid content can be ascertained is expressed in mgm. of  $\text{CaCO}_3$  per 10 gm. of dry soil, 5 mgm. for a soil that has lost 10 % by calcination, which corresponds to an error of 1071 lb. per acre; although this seems large, it should be noted that a strongly hyperacid soil often requires 1076 lb. of lime per acre to make it healthy.

2) *Determination of the excess of alkalis in a hyperbasic soil.* — The excess of alkalis still present with the humates can be determined by adding increasing amounts of  $\text{HCl}$ , instead of  $\text{CaCO}_3$ , to various 10 gm. samples. The amount of  $\text{HCl}$  required to neutralise the 10 gm. of analysed soil on the agar layer represents the excess of alkalis. In this way some "Hyperbasic" soils were found to contain an excess of nearly 26765 lb. of lime per acre.

3). *Determination of the total humic acid content (free and combined) and the calculation of the respective percentages of free and combined acid.* —

a) The metals combined with the humic acid are separated by dialysis with N/10 hydrochloric acid, or by boiling the sample with the same solution, then filtering and washing with distilled water till the  $\text{Cl}$  ions are completely eliminated. The entirely free humic acid is then titrated on the agar plate. b) To determine the combined humic acid content (always expressed in mgm. of  $\text{CaCO}_3$  per 10 gm. of dry soil) it is sufficient to subtract the known content of free acid from the total content of humic acid.

III. — APPLICATION OF THE RESULTS. — The authors have analysed a great many soil samples. For any soil, whether sand or peat, acid, neutral, or alkaline, the humic acid per gram of loss on calcination includes about 80 mgm. of  $\text{CaCO}_3$ . The humus of different soils therefore contains a constant amount of humic acid per unit of weight. It thus results that: 1) the total humic acid content may be determined directly, and the  $\text{HCl}$  method described above neglected, if the following are known: — a) wa-

ter content ; b) the loss on calcination (by means of which the total content in organic matter can be calculated) ; c) the free humic acid content. — 2) the too-acid or too-basic character of the soil depends on the percentage of free humic acid, i. e., the ratio *free humic acid : combined humic acid*. A "hyperacid" soil contains more than 60 % of free humic acid ; a healthy soil, from 50 to 60 % ; a "hyperbasic" soil, from 0 to 50 % ; in other words, if the ratio is  $> \frac{6}{10}$  the soil is "hyperacid" ; if the ratio is  $< \frac{5}{10}$  and  $> 0$ , the soil is healthy. The best percentage of free humic acid seems to be 25%.

*Influence of Fertilisers on these Sicknesses.* — Certain salts, by altering the percentage of free humic acid, especially near the roots, can have either a bad or good influence. For example, with potassium chloride, the calcium largely takes the place of potassium, and by washing is lost as soluble chloride ; as the potassium is utilised by plants, the result is an increased content of free humic acid. Magnesium chloride and ammonium sulphate have a similar effect. The contrary effect is produced by substances that diminish the content of free humic acid, as a result of the formation of compounds that can be assimilated by plants : lime, magnesium carbonate, sodium carbonate, sodium nitrate.

*Control of the Authors' methods.* — The results obtained with TACKE's method (determination of the free humic acid content by estimating the  $\text{CO}_2$  produced by the reaction soil +  $\text{CaCO}_3$ ) gave results that agreed with those obtained by the methods described in the present report. On the contrary, no efficient control could be made by comparing the results with those furnished by the method based on the determination of the hydrogen-ion concentration or by that based on the determination of the electrical conductivity (SVEN ODEN).

**GENERAL CONCLUSION.** — The direct and immediate cause of the appearance of these "soil sicknesses" has not yet been determined, but the close relation between their appearance and the free humic acid content of the soil has been established, a relation that enables the soil to be rendered healthy by means of suitable treatment.

624 — **Studies on Nitrification in Natural Soils and Its Importance from an Ecological Point of View, in Sweden.** — HESSELMANN, H. (Meddelanden från Statens Skogsförsöksanstalt), in *Skogsvårdsföreningens Tidskrift*, Year XV, No. 4-6, pp 312-446 + 30 Figs. Stockholm, 1917.

A consideration of the chief researches carried out of recent years on the chemical composition of the soil and the formation of humus (SUZUKI, ROBINSON, SCHREINER and collaborators, BAUMANN & GULLY, RINDEL, ODEN), especially as regards forest soils, leads to the following conclusions :

1) From a soil containing relatively little humus, and, to a lesser degree, peat, organic compounds of definite composition can be isolated; in certain cases, the compounds thus isolated and identified form a considerable part of the soil humus.

2) Many kinds of humus, especially those of dark colour, are largely formed of chemical compounds of undefined character.

3) The acid reaction of some humiferous soils is due to the presence of free organic acids.

4) The constituents of humus are mostly of colloidal nature, and, on account of this, the physical structure of humiferous soils is greatly influenced by the content in mineral salts or electrolytes of the soil or soil water.

The author distinguishes 2 types of humiferous soils: a) "sweet" humiferous soils, well aerated by the action of worms and insects; b) "strong" humiferous soils, formed of dead decomposed or decomposing vegetation. The former are characteristic of deciduous forests and, to a lesser degree, of pine forests on soils rich in inorganic salts; the latter, on the contrary, are found in pine forests of the ordinary type and often form a series of layers with varying stages of decomposition and which can be clearly separated from the mineral sub-soil.

The formation and distribution of nitrates in the soil directly influence its productive capacity. The dead covering always contains a certain amount of nitrogen and the knowledge of the processes by which the nitrogen becomes changed into assimilable compounds is of great importance. It is well known that the decomposition of humus is accompanied by a liberation of ammonia, which can be directly assimilated by certain plants. To determine the "degradation capacity" of a soil, it is inoculated with a sterile solution of peptones, and incubated for several days; the degree of decomposition is then ascertained by adding magnesia to the peptone solution and distilling off the ammonia into sulphuric acid. Though there are many organisms that can break up organic matter with the formation of ammonia, up to the present few are known that can change ammonia into nitrites and nitrites into nitrates: such are the nitrosobacteria and nitrobacteria discovered by WINOGRADSKY. As nitrobacteria can only act on ammoniacal compounds, the formation of ammonia appears to be an essential phase of nitrification in humiferous soils; denitrifying bacteria are also commonly found in humiferous soils, but, under normal conditions, the nitroso and nitrobacteria are much more active than the others.

According to the author, the sources of nitrogen in forest soils are: —

a) the dead, decomposing covering, to the nitrogen of which is added the atmospheric nitrogen fixed by leguminosae, alders and other plants;

b) the soil fungi and bacteria which can fix nitrogen, and which renew the energy required for this fixation by decomposing the organic matter in the soil;

c) the ammonia and nitric acid brought to the soil by rain.

In naturally wooded land, the second factor is the most important one.

The nitrogen of forest soils is lost in 3 ways: a) loss of nitrates dissolved in soil water; b) activity of denitrifying agents; c) removal of wood.

The preceding researches on nitrate formation in forest soils were carried out along 3 lines: — a) the examination of soil samples to find if nitrifying bacteria were present; b) determination of the nitrifying capacity

of the samples ; c) determination of the nitrogen content of the trees and plants at different seasons.

The author applied these different methods to the detailed study of different types of forest, obtaining the following conclusions : —

The "sweet" humus of beech woods contains as many nitrifying as denitrifying bacteria distributed in all its mass ; herbs and grasses also help considerably to increase the stock of nitric nitrogen in such a type of soil ; samples of this type of soil can form considerable amounts of nitrates if they are kept. The humus of pine forests with a mossy covering is characterised by the absence of bacteria capable of nitrifying ammonium sulphate ; denitrifying bacteria are also not present and no potassium nitrate can be found in the tissues of the plants covering the soil. The normal requirement of nitric nitrogen for this kind of forest must evidently be satisfied in some other way than by assimilation of nitrates. As regards the acidity of the dark humus soils of pine woods, the author observes that, as the colloids were coagulated by the addition of inorganic salts, it must be admitted that the humus lying on a subsoil very rich in soluble inorganic salts is less likely to give an acid reaction, because the humus particles unite and become granular, thus allowing the penetration of roots, worms and insects, all factors that favour the aeration of the soil. To support this theory, the author quotes as an example the fact that the water of peatbogs and marshy soils of the forests of Norrland on basaltic sub-soil is brown and turbid, while the same water in the limestone forest soils of Jemtland is limpid and clear.

The author remarks that, in spite of the importance of the researches carried out in the United States with the object of isolating numerous organic decomposition products partly toxic to plants, their significance should not be exaggerated, as there is not the slightest proof that such substances are present in the dark-coloured and acid humus of coniferous forests.

Many natural soils have the power of nitrification and it is characteristic that humus formation in such soils takes place under the influence of electrolytes or solutions of inorganic salts ; the formation of "sweet" humus is facilitated by the action of insects and worms that mix the soil water and humus. This is why humification, during the seasons when the salt-charged soil water flows rapidly, gives rise to forms of humus lacking the power of nitrification. On the other hand, on account of its physical constitution, "sweet" humus nitrifies, which does not take place with "strong" humus. In many places, nitrification is so rapid that a considerable amount of nitrogen accumulates in the covering vegetation ; this is best seen in dense beech, elm, oak, ash, and alder forests, especially where there is moving underground water ; in the higher mountainous regions, the soil covering also contains a considerable amount of nitrogen. In woodlands and spruce forests with grassy soil covering the nitrogen of the humus nitrifies without there usually being a resulting accumulation of nitrogen in the layer. On the contrary, plant associations on bare rocky soils are often composed of nitrophilous species that accumulate nitrogen in their tis-

sues. Again, in pine forests with a covering of lichens and mosses, the nitrogen is not nitrified and the decomposition of the dead covering gives rise to the formation of ammonia and its compounds.

Soils where nitrification is in progress are often acid and, in this case, can only slowly change ammonium sulphate to nitrate, whilst the denitrifying bacteria are usually found distributed among the moss. On the other hand, natural soils can, during nitrification, accumulate as much nitric nitrogen as ordinary cultivated soils.

Nitrification is not only largely influenced by the origin of the soil, but also by the climate, and as the degree of nitrification constitutes a powerful factor determining the composition of the plant associations of a given soil, the factors of the formation of the soil can have a decisive influence, in certain cases, on that composition. Thus, the same forest trees grow more rapidly on soils where nitrification takes place than where there is no nitrification, and a suitable forest system should make it possible to thin numerous forests in such a way as to favour soil nitrification, thus assuring a higher yield of wood; nevertheless, a good yield of pine and spruce wood can be obtained on soils where there is no nitrate formation; in this case, however, the rate of growth appears to be proportional to the rate of ammonification and the formation of the soil might well be influenced by a suitable system of forest management.

In conclusion, it should not be forgotten that lime, both in the soil and soil water, favours nitrification.

The text is illustrated by 28 photographs, constituting a useful series of ecological documents.

**625 - Irrigation of Rice in California, U. S. A.** — ROBERTSON, R. D., in *Bulletin No. 279, University of California Publications, College of Agriculture, Agricultural Experiment Station*, pp. 254-270. 7 Fig., 3 Tables. Berkeley, May, 1917.

Approximately 67 000 acres of rice were irrigated in California in 1916, the water supply being obtained principally from Sacramento and Feather rivers. Only about 37 00 acres were irrigated by pumping from wells. The land is prepared for irrigation in contour checks, preparation consisting mainly in making ditches and levees and installing gates. The gates must be wide enough to admit the large heads of water used in the initial floodings. The levees are made by means of implements described in the bulletin and amongst which the "ridger" is worthy of note. This implement, which is hauled by a tractor, is a simple, home-made affair. The appended figure shows a ridger in use, which can regulate the size of the levee. The runners for the sides are made of 3-in.  $\times$  12-in. plank, 20 ft. long and lined with steel. The front is 10 ft. wide on the bottom and the rear end 3 ft. wide on the bottom. The sides are 2 ft. high and slope outward. This implement makes a levee having a base of about 5 ft. and a height when settled of about 12 in.

On fairly even ground a crew of 2 or 3 men with a tractor will check 150 acres or more per day. Often the work is contracted and a common price paid is \$50 per day for the use of the tractor and checker.

Ridger for making irrigation levees

The irrigation season is divided into two periods. Frequent light irrigations with relatively large heads of water are given to germinate the seed and to maintain growth until the plant is 4 to 6 in. high, and thereafter the land is continually submerged to a depth of 6 to 8 in. until the rice is mature.

Measurements of the use of water in 1916 on 18 typical fields in Sacramento Valley showed a range of from 4.27 to 14.83 acre-feet per acre, an average depth applied of 8.23 feet and an average of 47 acres served per cubic foot per second.

The water used was measured by means of a standard contracted weir and an automatic register; the measurements are given in two tables.

Experiments in rice irrigation were made in 1914 to 1915, inclusive, in cooperation with the Bureau of Plant Industry, U. S. Dept. of Agriculture, on the Biggs rice field Station, the object being to determine the effect of varying irrigation treatments on the crop yield.

The results are given in the appended table (page 667).

The tests were made on  $\frac{1}{5}$ -acre plots enclosed by well-constructed levees and arranged so that they could be irrigated and drained separately.

The results of the experiments show that, on the black clay adobe soil near Biggs, 30 days after emergence of the plant is the best time for commencing submergence, and that 6 inches is probably the best depth of submergence. Very poor yields were obtained where no water was held on the land. Varying the depth of water had very little effect on plant growth. More uniform temperatures of the water were found with the greater depths of submergence.

*Effect of Irrigation Methods and Treatment  
on Yields at Biggs Rice Field Station in 1914, 1915 and 1916.*

626—On Green Manures. — SCHRIBAUX and BRÉTIGNIÈRE, L., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 10, pp. 354-357 and 360-365. Paris, March 13, 1918.

MANURES  
AND MANURING

M. SCHRIBAUX (professor of the "Institut National Agronomique") communicated to the Academy a note by M. BRÉTIGNIÈRE (professor of Agriculture at the "Ecole Nationale d'Agriculture" at Grignon) in which M. BRÉTIGNIÈRE describes the results he obtained with clover and black medick as green manures. The sowing of these two Leguminosae in cereal fields is highly recommended. The practice, which is already adopted in some cases, should be general, especially in view of the shortage and high price of nitrogenous manures. By this means, as at Grignon from 1913 to 1916, the growing of three successive cereal crops becomes possible. The following table shows the difference in yield obtained when oats were sown on green manure as compared with that grown in the control plots; in each case the difference is in favour of green manure.

	Grain cwt. per acre	Straw cwt. per acre
Oats on black medick . . . . .	8.95	14.96
» » clover . . . . .	6.27	10.79
» » vetch. . . . .	4.32	4.84
» » white mustard . . . . .	0.42	1.14

The superiority of the black medick and clover is obvious, especially that of the black medick, which has the further advantage of costing only

£4.14.0 to £5.6.0 per cwt., whereas clover costs from £7.2.0 to £8.2.0 per cwt.

Besides the black medick and clover recommended by M. BRÉTIGNÈRE, M. SCHRIBAUX also advises the use as green manure of crimson clover, which is to be recommended on account of its rapid growth and the relatively low cost of its seed. Fentugreek might also be useful for the same purpose, especially in the south of France, on account of its hardness and well developed roots. The adoption as a green manure of white melilot, already used as such in America, might also be studied.

627 - **Fertilizers in South Africa** — in *The South Africa Journal of Industries*, Vol. I, No. 5, pp. 465-467. Pretoria, 1918 (1)

The growing scarcity of fertilizers has long been evident to the South African agricultural community, and the Minister of Mines and Industries, in his address to the Scientific and Technical Committee at their inaugural meeting in Capetown on April 17, 1917, especially commended this urgent question to their consideration as an important subject for investigation and research.

In accordance with this mandate the Committee at once commenced inquiries in various directions, especially with the object of ascertaining what practical possibilities existed of replacing imports by locally manufactured fertilizers. The large amount of fertilizer imports and their steady decrease since the war began are illustrated in the following table, but at the present time importation has practically ceased, and there is no available supply to make good the deficiency.

*Imports into South Africa of Manures and Fertilizers, 1913-16*

(1) See INT. INST. OF AGR. *Production et consommation des engrais chimiques dans le monde* II ed. 1914 and the half-yearly reviews *The International Movement of Fertilizers and Chemical Products useful to Agriculture*. (Ed.)

As is generally recognized, South Africa's fertilizer requirements, in descending order of importance, are the various forms of phosphoric oxide, nitrogen and potash. South African soils are usually not so deficient in the last-mentioned item as in the others, and deficiencies can be partially supplied by kraal manure. Phosphates are needed for maize and practically all other crops to promote root growth for withstanding drought and ensuring early maturity, whilst nitrogen is a prime requisite for wheat and sugar crops. The fact that South Africa imports so much of its food supplies under normal conditions (even at the present time wheat and wheat products are imported to the extent of nearly £ 2 000 000 yearly) makes the present necessity still greater for stimulating local food production, and for this purpose the utilization of fertilizers from various local sources must play a most important part. Apart from the serious drain on the country's wealth in payment for food and fertilizer imports from overseas, the exigencies of shipping shortage may, as the Minister recently stated in public, cause a total cessation of wheat imports.

The Scientific and Technical Committee has surveyed the problem in its various aspects and the inquiries started include : South African guano supplies ; the increased employment of green-manuring ; the use of ground limestone ; the possible utilization of woolwashery and sawdust waste, and of kelp for supplies of potash ; cotton-seed by-products ; locally produced ammonium sulphate ; the supply of phosphates from the Seychelles and elsewhere ; and the possible utilization of Saldanha Bay and other local phosphate rocks. Eventually the main centres in the Union were visited to investigate abattoir and fishery refuse production, and it was ascertained that much waste existed in the discarding of potential phosphatic-nitrogenous fertilizers. For instance, at the most important abattoir in the Union, 80 per cent. of the offal was buried at considerable cost owing to inadequacy of plant for conversion into a high-grade fertilizer for which the demand far exceeded the supply. For similar reasons 12 000 tons yearly of potential crayfish fertilizer was thrown into the sea, and at many other centres waste occurred which, though often individually small, accounted in the aggregate for a considerable quantity. Steps were then taken by the Engineering Sub-Committee of the Scientific and Technical Committee to ascertain whether fertilizer plants could not be locally constructed so as to avoid delay from restriction by machinery importation.

In the meantime strenuous efforts are being made by those interested to convert the large deposits of iron-alumina phosphates known to exist in South Africa into a form suitable for agricultural use, and the technical aspect of this known problem is attracting much attention in South Africa. Inquiries are also being made as to the extent and nature of alleged phosphatic deposits in South-West Africa and elsewhere, and the chemists of the Department of Agriculture and others have periodically published articles on the proper use of fertilizers, great being the need for this educational propaganda.

At the present time about 200 tons per month of ammonium sulphate is being produced from coal at the works of the Natal Ammonium Company

but practically all this is exported to Mauritius for use in sugar growing. Very little is used in the Union, but export is only allowed after all local demands are satisfied. Should the oil-pressing industry in South Africa grow to provide more fully for local glycerine requirements, this would result in increased oil-cake production. Of this by-product, Mafureira (1) and castor oil-cake are unsuitable for stock food, owing to their poisonous properties, but as fertilizers they provide nitrogen and some phosphoric oxide and potash at a cost much less than in the more usual form of nitrogen fertilizers.

628 — **Plants Imported into the United States by the Bureau of Plant Industry of the Department of Agriculture, during the Half-Year July 1 to December 31, 1917** (2).

— U. S. Department of Agriculture, Bureau of Plant Industry, *Inventory of Seeds and Plants Imported by the Office of Foreign Seed and Plant Introduction: I. During the Period from July 1 to September 30, 1914* (Inventory No. 40; Nos. 38 666 to 39 308), pp. 110 + 10 Plates; *II. During the Period from October 1 to December 31, 1914* (Inventory No. 41, Nos. 39 309 to 39 681), pp. 67 + 4 Plates. Washington, 1917.

Of the many newly-imported plants the following are mentioned as being of special importance: —

I. — **CEREALS.** — A collection of 13 varieties of the grass *Coix Lacryma-Jobi* (from Burma), some of which produce soft grain and are cultivated for food; 33 varieties or species of the maize characteristic of Copacabana, Peru; 5 varieties of maize from Yachow, western China; a collection of sorghum varieties from Java; 20 varieties of rice from Java; the 2 commercial varieties of rice grown in Valencia, Spain (3).

**FORAGE PLANTS.** — The Australian Rhodes Grass (*Chloris virgata* var. *decora*) which has done exceedingly well on clay-pan, wind-swept and sun-scorched soils, where other grasses are difficult to grow; 12 species of forage grasses (*Andropogon erianthoides*, *Alloteropsis Ekloniana*, *Eragrostis curvula*, *E. poa*, *Fingerhuthia africana*, *Ischaemum glaucostachyum*, *Panicum maximum*, *P. nigropedatum*, *Chaetochloa aurea*, *C. Lindergiana*, *C. nigrirostris*, *C. sulcata*) from S. Africa, some from the Kalahari desert region, and some from the Transvaal and Caldeon coast district; if any of these plants prove as valuable as the Rhodes grass, from the same climatic district, their introduction will be a decided gain. The following plants are also valuable acquisitions: — 1 cowpea (*Vigna sinensis*), called "im-

(1) *Trichilia emetica* Wahl. supplying oleaginous seed. (Ed.)

(2) See R. Feb., 1918, No. 138. (Ed.)

(3) The two commercial varieties of rice grown in the Valencia district, especially on the banks of the Jucar, are the "Benlloch" or "Belloch" and "Amonquili". In 1913, 80 % of the first variety and 20 % of the second was grown, and the first is being grown in continually increasing quantities. The origin of the "Benlloch" variety is uncertain. It was introduced and distributed to growers by the Agricultural Station of Burjasot, near Valencia. It was immediately acclimatised and seems particularly well suited to the soil. It germinates easily and is resistant to transplanting, which is a common practice in the district; the straw is strong. It ripens, however, somewhat later than the other varieties, and its food value is said to be inferior to that of the "Bomba" variety. In 1913, "Benlloch" rice gave an exceptionally high yield, as much as 4.42 tons per acre, and was sold on the threshing floor at \$4.86 per 220 lb.

boomba", grown for food by the Zulus of S. Africa; 1 selected forage sugar cane, called "quacsofoca", which in Queensland has proved superior to all the old standard types by its hardiness, yield, softness and food value; *Erianthus rufipilus*, from the Himalayas; *Pollinia fulva*, from the interior of Australia, much relished by cattle; *Eriochloa subglabra* ("capim angolinha") from Brazil.

VEGETABLES. — A fine variety of the winter "pe-tsai", or Chinese cabbage (*Brassica pekinensis*) with very white heads of a mild flavour; 2 species of rhubarb (*Rheum acuminatum* and *R. nobile*), from Darjiling, India, the two species might be hybridised with *R. rhaponticum*; 22 varieties of cassava (*Manihot esculenta*), representing the most important varieties grown in the State of Bahia, Brazil; a variety of pumpkin (*Cucurbita Pepo*), from the Oasis of Merv, Turkestan, which has withstood the heat and drought of Sonora, Mexico, better than any other variety tested there; 1 long, blood-red carrot (*Daucus Carota*) for pickling, from Sianfu, China; a shrubby species of indigo (*Indigofera dosua*), from the temperate Himalayas, the flowers of which are eaten as a vegetable, while the plant is used for fodder.

FRUIT TREES. — *Feijoa Sellowiana* remarkable for its large fruit (3  $\frac{1}{2}$  × 2  $\frac{1}{2}$  inches) from Pasadena, California; the Pelese apricot from Somma Vesuviana, Italy, with very firm flesh, fine flavour and good shipping qualities; the "wampi" (*Claucaena lansium*) with fruit related to the orange, which promises to be a good stock for the orange and grapefruit: a vigorous tropical vine (*Vitis tiliæfolia*), the fruit of which is good for jelly, and which may be used for producing good-quality varieties of tropical grapes; 6 varieties of "kuruba" (*Passiflora maliformis*), the fruit of which is much appreciated in the Bogota market, especially that of a red-fruited variety; *Eriobotrya petiolata*, from the eastern Himalaya district, which may prove valuable as a stock for the loquat; the Luisa mango (*Mangifera indica*) with excellent fruit, from Cuba, though the seed is probably of Philippine origin; a quantity of "litchi" seeds (*Nephelium Litchi*) from trees in the Hawaiian Islands; *Pouzpartia axillaris*, a fruit and shade tree from the western Hupeh and Szechwan Provinces of China, which has proved hardy in Georgia; *Sorbus cuspidata* and *S. insignis*, natives of the Eastern Himalayas; *Dillenia pentagyna*, from Oudh, Bengal, Assam and Burma, the flowers, buds and green fruit of which are eaten by the natives; *Rubus niveus* from Kashmir and Sikkim, a Rambler bearing fruit superior to that of the English blackberry.

ORNAMENTAL, SHADE AND WIND-BREAKING TREES. — The 80-foot high, wild, pink-flowered cherry of Japan (*Prunus serrulata sachalinensis*), which deserves to be widely planted on account of its hardiness and beauty; the Nepal ash (*Fraxinus floribunda*), which, though not hardy in England may prove to be so in the south of the United States; the East African Cedar (*Juniperus procera*) from Eritrea, the wood of which makes better pencils than those of the American juniper; *Balanites Maughamii*, a native of Portuguese East Africa, from the seeds of which a clear, yellow, odourless oil is obtained; *Picea Smithiana*, from Darjiling, India, the wood of which

is used for packing-cases and charcoal; *Aesculus assamicus*, from northern Bengal; *Tilia mongolica* from Tahuashan, China; 3 varieties of the Chinese soap-bean tree (*Gleditsia sinensis*), remarkably resistant to drought and alkalinity, and very ornamental because, all through winter, they bear their pods, which are very rich in saponin; the cigar-boxwood tree (*Toona sinensis*) from Changli, China, a fine shade and ornamental tree which also gives good timber; *Corylus ferox*, the edible Nepalese hazelnut; a large bamboo (*Dendrocalamus Hamiltonii*), from Darjiling, with shoots 80 feet high, the young sprouts of which are edible, it might prove hardy in the south of the United States and be used as a windbreak; *Cotoneaster microphylla*; 18 species of Himalayan rhododendron:—*Rhododendron anthopogon* (a shrub about 2 feet high with sulphur-coloured flowers), *R. arboreum* (often attaining a height of 25 feet), *R. arboreum Campbelliae*, *R. arboreum* Smith, *R. barbatum*, *R. camelliaeflorum*, *R. campanulatum*, *R. campylocarpum* (with pale yellow flowers), *R. ciliatum*, *R. Roylei*, *R. Dalhousiae*, *R. Falconeri* (admirably adapted to the parched, arid climate of Tibet), *R. fulgens*, *R. grande*, *R. lanatum* (with pale sulphur-coloured flowers), *R. Lepidotum*, *R. setosum*, *R. Wightii* (with pale yellow flowers); a Nepal barberry (*Berberis nepalensis*), which, in Nepal, flowers from October to March; *Polygonum vacciniifolium*, an autumn-flowering plant very popular in England; 3 forms of evergreen shrubs (*Euonymus* spp.), from Tahuashan, in the Shensi Province of China.

II. *Edible plants.*—A collection of 38 varieties of Chinese barley, which it is hoped will yield good new varieties in some parts of the United States; 8 varieties of sweet potatoes from the Cuba Experiment Station; 1 wild tomato of Funchal which grows wild among the dry rocks of the Island of Madeira, believed to be from the original stock from which the cultivated tomato is descended, it is very resistant to drought and will probably prove valuable in selection work; the "Mahwa" tree (*Madhuca indica*), the fleshy flowers of which produce annually in India food worth over a million dollars has been imported into Florida and Porto Rico.

LEGUMINOSÆ USED AS GREEN MANURE AND FODDER LEGUMINOSÆ.—The Sarawak bean (*Dolichus Hosei*) is used as a cover crop to keep down weeds in rubber plantations in the Malay States, and could be used for the same purpose in the citrus orchards of Florida; 1 wild, prostrate form of alfalfa from the mountains between Hotien, Honan, and Luanfu, Shansi province, China.

TEXTILE PLANTS.—The "chingma", also known as Chinese jute or Tientsin fibre (*Abutilon Theophrasti*), which yields a harsher and stronger fibre than Indian jute and is used for carpet-making; it was imported from Ichang, China, and, if improved methods for extracting the fibre be found, may prove of value in America; seeds of *Kokia drynarioides* (closely related to cultivated cotton, but now almost extinct) have been imported from Molokai.

ORNAMENTAL AND WIND-BREAKING TREES.—The "doorn-boom" of the S. African veldt (*Acacia horrida*) is promising as a hedge and wind-breaking tree in Texas; 2 species of Tamarix (*Tamarix pentandra* var. *brachystachys* and *F. Karelini hirta*), have been imported from the desert

of Farab, Bokhara, Turkestan, in view of the good results obtained in Texas with *Tamarix* as low windbreaks; the Himalayan *Rosa odorata gigantea*, with white flowers 6 inches across, a climbing rose which may be crossed with others; the most beautiful flowering tree of Java, *Spathodea campanulata*, imported from Africa into the island, where it flowers almost all the year; as it has flowered in southern Florida new importations have been made.

**FRUIT TREES.**—The rapid growth of avocado (*Persea gratissima*) groves in California and Florida and the ever-growing appreciation of the value of the fruit, which contains over 29 % of fat, make the Guatamalan and Mexican hard-shelled varieties of much interest, they ripen in spring and winter and have remarkable shipping qualities; they have of late years been grown in California; a Ceylonese mango, almost as large as a coconut, of a bright red colour and with almost no fibre; a *Feijoa Sellowiana* seedling, with exceptionally large fruit; this species has proved exceedingly hardy in the south of the United States; 1 rosy-fleshed anona, called "ilama" (*Annona diversifolia*), one of the best of this class of fruit, and *A. purpurea*, with large aromatic fruit; 1 Chinese "wampi" (*Claucena lansium*) which grows well in Florida and may be cultivated for its fruit; 1 variety of coconut rich in oil, from Punta Burica, Panama; 4 varieties of apples resistant to the woolly aphis (*Eriosoma lanigera*); *Pyrus betulaeifolia* sent by Dr. BRETSCHNEIDER to the Royal Botanical Gardens, Kew, and the Arnold Arboretum, Jamaica Plain, Massachusetts, it may be used as stock and should be useful in selection work; *P. Bretschneideri*, very valuable as an ornamental tree, and yielding yellow, round, juicy fruit; according to SARGENT the best Chinese pear trees are derived from this variety; *P. ovoidea*, which is probably the parent of the KIEFFER blight resistant pear, it has large, abundant flowers, and foliage that turns scarlet in autumn; *P. phaeocarpa*, with pyriform fruit, which appears to be immune to blight (*Bacillus amylovorus*), for a large tree in the Arnold Arboretum for many years has never contracted the disease although exposed to infection. This collection of Chinese pear trees, made by the Arnold Arboretum, will facilitate a comparative study of Chinese species (from which KIEFFER and LE CONTE obtained their blight resistant pears, by crossing and selection) and the determination of their value for grafting and selection purposes; a wild apricot from the Shansi Province of China, where the natives pickle the kernels in brine and eat them as an appetiser; 2 small, sour, wild free-stone peaches from Sianfu, Shensi Province and Chaoyu, Shansi Province, China, respectively; *Prinsepia uniflora* from near Fucheng, Shansi, China, a hardy, shrub, bearing dark red, juicy and sour fruit resembling cherries.

629 — The Separation of Autogenous and Added Hydrocyanic Acid from Certain Plant Tissues and its Disappearance during Maceration. — ALSBERG, CARL L. and BLACK, OTIS F. (Office of Drug Plant, Poisonous Plant, Physiological and Fermentation Investigations, Bureau of Plant Industry, United States Department of Agriculture, Washington), in *The Journal of Biological Chemistry*, Vol. XXV, No. 1, pp. 133-140. Baltimore, Md., May, 1916.

In this paper it is shown that the leaves of *Prunus virginiana* must be

distilled with acid 4 hours before all of the hydrocyanic acid is liberated, whereas in *Andropogon* and *Panicularia* less than 1 hour is sufficient to liberate all hydrocyanic acid present. It is further shown that in macerating plant tissues that contain hydrocyanic acid a certain amount of the hydrocyanic acid present or of cyanide that may be added is so converted that it is not recoverable by distillation with sulphuric acid. This is not due to the action of enzymes or to the presence of glucose. It is thus shown that in determining hydrocyanic acid in plants several methods in corroboration of each other must be used.

630 — **The Direct Influence on the Stock of the Sap produced by the Scion, and the Action on the Plant of Acid Solutions Absorbed Directly: Experiments in Italy.**

— CAMPBELL, C., in the *Atti dell' Reale Accademia dei Lincei*, Series V, *Rendiconti*, Vol. XXVIII, 1st. Half-Year, No. 1, pp. 57-61 Rome, January 6, 1918

Plants that are wild or have become so are usually more resistant to parasites than cultivated plants; this has suggested the hypothesis to Prof. COMES that this difference in behaviour is due to the greater acidity of the sap of wild plants (1).

The author has tested Prof. COMES' hypothesis in two different ways: 1) by grafting a wild plant on a cultivated plant of the same genus (plum on peach or wild apple on an ungrafted apple) and studying the influence on the latter of the sap produced by the former; 2) by making the plant take up acid solutions through its aerial parts by the method of Prof. ACQUA (*Rendiconti della R. Accademia dei Lincei*, 1914).

**ACTION OF THE SAP PRODUCED BY THE WILD SCION ON THE CULTIVATED STOCK.** — If Prof. COMES' hypothesis is correct, the sap produced by the scion, being more acid, should increase the resistance of the stock to parasites. This was confirmed experimentally; in fact, after the 2nd and 3rd year of grafting, the influence of the scion on the stock is shown by the deeper colouring of the leaves of the cultivated plant (more marked in the peach) and its greater resistance both to drought and certain parasites: in the peach, against *Expasculus deformans*; in the apple, against *Oidium farinosum*.

**DIRECT ABSORPTION OF ACID SOLUTIONS BY THE AERIAL PARTS.** — Up to the present, the author has studied 0.5, 1 and 2 % solutions of tartaric, citric and malic acids in pure distilled water or plus a little saccharose to vary the osmotic pressure. By means of a cut branch immersed in water, an apple-tree heavily attacked by *Myzoxylus laniger* (= *Schizoneura lanigera*) and peach-trees heavily attacked by the aphid *Amuraphis persicae* (= *Aphis persicae*) were made to absorb acid solutions at first in 1915, then in 1916 and 1917. In the spring of 1917, it was found that, as regards the apple-tree which had absorbed the acid solution, the *Myzoxylus laniger* had almost completely disappeared and that, in comparison with the controls, the upper leaves were better developed and of a deeper green. The infection with the conidial form (*Oidium farinosum*) of *Podosphaera leucotricha*, with which all the other ungrafted plants were attacked, did not affect the plant in question or the wild plants. Of the 2 peach-trees most

(1) See B., 1913, No. 881; 1914, No. 978; R., 1916, No. 937. (Ed.).

severely attacked by the aphids, the one that had absorbed the acid solutions (and which was in worse condition than the other at the beginning) has survived, while the one that was not treated died.

The author has the intention of continuing and enlarging these researches, and he considers it will be useful to try again the influence of an American vine-scion on a European stock, as regards resistance to phylloxera, to establish the value of the change taking place in the chemical conditions and to include the direct absorption of liquid in his experiments.

**631 - The Influence of Acids on Germination (1).** — MAQUENNE, L. and DEMOUSSY, E., in the *Comptes Rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 14, pp. 547-552. Paris, April 8, 1918.

Up to the present there is no precise information available as to the influence of acids on germinating seeds. It is certain that they are injurious at concentrations of 1/1000, but nothing is known as to the minimum at which they begin to take effect. The latest work on this subject has been carried out by Mlle PROMSY (2) and M. MICHEELS (3).

For their experiments the authors used peas and wheat, previously swollen by soaking in pure water for 24 hours. The experiments were carried out in two ways: — in saucers, in sand soaked with weak hydrochloric or sulphuric acid, and in quartz tubes filled with the same solutions 100 times more dilute.

**CONCLUSIONS.** — Mineral acids should be placed among the substances that are most injurious to germination. Their toxic action which, when the acid is free from other substances apparently cannot be changed to a favourable one, can be modified by the presence of electrolytes of salts.

In this, acids behave like all other mineral poisons: especially harmful when acting alone, they are sensitive to the influence of antitoxins amongst which calcium appears to be one of the most powerful. And, as with the salts of heavy metals, mineral acids sensibly diminish the efficacy of calcium sulphate.

**632 - Some Effects of Organic Growth-Promoting Substances (Auximones).** — I. BOTTOMLEY, W. B. (Professor of Botany, University of London), Some Effects of Auximones on the Growth of *Lemna minor* in Mineral Culture Solutions, in the *Proceedings of the Royal Society (Biological Sciences)*, Series B, Vol. 89, No. B621, pp. 481-507 + 13 Tables + 7 Fig. + 2 Pl. London, 1917. — II. MCKERIDGE F. A. (King's College, London), Some Effects of Auximones on the Soil Organisms concerned in the Nitrogen Cycle. *Ibid.*, pp. 508-533, + 15 Tables, 1917.

I. — In a previous communication (3) the author showed that bacterised peat (4) contains certain organic growth-producing substances which he calls "auximones" and which, when added in very small amounts to wheat seedlings growing in water culture, cause a marked increase in growth.

(1) See R., September 1917, No. 803. (Ed.) — (2) Thesis No. 1479 of the Science Faculty of the University of Paris. Marseilles, 1912. — *Bull. Acad. Royale de Belgique*, Science Section, 1913. (Author).

(3) See R., January 1917, No. 21. — (4) See B., 1914, No. 1102. (Ed.)

The author started fresh experiments with *Lemna minor*, a plant whose rapid growth can be easily noted. A number of comparative culture tests (control cultures in Detmer's culture solution — cultures in that solution plus small quantities of extracts of bacterised peat as : - a) aqueous extract ; b) alcoholic extract ; c) phosphotungstic acid fraction ) have led to the following observations :—

1) The auximones contained in bacterised peat have an enormous influence on the growth of *Lemna*, even when added in small quantities: the plants grow in number and weight, the cells are larger, the protoplasm is denser, the nucleus larger and the chloroplasts are more numerous.

2) In *Lemna* normal growth and multiplication cannot be sustained for any length of time in the absence of auximones in an exclusively mineral solution ; auximones are essential for the effective utilisation and assimilation of the mineral substances supplied to these plants.

The addition to the mineral culture solution of 368 parts per million of organic matter from the water extract of bacterised peat resulted, after 6 weeks, in multiplication of the number to 20 times, and an increase in weight to 62 times, that of the control plants.

3) It is highly probable that these auximones are organic decomposition products, for bacterised peat is simply organic matter, already partly decomposed by anaerobic action, which has been further decomposed by the agency of aerobic bacteria under suitable conditions. Some of them may be absorbed and utilised directly as plant nutrients. SCHREINER and SKINNER have shown that such nitrogenous decomposition products as creatinine, histidine and arginine can replace nitrates in a culture solution, and that, even when nitrates are present, these substances are absorbed by the plants ; these compounds are absorbed as such and utilised directly for building up the proteins and other complex nitrogenous constituents of vegetable material. They also suggest that the energy required for the transformation of inorganic nitrogen into an organic form being no longer required, it can be expended otherwise when these substances are supplied to the plant and results in more rapid growth and increased plant efficiency. Other auximones may have a similar effect to the accessory food bodies or growth vitamins concerned in animal growth, which would explain the enormous effect produced in comparison with the quantities present.

5) The great sensibility of the plant to the action of these substances is shown clearly when the quantity of auximones is progressively diminished or when the culture solutions are exchanged.

6) The fact that plants can grow in exclusively mineral solutions does not constitute an objection to the suggestion that the presence of organic substances is necessary, for BROWN has shown that nitrogenous organic growth-promoting substances may be produced in the endosperm during germination and absorbed by the embryo.

II. — The author has made different cultures of the organisms concerned in the nitrogen cycle (nitrogen-fixing, nitrifying, ammonifying and denitrifying bacteria), which were mixed with extracts of bacterised peat. The results of the researches indicate that : —

1) Soluble humus is a very important factor from the point of view of the activities of soil bacteria. Its effect on the organisms appears to be largely independent of any organic matter it may contain; it is shown to be due to the presence of auximones;

2) auximones increase the rate of nitrogen fixation and nitrification, depress the rate of denitrification, and do not appreciably affect the rate of ammonification.

If auximones play some definite part in the building up of the complex nitrogenous molecules of the organism, it follows that a directly opposite effect should be produced on the two classes of bacteria (nitrifying and denitrifying) whose activities are directed upon such widely divergent lines.

633 — **Translocation of Seed Protein Reserves in the Growing Maize Seedling.** — PETTIBONE, C. J. V. and KENNEDY, CORNELIA (Biochemical Laboratory, Department of Physiology of the Medical School, University of Minnesota, Minneapolis), in *The Journal of Biological Chemistry*, Vol. XXVI, No 2, pp. 519-525, 2 Diagr. Baltimore, Md., September, 1916.

In view of the establishment of the fact that in animals the proteins of the food enter the blood stream and are transported to the tissues at least in large measure in the form of amino-acids, the authors have judged of interest to settle the same problem in connection with the transference of reserve seed proteins in plants and have undertaken the study of the form in which the reserve proteins of the kernel are transported in the growing maize seedling. The conclusion arrived at from the results is given below:—

It is clear that amino-acids are present in the flowing sap of maize seedlings. Since these compounds are present at all times in seed, rootlet and plumule, their presence in the flowing sap coupled with the migration of nitrogen, indicates beyond question that the process of transportation of the reserve proteins of the seed, to furnish building material for the proteins of the growing parts, takes place in a manner analogous to the transportation of protein food supplies in the animal organism. The appearance of a slight cloudiness when the sap was mixed with alcohol, and the relatively slight increase in amino-acid nitrogen after hydrolysis suggest, however, that a portion of the nitrogen may be transported in the form of soluble protein or protein hydrolytic products of peptide type.

PLANT  
BREEDING

635 — **Two New Varieties of Field Pea Obtained by Pure Line Selection, in Norway.** — CHRISTIE, W., in *Aarsberetning angaaende de offentlige foranstaltninger til Landbrugets fremme i aaret 1916*, pp. 515-518. Christiania, 1917.

The field pea (*Pisum arvense*) cultivated in Hedemarken (Norway) consists of a mixture of forms that differ in their yield of seed and straw, in their earliness, and other characters.

The article under consideration gives the results of researches carried out with the idea of isolating the best of the different forms. Thus, in 1905 and 1906, a choice was made from 118 and 225 specimens (destined to serve as parents for the new lines) in the localities of Nordre Lund and Buttekvaern, province of Furnes. A series of comparative trials, with progressive elimination of unpromising types, gradually reduced the number

of lines to 2 only, which were worth considering as valuable new varieties. These were "Möistad gulgrönne ert" (Möistad yellow-green field pea) and "Möistad brandede ert" (Möistad mottled field pea), entered in the genealogical register as No. 0203 and No. 0402.

As regards the yield of the different varieties and the length of their growing period, the following data is available for the 4 year period 1909-1912:

**YIELD IN SEED.** — The mottled field pea 0402 (relative yield: 100) takes first place with an average of 2248 lb. per acre, *i. e.*, 946 lb. more than the common Hedemarken field pea (relative yield: 83) and 242 lb. more than the yellow-green field pea 0203 (relative yield: 96), which only surpassed it in yield in 1911.

**YIELD IN STRAW AND EARLINESS.** — Both mottled and common field pea give practically the same yield in straw (3729 lb. and 3899 lb. respectively per acre) while the yellow-green field pea (3131 lb. per acre) gives a much inferior yield to both the others, probably on account of its earliness. In fact the length of the growing period is 109 days for the yellow-green field pea, 118 days for the mottled field pea, and 116 days for the common field pea. The more early a variety is, the smaller is the amount of green parts that it produces.

The following are the chief characters of the two new varieties: —

1) Möistad yellow-green field-pea No. 0203 — It is a form of *Pisum arvense* var. *unicolor* ("ensfarvet graaert") which differs from the common Hedemarken field pea in greater earliness and bigger yield of seed, while it is slightly inferior as regards yield in straw. The seeds are round, small, and of a fine yellow-green colour.

2) Möistad mottled field pea No. 0402. — It is a form of *Pisum arvense* var. *punctato-maculatum* ("prikket-marmoreret graaert") It is clearly superior to the common Hedemarken field pea for yield in seed, while retaining the useful earliness and high yield in straw that characterise the common variety. The seeds are mottled with brown on a grey-green ground, thus giving it its name 'mottled' field pea.

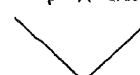

636 - **Maternal Inheritance in the Soy Bean.** — TERRAO, H., in *The American Naturalist*, Vol. LII, No. 613, pp. 51-56 New York, January, 1918

The cotyledons of the soy bean (*Glycine hispida* Maxim.) may be green or yellow. In the first case the seed-coat is always green, in the second it is either green or yellow. The results of the author's experiments since 1910, summarised below, show that these colours are transmitted by the maternal plant only.

1) **TRANSMISSION OF THE COLOUR OF THE COTYLEDONS.** — Reciprocal crosses between varieties with yellow cotyledons and with green cotyledons give, in the  $F_1$ , hybrids of the same character as the female parent. In  $F_2$  this phenomenon is repeated without there being any Mendelian segregation of characters such as might be expected. Table I illustrates the results.

TABLE I. — *Transmission of the colour of the cotyledons.*

Parents . . . . .	green ♀ × yellow ♂	yellow ♀ × green ♂
		
F <sub>1</sub> . . . . .	Plants with green cotyl. 100 %	Plants with yellow cotyl. 100 %
F <sub>2</sub> . . . . .	Plants with green cotyl. 100 %	Plants with yellow cotyl. 100 %

2) TRANSMISSION OF THE COLOUR OF THE SEED COAT. — This is more complicated. In the cross *Green* ♀ × *Yellow* ♂ (See Table II) the colour of the seed coat is transmitted exclusively by the female plant, as in the case of the cotyledons. The cross *Yellow* ♀ × *Green* ♂, however, gives in F<sub>1</sub> hybrids with yellow cotyledons and green seed coats, and in F<sub>2</sub>,  $\frac{3}{4}$  of the individuals have green seed-coats and  $\frac{1}{4}$  yellow seed coats according to the Mendelian ratio 3 : 1.

TABLE II. — *Transmission of the colour of the seed coat.*

Parents . . . . .	Green ♀ × Yellow ♂	Yellow ♀ × Green ♂
Colour of cotyledon . . . .	green      yellow	yellow      green
Colour of seed-coat . . . .	green      yellow	yellow      green
		
F <sub>1</sub> . . . . .	100 % green	100 % yellow
Colour of cotyledon . . . .	green	green
Colour of seed-coat . . . .	green	green
		
F <sub>2</sub> . . . . .	100 % green	25 %    50 %    25 % yellow   yellow   yellow
Colour of cotyledon . . . .	green	green   green   yellow
Colour of seed-coat . . . .	green	green   green   yellow

EXPLANATION OF THESE PHENOMENA. — The behaviour of the chlorophyll of the aerial parts of the plants is identical with that of the cotyledons; when the plant ripens the leaves and stem of individuals with yellow cotyledons turn yellow, whereas, in plants with green cotyledons, the parts keep their green colour without changing for a longer period. There are, then, two types of chlorophyll: — Y, which can be changed to yellow and, G which remains green. Both of these characters probably have their seat in the cytoplasm of the egg-cell, and are, thus, transmitted directly by the female plant.

The action of the chlorophyll of the seed coat, however, which may be green even in plants with yellow cotyledons, is probably due to the presence of a factor *H*, which prevents *Y* from colouring the seed coat yellow, so that it remains green even in the absence of *G*. The absence of the inhibitory factor *H* is expressed by *h*. In varieties with *G* chlorophyll the presence or absence of *H* is shown by the varying intensity of the green.

These facts make possible an explanation of the phenomena described above. Thus the cross *green* ♀ × *yellow* ♂, with the formula (*G*) *HH* ♀ × (*Y*) *hh* ♂, gives in *F*<sub>1</sub> a hybrid (*G*) *Hh*, which is green, and, in *F*<sub>2</sub> three hybrids (*G*) *HH*, (*G*) *Hh*, (*G*) *hh*, all of which have green cotyledons and seed coats (see Table III).

On the other hand, the cross *Yellow* ♀ × *Green* ♂, with the formula (*Y*) *hh* ♀ × (*G*) *HH* ♂, gives in *F*<sub>1</sub> individuals (*Y*) *Hh* with green seed coats, and in *F*<sub>2</sub>, 1/4 of the individuals (*Y*) *HH* green, 2/4 (*Y*) *Hh* green, and 1/4 *Yhh* yellow, as would be expected.

Table III shows the transmission of the characters "green" and "yellow". In each case *G* and *Y* are transmitted by the female plant only; thus, in the cross in the first column, the *F*<sub>1</sub> hybrid has the formula (*G*) *Hh* instead of *YGHh*. Similarly, in the cross in the second column the formula of the hybrid is (*Y*) *Hh* instead of *YGHh*. The factor *H*, however, is obviously contained in the nucleus and is also transmitted by the male plant, in accordance with the Mendelian law.

TABLE III. — *Transmission of the characters "Green" and "Yellow".*

<i>Parents</i> . . . . .	( <i>G</i> ) <i>HH</i> ♀ × ( <i>Y</i> ) <i>hh</i> ♂			( <i>Y</i> ) <i>hh</i> ♀ × ( <i>G</i> ) <i>HH</i> ♂		
Colour of cotyledons . . . .	green		yellow	yellow		green
Colour of seed coat . . . .	green		yellow	yellow		green
<i>F</i> <sub>1</sub> . . . . .	( <i>G</i> ) <i>Hh</i>			( <i>Y</i> ) <i>Hh</i>		
Colour of cotyledons . . . .	green			yellow		
Colour of seed coat . . . .	green			yellow		
<i>F</i> <sub>2</sub> . . . . .	( <i>G</i> ) <i>HH</i>	( <i>G</i> ) <i>Hh</i>	( <i>G</i> ) <i>hh</i>	( <i>Y</i> ) <i>HH</i>	( <i>Y</i> ) <i>Hh</i>	( <i>Y</i> ) <i>hh</i>
	25 %	50 %	25 %	25 %	50 %	25 %
Colour of cotyledons . . . .	green	green	green	yellow	yellow	yellow
Colour of seed coat . . . .	green	green	green	green	green	yellow

CONCLUSIONS. — The colour of the cotyledons is transmitted by the female plant only, and is due to two determinants, *G* and *Y*, contained in the cytoplasm of the egg-cell, and each subjected to the action of a third determinant, *H* contained both in the ovule and in the pollen grain, which has two effects on the seed coat: — 1) it modifies the intensity of the green colour, *G*; 2) it prevents plants containing *Y* from turning yellow.

The maternal inheritance described by the author seems to be identical with the character "*albo maculata*" studied by CORRENS in *Mirabilis Jalapa* (1) and by BAUR in *Antirrhinum majus* (2), which is only transmitted by the female plant.

637 - **Hybridisation Experiments between Different Varieties of the Cultivated and Wild Strawberry, in Alaska, U. S. A.** — *Annual Reports of the Alaska Agricultural Experiment Station* for the Years 1904-1915. Washington, 1905-1916.

Numerous hybridisation experiments were carried out from 1904 to 1915 at the Agricultural Station of Sitka, Alaska, with a view to obtaining a new type of strawberry combining the following characters: —

1) Resistance to winter cold and the capacity to ripen fruit regularly during the cold, damp summer of the coastal district.

2) Firm, slightly juicy fruit.

Both these characters are found in the wild Alaskan strawberry, *Fragaria chiloensis*.

3) High yield.

4) Large fruit.

These two qualities are characteristic of the cultivated varieties.

**ALASKAN WILD STRAWBERRY.** — *Fragaria chiloensis* is plentiful along the coast from Icy Strait to Prince William Sound, in the most sterile sandy soils, to which it has adapted itself so well that, when transplanted into richer soils, it produces abundant vegetation but no fruit. The leaves of this species are characterised by having a large number of leaflets, 4 on an average, sometimes even 5 or 6. Flowering begins during the first 10 days of June, 2 or 3 weeks earlier than the cultivated varieties. The first fruits appear at the beginning of July and the plant continues to bear fruit until very late in autumn. The fruit is of average size, conical shape, very delicate flavour, with firm, slightly juicy flesh, very resistant to packing and transport.

**CROSSINGS.** — The female parents were the cultivated varieties Enhance, Magoon, Bismark and Hollis. The last named, which may be a native of Michigan, has not as yet been identified and has received the name of the place from which it came last — Hollis, in Prince of Wales Island, Alaska.

The cultivated varieties, kept in greenhouses, so that they should flower at the same time as the native species, were first castrated then fertilised with pollen from *Fragaria chiloensis*. The  $F_1$  hybrids had the following characteristics: —

1) Vigorous, even excessive, growth.

2) Leaves similar to those of the native species, with 4 leaflets, but less well-developed blade, and longer and stronger petiole.

3) Earliness; resistance to unfavourable climatic conditions, but with very marked individual differences.

(1) CORRENS, C., *Zeitschrift für induktive Abstammungs- und Vererbungslehre*, Vol. I, 1909, pp. 291-329; Vol. II, 1909, pp. 331-340. — (2) BAUR, E., *Ibid.*, Vol. IV, 1910, pp. 81-102.  
(Author).

4) Fruit as large as that of the parent Hollis, sometimes even larger, possessing at the same time the valuable characters of the native strawberry — firm, slightly juicy flesh, delicate flavour.

5) Shape of fruit varying from round to conical with all intermediate graduations; the pointed forms usually have a better flavour.

6) High productivity — more than 250 fruits per plant in the hybrids Nos. 1503, 537, 320.

The crossings, therefore, gave positive results, since it was possible to unite in one plant the valuable characters of both parents. The selection work is being continued with a view to isolating and fixing the most promising lines and thus create a good type of strawberry capable of being propagated throughout the coastal district of Alaska. It should be noted that the development of the blade and the size and number of the stomata make the new varieties absolutely incapable of resisting even a short drought and thus limit their being grown further south than a little beyond the 50 th parallel.

638 — **Acclimatisation, Selection and Hybridisation Experiments with Fruit Trees in Alaska, U. S. A.** — *Annual Reports of the Alaska Agricultural Experiment Stations for the Years 1904-1915.* Washington, 1905-1916.

The results are given of a series of acclimatisation, selection and hybridisation experiments, carried out from 1903 to 1915 at the Agricultural Station of Sitka, in order to obtain types of apple, plum and cherry trees capable of growing and bearing fruit in the coastal regions of south-east Alaska.

In the interior (Yukon Valley) experiments with arborescent Rosaceae gave absolutely negative results from the beginning; the summer, though relatively warm, is too short for the wood and fruit to ripen, and the very severe winter never allows the plant to hibernate. Sitka is on the west coast of Barabanov Island in N. latitude 57° 3' and W. longitude 135° 20' (Greenwich meridian), and its climatic conditions are totally different from those which are suitable for the regular development of fruit trees. The summer-autumn period, from the last destructive spring frost to the first autumn frost, is fairly long (from May to September), but wet and cool, thus having an inhibitory influence on the ripening of fruit and wood. The winter, though less severe than in the interior, is nevertheless very cold and kills and, to a certain extent, causes necrosis of the buds which form during the favourable season. The absence of a hot and dry period prevents the plant from developing resistance to low temperatures by loss of water and thickening of the cell walls. The experiments dealt with varieties of apple, plum, and cherry trees.

I. APPLE TREES. — 1) *Acclimatisation.* The plants used in the acclimatisation experiments may be divided into three groups: — a) *Pyrus baccata*, a native Siberian variety; b) certain varieties known in North America as crab-apples, probably derived from a cross between *P. Malus* and *P. baccata*; c) different varieties of *Pyrus Malus* cultivated in the cold districts and known for their resistance to low temperatures.

*Pyrus baccata*, from Siberia and Manchuria, was first planted at Brandon, Manitoba, in 1890, and spread rapidly through the cold and wet districts of north-western Canada, where it thrives and bears fruit regularly every year. It is a fine tree with a thick crown, smooth bark, compact wood and tasty, reddish-yellow fruit, about the size of a cherry (diameter = 18 mm.) At Sitka it gave good results. Four times from 1908 to 1914 the fruit formed in good time, *i. e.*, before the first autumn frost; both the fruit and the wood ripen fairly rapidly.

Although few data on the subject are available the dates of the principal vegetative phases may nevertheless be stated approximately: — 1) Leafing during the first 10 days of June; 2) flowering during the last 10 days of June; 3) complete maturity towards mid-October. The first fruit was obtained in 1911 from trees 8 years old, planted at Sitka in 1903.

*Pyrus baccata* × *P. Malus*. — As has already been said the varieties of crab-apples are probably a cross between the two species *baccata* and *Malus* rather than products of a pure selection of *P. baccata*. These trees have already given very satisfactory results in different parts of Canada, and the experiments in Alaska justified the hopes placed in them. Only a few of the numerous varieties imported from time to time into Sitka responded to acclimatisation, but the greater part of those which succeeded belonged to the crab-apple varieties. They were Whitney, Transcendent, Martha, Sylvan Sweet, Buir Sweet, Hyslop, Yellow Transparent, and Livland Raspberry. The two last hold first place. (The Report gives two photographs of Whitney and Livland Raspberry apple trees, with their fruit).

*Pyrus Malus*. — The varieties Duchess, Peerless, Wealthy, Tetofski, Keswick's Codlin and a few others are resistant to low temperatures and bear fruit, which, however, rarely ripens. In 1915 only, chiefly owing to the relatively warm September, all the above-mentioned varieties gave good yields, and the fruit ripened completely, but differed from fruit of warmer climates in its smaller size and longer, conical shape. Only summer varieties, ripening generally in the United States at the end of July or during the first 10 days of August, should be imported. None of the autumn varieties, although resistant to cold, can ripen early enough, *i. e.*, during the first 10 days of October at the latest. The approximate dates of the various phases of development are: *a*) growth of the wood-buds, towards mid-May; *b*) leafing during the first half of June; *c*) flowering during the second half of June; *d*) ripening during the first half of October; *e*) fall of leaves during the second half of October.

2) *Hybridisation*. — Along the Alaskan coast and near the sea, the native Alaskan Crab (*Pyrus rivularis* L.; a photograph of a branch is given) grows wild in dense thickets which are sometimes impassable. It rarely has a single stem, but usually a clump of shoots which branch out a few inches from their base and may reach a height of 18 to 22 feet, and a diameter of from 4 to 6 inches. The leaves are ovate-lanceolate with long petioles. The yellowish-red fruit, hardly bigger than a pea, looks like miniature apples, and has a very delicate taste and smell. It makes excellent jam. *Pyrus rivularis* flowers abundantly during the first days of June

(10 to 12 days earlier than the varieties under consideration) and ripens remarkably early, during the first days of October. As a rule the wood and new tissues attain a sufficient degree of ripeness and compactness each year to resist the winter cold.

The most important characters required are productivity, good quality fruit and resistance to adverse climatic conditions. An example of a satisfactory realisation of such factors is found in the wheat selected for southern Sweden. Crosses between the native varieties of Swedish wheat, early and resistant to cold, but with low yields, with the very productive, but late and slightly resistant English Squarehead varieties, gave hybrids uniting satisfactorily all the desired characters thus helping to increase considerably the grain yield of southern Sweden. Similarly it was thought that *Pyrus rivularis*, a native Alaskan apple, early and resistant, might be crossed with varieties of *P. Malus* with a view to increasing their resistance and also producing larger and better quality fruit.

So far the results of the experiments have been unsatisfactory. This is not surprising considering the bad state of preservation of the pollen used (collected in the United States from trees flowering 1 or 2 months before the Alaskan apple and sent by post). This difficulty has been overcome by using pollen from a resistant variety of *Pyrus Malus* flowering at Sitka almost at the same time as *P. rivularis*. The crosses were successful, but a large proportion of the fruit fell before fully ripe. A small quantity of seed obtained in 1914 was used, and positive results are hoped for eventually. It must be remembered that:— 1) certain varieties of *P. Malus* have succeeded, in favourable years, in ripening their fruit completely; 2) crosses with *P. baccata* have already produced very resistant types, with relatively large and well flavoured fruit. The greater part of the varieties crossed satisfactorily at Sitka and acclimatised there are crab-apples; 3) if, therefore, satisfactory results have been obtained with *P. baccata*, it is probable that *P. rivularis*, when the hybridisation has succeeded, will give yet better results. The hard varieties of *P. Malus*, the Siberian crab-apple (*P. baccata*), the hybrids *Malus* × *baccata*, the Alaskan apple (*P. rivularis*) supply material rich in varied characters, which, when suitably selected and combined, will probably lead to the formation of types specially adapted to the extreme northern districts.

II. PLUM TREES. — Numerous species and varieties of plum trees have been tested at the Sitka Experiment Station. Among them may be mentioned May Day, Tomahawk, Sayles, Wyant, Hawkeye, Forest Garden, De Lota, Rollingstone, Siont, Red June and Ait Kin, which flower during the first half of July, but do not bear fruit on account of the rain and damp which prevent setting. Varieties known for their resistance to cold obtained by HANSON in South Dakota for crossing with *Prunus Besseyi* Bailey, also gave absolutely negative results. In reality it is not the severe winter which prevents the growing of plums in south-west Alaska, but rather the heavy rains, absence of high summer temperature (see Table I), and the unfavourable weather conditions, which prevent the fruit from setting and the wood from ripening. The tissues which form in summer remain

turgid and without cohesion, and are destroyed every winter by temperatures which in other latitudes the plum could bear without suffering such serious damage.

In 1914 and 1915 a greengage produced ripe fruit in a garden at Sitka; the plant, however, had been grown on a trellis well protected from the wind. A hybrid from Koslov, obtained from the Botanical Garden of Chico, California, also promises well and good results are expected from varieties imported from northern Europe. Nevertheless, the results so far obtained must, on the whole, be considered as absolutely negative.

III. CHERRY TREE. — The varieties of sour cherry cultivated at Sitka flower profusely every year, but only a small proportion of the flowers (slightly more than 10 %) set. This is due to two causes:— 1) the summer rains and moisture which largely prevent normal setting; 2) the absence of pollinating insects. The little fruit which forms rarely ripens in good condition; rains and moisture crack the skin and cryptogamic diseases often attack the fruit and spoil it entirely. The 4 varieties, Early Richmond, English Morello, Ostheim and Dyehouse, planted in 1903, with the exception of the disadvantages already mentioned, stood the test well and began to bear fruit in the 5th year. The dates of the different stages of development are:— 1) leafing, first days of June; 2) flowering, on an average towards the end of June or the first days of July, with great annual variations. Thus, in 1909, English Morello began to flower towards June 15, but in 1908 towards July 15. The same applies to the other 3 varieties. In very cold and damp seasons flowering is slow and may continue till August, but, in this case, the fruit does not ripen, as was the case in 1907. Setting occurs between the 10th and 20th day after the beginning of flowering, but, as has been said, it is rare; in 1906 only, under exceptionally favourable climatic conditions, the percentage of fertile flowers reached 40 %.

*Ripening.* — The English Morello and Dyehouse varieties usually ripen towards August 12, Ostheim towards the 10th, and Early Richmond (of which the Report gives a photo), the earliest variety, towards the 8th.

*Duration of growing period and the various sub-periods.* — a) between the fall of the leaves, which occurs about October 15, to the leafing of the following season, there is a period of about 7 ½ months; b) there are, on an average, 30 days between leafing and flowering; c) in spite of the low temperature and great moisture, there are barely 40 to 45 days between flowering and ripening. In this case the first place is again held by Early Richmond, with a real record for earliness, 1 month (1); in 1908, flowering July 15, ripening August 15; in 1906, flowering July 1, ripening August 1; d) there is usually a little more than 2 months between ripening and the fall of the leaves. In order to compare the effect of meteorological factors on growth, Tables I and II reproduce the figures obtained at Sitka in 1906. Table I gives an idea of the peculiarities of the climate at Sitka during the formation and development of the fruit:— 1) heavy rains (July and August);

(1) In Italy an average of 71 days (Azzi, G., *Climatology and Phytogeography*, in *Rivista meteorico-agraria*, Year XXXVI, No. 33, p. 24. (Ed.)

2) relatively low average daily temperature (July; 10°C., whereas at Rampart, in the interior, it was 12.1°). In spite of that the first ripe fruit was obtained on August 1, so that the total average daily temperature during the 3rd sub-period of growth (from flowering to ripening) is a little over 3000° C. (3060°C.) (1).

CONCLUSIONS. — 1) *Plum trees*, results almost completely negative; the fruit and wood ripen in exceptional cases only; 2) *Cherry trees*, certain cultivated varieties of sour cherry may, without any morphological change, develop in the south-west of Alaska, limiting the duration of the 3rd sub-period to a minimum of one month, in spite of the damp and coolness of the coastal districts; 3) *Apple trees*, none of the cultivated varieties of *Pyrus malus* can be successfully imported, hybrids obtained from crosses with crab-apples give no regular annual crop, and only bear fruit every two years or more rarely. Nevertheless the wild Alaskan *P. rivularis* may be crossed with *P. malus*, and it is probable that, by a series of such crosses, the small fruit of the wild apple might be improved without decreasing the resistance which allows the tree to flower and bear fruit regularly each year. Alaska can certainly never become a fruit-producing country, but this in no way diminishes the great practical and scientific importance of these investigations, the results of which may be profitably applied in the high mountains and vast northern regions of America, Asia and Europe.

TABLE I. — *Meteorological data obtained at the Sitka Station, Alaska, during the period January-October, 1906.*

(These meteorological data should be compared with the data for the growth of the apple and plum trees given in the text).

639 — **The Germination and Purity of Seeds in Montana.** — ATKINSON, A., WHITLOCK, B. W. and JAHNKE, E. W. *University of Montana, Agricultural Experiment Station, Bulletin No. 113, Third Annual Report of the State Grain Laboratory of Montana*, pp. 79-100. Bozeman, Montana, December, 1916.

AGRICULTURAL  
SEEDS

The work of the Montana State Grain Laboratory during the year 1915-1916 consisted of: — 1) Purity and germination tests of 5 035 samples received; 2) a study of the seed value of frosted wheat; 3) a continuation of the study, begun in 1915, of hard seeds in clover samples; 4) a study of the germination of seeds at different periods after harvesting; 5) cooperation with the Association of Official Seed Analysts of America in studies on the standardization of grain laboratory methods; 6) a continuation of milling and baking studies of Montana wheat.

The two outstanding features of the year's work were a great increase in the number of samples sent for testing, and the very marked increase in the weed-seed content of alfalfa, clover, timothy and sweet clover. There is a tendency for the impurities in seed samples to increase each year; for example, in 1913-14 the average percentage of impurities was 5.91, in 1914-15 it was 6.32, and in 1915-16 it rose to 8.3. The purity of alfalfa and clover was higher in 1915-16 than in the two preceding years, but was still considerably below the standard. There is no doubt that there is an increased percentage of bad weeds in all crops, and, unless great care is taken to insure the use of clean seed, this increase may become very serious.

Numerous tests were made of the average germination of the principal grains and grass seeds grown. Maize, oats, barley and flax, had a somewhat lower average germination for the year 1915-16 than for 1914-15, though the decrease was of importance in maize only, the average germination of which was below 80 %, thus again showing the importance of carefully testing seed maize. The average germination of alfalfa and clover was satisfactory, very little of the seed falling below the Government standard. Many vegetable seeds were also tested and, except in the case of parsnips and carrots, the average germination quality was generally high.

To determine the value of frosted grain for seed, comparative field tests were made of the germinating capacity of frosted and unfrosted seed. The results given in Table I showed that frosted grain has a slightly lower field germination, but gives a greater number of heads per row and a higher yield.

Experiments with Marquis wheat have been carried out at the Experiment Stations of 13 States, from Iowa to Minnesota in the east to Oregon and California in the west. In this vast stretch of land the adaptation and value of the new variety vary with the local conditions. This part of the United States may be separated into four divisions according to the chief conditions of the districts ; 1) the northern Prairie or sub-humid zone, 2) the northern Great Plains or semi-arid zone ; 3) the western Basin and the Coast or arid zones, 4) the irrigated districts of the northern Rocky Mountain region and great Basin zone.

A. — VALUE IN THE SUB-HUMID ZONE. — Wherever possible winter wheat should be grown. Where spring wheat can be grown the Marquis variety may be recommended. The varieties of Fife, Bluestem, and Preston grown should not be hastily discarded ; the Marquis should be compared with these spring wheats and the best one chosen.

B. — VALUE IN THE SEMI-ARID ZONE. — 1) The winter varieties are best wherever they can be grown in the north of the Great Plains districts ; 2) durum wheats are better than any common spring wheats in this zone ; 3) Marquis is better than any other variety of common spring wheat in some parts of this zone and equal to any throughout the district. Where spring wheat is grown and durum is not used Marquis is a safe variety to cultivate.

C. — VALUE IN THE ARID ZONES. — The dry lands of the States west of the Rocky Mountains are included in the arid zones. Marquis wheat is not to be recommended for this district.

D. — VALUE IN THE IRRIGATED ZONES. — Marquis wheat has not yet been largely grown in the irrigated valleys of the western States. According to the information available it has given good results in western South Dakota and in Montana. In Idaho and Nevada the soft white spring wheats, such as Dicklow, Defiance, Palouse, Bluestem and Little Club all out yielded Marquis under irrigation.

MILLING VALUE. — Marquis is a first class wheat for flour making, being at least equal to Fife and Bluestem in this respect.

II. — The results obtained with Manitoba wheat in France and North Africa have exceeded all expectations ; it has proved to be a spring wheat suitable to all the districts of France, and in the south of this country, in Algeria and Morocco it seems capable of replacing winter wheat, Marquis wheat appears to have all the good qualities of this wheat without its defects.

Marquis wheat was studied by the author in the Paris district, at Grignon, and by M. SÉBASTIAN in the south of France, in the Bouches-du-Rhône. The results confirmed those of M. DE VILMORIN (1). — Marquis wheat proved earlier and more productive than Manitoba wheat. In M. SÉBASTIAN'S field it developed in 107 days, ripened 8 days before Manitoba and 12 days before Red Fife (the chief variety of the mixture of wheats forming Manitoba). It yielded 0.030 lb per square foot, whereas the two other varieties barely yielded 0.024 lb. per square foot.

642 - **The Origin, Characteristics, and Quality of Humpback Wheat.** — THOMAS, LEVI M. (Assistant in Charge of the United States Grain Standardization Laboratory at Fargo, N. Dak.), in *U. S. Department of Agriculture, Bulletin* No. 178, 4 pp + 1 Plates. Washington, D. C., December 30, 1916.

Humpback wheat is a bearded spring wheat characterized by a velvet chaff. It is being grown in increasing extent in Minnesota and to a limited extent in the Dakotas. This wheat has found favour with the producers because of the large yields claimed for it, but it is generally discriminated against by the grain trade because of its alleged inferior milling qualities.

This strain of wheat is said to be the result of a field selection by J. P. BERGLUND, a farmer living near Kensington, Minn., who about 18 years ago found, growing in a field of Bluestem wheat, a plant distinguished from the rest of the field by bearded heads and a more vigorous growth. The seed from this plant was planted separately, and produced a strain of wheat known as Humpback, which wheat was first distributed among the Kensington farmers 11 or 12 years ago. It was originally called Bearded Bluestem, a name given to it by Mr. BERGLUND because it has the characteristic velvety chaff of Bluestem, but it soon earned the more popular name of Humpback, owing to the peculiar shape of the kernels, the dorsal side being characterised by a prominence immediately to the rear of the germ and a curved slope toward the brush, making the term Humpback quite descriptive. The term Marvel, and perhaps other names, has been applied to this variety by distributors of the seed. This wheat should not be confused with the so-called Velvet Chaff wheats of the Northwest, which are bearded spring wheats of the Red Fife type and have a smooth chaff.

Humpback wheat has a large berry, somewhat soft in texture, giving a high yield of flour. The weight per bushel of this wheat is higher than that of Bluestem wheat.

The flour from the samples of Humpback wheat was lower in baking strength and general quality than the flour from the other spring wheats which were tested.

Milling and baking tests of Humpback wheats gave the following average results : — yield of straight flour, 71.2 per cent ; volume of loaf per 340 gm. of flour, 2145 cc. ; absorption (water used per 100 gm. of flour), 49.8 ; colour of crumb (score), 95.1 ; crude protein (N  $\times$  5.7) : in flour, 13.76 % ; in wheat, 14.35 %.

643 - **Plants Yielding Tannin, in India.** — See No. 699 of this *Review*

644 - **Venezuelan Production of Balata.** — BRETT, H., in *Commerce Reports*, No. 272, pp. 698-699. Washington, D. C., 1917.

Balata, a gum similar to gutta-percha, is largely used in the manufacture of belting. It is obtained from the sap of *Mimusops globosa* Gärtn., a tree reaching 100 feet or more in height, which is widely distributed over eastern Venezuela and the Guianas. The latex is secreted between the bark and the wood of the tree ; it contains nearly equal proportions of resin and gutta, the latter being identical with true gutta-percha.

PLANTS  
YIELDING  
TANNIN

RUBBER,  
GUM AND RESIN  
PLANTS.

The word "balata" is of Carib origin and is used by the natives of British, Dutch, and French Guiana as well as by those of Venezuela, but it is applied solely to the gum, the tree being known as the "purguo". On the coast between Puerto Cabello and Cape Codera the tree is called the "nisperillo".

The commercial exploitation of this tree in Venezuela began near Maturin, where by 1894 it had already been exterminated. Sap collecting was then begun near San Felix in the State of Bolivar and, as the tree became scarcer, the area of operations was extended eastward to the boundary of British Guiana and southward along the Orinoco and its tributaries to all accessible regions. In Venezuela the custom is to cut down the trees in order to obtain the sap, and the industry has thus been progressively destroying itself. A governmental commission estimates that in the last 10 years alone the 10 000 collectors have destroyed 36 000 000 "purguo" trees and that the direct loss to the nation from this cause amounts to more than half a billion dollars. In spite of the fact that in British and Dutch Guiana felling is prohibited and that regular production of latex is obtained by tappings that do not kill the trees, the merchants of Ciudad Bolivar have opposed any governmental prohibition of the cutting down of trees, arguing that in whatever manner the tree is cut it will die and that there is no better method of obtaining the latex than felling.

The "purguo" is of slow growth, the period required for a tree to reach the productive stage being more than 10 years and full development not being attained for 30 years or more. The fruits, being agreeable in taste, are nearly all eaten by wild animals, so that natural reproduction is slow. The trees usually grow at the foot of hills where the soil is fertile and moist but not waterlogged, always scattered among other species and never densely. Land on which there are 16 purguos to the acre is considered rich.

The balata harvest begins in May and ends in August, but in years of continuous rains work may be carried on at all times except when the tree is in flower, the sap being then so poor as not to be worth gathering. The collector leaves his camp at 5 a. m., fells the first tree he finds, and makes four cuts on each side of the fallen trunk, to each of which he attaches a tin receptacle to catch the flow of latex. Having worked two trees he returns to his camp about noon carrying the product of his toil in a bag waterproofed with the same sap. The contents of the bag are emptied into a large receptacle. On Saturday all the collection of the entire week is coagulated by cooking, and afterwards the gum is pressed in wooden moulds into slabs weighing from 50 to 100 lb.

Under present methods the average production per tree is 3 gallons of latex, producing 18 lb. of balata worth from 15 to 40 cents a pound. By tapping properly it is estimated that each tree would produce latex worth \$2 each year for 30 years or more.

For a number of years balata, ranking immediately after coffee and cocoa, was third in importance among Venezuelan exports. The amount

and value of the shipments (stated in metric tons of 2 204.6 pounds and in American currency) from 1905 to 1916 were: —

Year	Tons	\$	Year	Tons	\$
1905 . . . .	1 461	755 400	1911 . . . .	2 222	2 449 070
1906 . . . .	1 280	863 830	1912 . . . .	1 698	1 767 260
1907 . . . .	1 545	1 128 595	1913 . . . .	2 219	2 032 870
1908 . . . .	1 465	1 149 600	1914 . . . .	894	698 625
1909 . . . .	1 650	1 283 575	1915* . . . .	1 069	789 325
1910 . . . .	1 903	2 193 800	1916* (six months)	287	226 215

(\*) According to *Documentary Leaflets of the International Institute of Agriculture*, April 1918, the exports for 1915 and 1916 were 1027 and 623 metric tons respectively (*Ed*)

The war has caused great changes in the course of the trade in Venezuelan balata. During 1913 Germany led among the buyers of the gum on the Ciudad Bolivar market, France ranked second, the United States third, and Great Britain fourth. In 1914 the United States rose to first place, followed by France, Germany and Great Britain in the order named. In 1915 Great Britain occupied first place, the United States was second, and France was a poor third, Germany disappearing from the list. In January-June, 1916, Great Britain and the United States again ranked first and second, respectively and France and Germany were both missing from the list.

In 1906 the price of balata in Ciudad Bolivar reached the then high mark of 35 cents a lb.; the average price is between 14 and 21 cents. The best price in 1915 was 23.7 cents, but the latest official tariff of exportable products issued by the Ciudad Bolivar custom house fixed the official valuation of balata at 5 bolivares per kilo, or 43.8 cents per lb.

645 — The Nature of the Soil and Manuring as Factors Determining the Tendency of Beets to Bolt (Set Seed) the First Year (1). — MUNERATI, O. and ZAPPAROLI, T. V., in *Le Stazioni sperimentali agrarie italiane*, Vol. LI, Pt. 1-2, pp. 24-40 + 2 Diagrams + 2 Pl. Modena, 1918 (*Authors' summary*).

SUGAR CROPS

The observations and researches of various experimenters (PRASKOWETZ, HERZOG, HOLRRUNG, DEUTSCH, MONTE MARTINI) had already shown that the tendency of the beet to become annual is favoured by special external conditions, particularly by heavy applications of manures, especially organic ones, but no information was available derived from careful and systematic work. At the R. Stazione Sperimentale di Bieticoltura (Royal Beet-growing Station) the authors, after some preliminary work carried out between 1912-1914 (which shows that the phenomenon of "bolting" is certainly favoured by external conditions which place the plants in a condition to benefit from a copious supply of food material), started more rigorous and far-reaching experiments in 1916, both in the field and in boxes (DEHÉRAIN type), by varying the kind of soil and using, as well as various fertilisers, exaggerated quantities of farmyard manure, in order to reproduce the case, fairly common in practice, of badly spread farmyard manure or of heaps washed for a long period by the rain.

(1) See also R., May 1917, No. 427. (*Ed*.)

Sowing was carried out about a month before the usual time when the stoppages of growth take place that more or less usually cause the beet to bolt. Germination took place simultaneously in both manured plots and boxes and in those that received no fertiliser, but in the former, growth was naturally much better. Below are given the percentages of plants obtained:—

	Percentages of annual plants			
	Without manuring	With manure		
		Complete mineral	Organic	Complete organic and mineral
Plots of medium soil (naturally fertile). . .	23	50	51	55
Boxes with sandy soil. . . . .	1-2	15	25	29
Boxes with medium soil (naturally fertile). . .	11-15	24	48	40
Boxes with organic soil (peaty). . . . .	28-34	41	44	41

CONCLUSIONS:— 1) It is clearly shown that the nature of the soil and manuring influences the bolting of beets.

2) The soil has an influence all the more as its fertility and richness in organic matter are greater.

3) The manuring, whether chemical or chemical plus organic, caused a considerable increase in the percentage of annual plants.

4) With the same seed sown at the same time, the extremes in the number of plants that bolted varied from 1-2 % in sandy, unmanured soil, to 55 % in fertile, heavily-manured soil.

5) It is impossible to say whether the increase in soil temperature caused by a heavy dressing of farmyard manure, independently of the food material it contains, has any influence; in any case, the number of plants that set seed was considerable even in those plots and boxes that had only received a dressing of mineral manure.

6) It cannot be stated whether the organic, chemical, or mixed manuring causes an increase in the number of annual plants on account of the finer growth of the plants in the beginning, as the same tendency was shown even by weakly plants.

7) These observations confirm the necessity of considering *Beta vulgaris* as a facultative biennial and annual form (DE VRIES). It appears inexact to consider the setting of seed by the beet during the first year as a phenomenon of atavism.

646 — Experiments on the Cultivation of Sugar Beet in Sicily. — BORZI, A., in *Bollettino di Studi ed Informazioni del R. Giardino coloniale di Palermo*, Vol. IV, Pt. 1-2, pp. 10-26. Palermo, 1917.

Sugar beets were first grown experimentally over 1 195 square yards of the Colonial Garden, and then by farmers who were supplied with seed from the Garden. The following varieties were tested:— Rich French white sugar variety (Fouquier d'Hérouel); improved white sugar, original selection A; improved white sugar, original selection B; Klein-Wanzleben. Sow-

ing was carried out in mid-January, and harvesting at the end of June. At the Colonial Garden a harvest equal to 14.33 tons per acre was obtained. The average percentage of sugar was 12.7, with a minimum of 11.45 and a maximum of 14.10. Taken as a whole the results showed that conditions favourable to growth may be obtained if the date of sowing is advanced by about 3 months so that the critical period during which the crop demands the maximum amount of water includes a good part of the winter and spring, and the vegetative period continues till the beginning of summer, when heat has an accelerating influence. By this means the economic utilisation of beet is rendered possible in Sicily as a rotation crop where cereals are grown.

647 — **Varieties of Strawberry (1) and Their Culture in Indiana, U. S. A.** — OSKAMP, J., under the direction of WOODBURY, C. G., in *Purdue University Agricultural Experiment Station*, Vol. XX, *Bulletin* No. 200, pp. 16 + 14 Figs., Indiana, July, 1917. HORTICULTURE

Using as basis the observations made on the trials carried out at the Lafayette Agricultural Experiment Station (Indiana), 32 comparatively new varieties of strawberry are described, brief mention being made of 16 which, amongst those previously described (*Bulletin* No. 154, *Purdue University Agricultural Experiment Station*), are most popular in Indiana. The list indicates the self-fertile flowers and the pistillate or imperfect blossoms. In planting pistillate sorts, a staminate flower should be set every four rows to ensure proper pollination. Forty-two of the varieties are midseason; 6 (Americus; Dewdrop; Pan American; Progressive; Superb; Productive) are autumnal; among them only the last one requires cross fertilisation; of the mid-season varieties, 33 (Baldwin's Pride; Baltimore; Barrymore; Chesapeake; Class A; Early Jersey Giant; Early Market; Early Ozack; Evening Star; Fuller; Gandy; Grand Marie; Helen Davis; Hub; Indiana; Joe Johnson; Late Jersey Giant; Lea; Manhattan; Missionary; Ohio Boy; Orem; Pearl; Posey; Rewastico; Senator Dunlap; Sons Prolific; St. Louis; Twilley; Warren; William Bell; Winner) are self-fertile and 9 (Anna; Bauer; Class B; Columbia; Haverland; Knaub No. 1; Knaub No. 6; Sample; Warfield) require cross fertilisation.

For each of the 32 comparatively new varieties, the name of the person or firm supplying the original plants is given.

648 — **Varieties and Cultivation of Raspberries, Blackberries, Gooseberries and Currants in Indiana, U. S. A.** — OSKAMP, J., under the direction of WOODBURY C. G. I. Varieties of blackberries and raspberries with notes on their care, *Purdue University, Agricultural Experiment Station, Bulletin* No. 201, Vol. XX, pp. 12 + 6 Figs. Lafayette, Ind., August, 1917. — II Gooseberries and currants, *Ibid.*, *Bulletin* No. 207, Vol. XX, pp. 11 + 10 Figs. Lafayette, August, 1917.

The author, taking as basis observations made during five years' experimental work at the Agricultural Station of Purdue University, Lafayette, describes 24 varieties of *blackberries*, the best of which are Agawam, Ancient Briton, Eldorado, Stones Hardy, Taylor; 9 varieties of *black raspberries*,

(1) As regards strawberry selection and variety tests see R. 1916, Nos. 408 and 748: R. 1917, Nos. 18, 322 and 637. (Ed.)

among which may be recommended Cumberland, Kansas, New Stone Fort, Plum Farmer; 15 varieties of *red raspberries*, the best of which are Cuthbert, Early King (King), Loudon; 17 varieties of *gooseberries*, specially recommending Downing, Houghton, Josselyn (American Red Jacket), Oregon Champion, Pearl; 14 varieties of *currants*, with special mention of North Star, Red Cross, Red Dutch, Wilder.

For each plant is given a short note on the method of cultivation and pruning, its enemies, diseases and methods of controlling them.

**FRUIT  
GROWING**

649 — **The Common Honey Bee as an Agent in Plum Pollination.** — HENDRICKSON, A. H., in the *College of Agriculture, Agricultural Experiment Station, University of California, Bulletin* No. 274, pp. 127-232, 2 Figs. Berkeley, December, 1916.

The experiments described, carried out in the Santa Clara Valley, forms part of a series undertaken to determine why, under certain conditions, some plums bear abundant crops and under other conditions bear light crops or none at all.

In a large orchard two pairs of adjacent French and Imperial plum trees, as nearly as possible of the same age and size, were enclosed in a tent of white mosquito net, so as to exclude all insects. In every other way the trees were under the same conditions as the other trees in the orchard. The tents were put up before any of the blossoms opened, and taken down when there was no longer any danger of outside pollination. As soon as 25 % of the blossoms had opened a hive of bees was placed under one tent, and kept there throughout the blossoming period (about 5 days.) The bees seemed to prefer the flowers of the French plum to those of the Imperial plum. The results are given in the following table.

Trees	No. of blossoms counted. April 11, 1916	No. of fruits matured. August 7, 1916	Percentage
French plum under tent with bees . . .	1 069	193	18.05
French plum under tent from which bees were excluded . . . . .	1 058	11	1.94
French plums, average orchard set . .	9 991	359	3.54
Imperial plum under tent with bees	1 060	18	1.89
Imperial plum under tent from which bees were excluded. . . . .	1 050	0	0
Imperial plum, average orchard set. .	2 180	157	7.20

It is seen that the French plum under the tent with the bees set a much higher percentage of fruit than the other trees. The light crop obtained from the Imperial plum under the tent with the bees is unaccounted for, and it is intended to carry out further experiments to determine the cause.

The results show the honey bee to be one of the most important factors in carrying pollen from one tree to another. The most satisfactory method of introducing bees into orchards has not yet been decided, but it seems as if the best results would be obtained by placing about one hive to

the acre during the blossoming period, after which the hives could be removed.

650 - The Selection and Acclimatisation of Fruit Trees in Alaska, U. S. A. — See No. 638 of this Review.

651 - Grafting Stock in Sicily: the Experimental and Demonstration Vineyards Attached to the Royal Nursery of American Vines at Marsala. — PAULSEN, F and MAGGIONI, N. in *Relazione sull'andamento del R. Vivaro di Viti Americane di Palermo*, pp. 42 + 5 Tables + 1 Map. Palermo, 1916. Abstract in *Le Progrès agricole et viticole*, Year XXXIV, No. 48, pp. 537-454. Montpellier, December 2, 1917.

VINE GR

The authors give the results of observations on grafting stock made by them in Sicily from 1907 to 1912. The hybrids obtained in the Palermo nursery were kept under observation for some time in the Luparello vineyard for parent plants and in the Rocazzo experimental vineyard, in deep, rather heavy loam, free from lime, and much infected by phylloxera. The hybrids which showed the best qualities were propagated and transferred to the experimental vineyards of the Marsala district (Vineyard of Casa Bianca, Spagnola, and Misilla) in order to study their resistance to lime and drought, their affinity for the various local stocks, some of which are the same as those of the province of Palermo, and their productivity as compared with that of these stocks. The authors' observations are not only of interest to vine-growers in Sicily, but also to those in Algeria and hot countries.

The resistance to chlorosis of the stock imported from France into Sicily is greater there than in their native country or Upper Italy. This is due to the very different climatic conditions, and chiefly to the difference in the distribution of rain in the southern and northern countries. In the northern countries rain usually falls during the period of vegetative growth, whereas in Sicily it falls during the winter rest, so that much less calcium carbonate is absorbed. Tolerance to this substance may also vary very greatly, by 20, 30 or 40 %. This influence of climate and the seasons is still more emphasised by the fact that rain water, unlike telluric water, always contains some carbonic acid which acts as a solvent on the calcium carbonate, thus greatly facilitating its absorption, and consequently, increasing its harmfulness.

According to the authors the high resistance of some vines to chlorosis depends on a selective faculty possessed within certain limits by the absorbing roots, which special environmental conditions, such as those mentioned above, can only decrease or increase.

Resistance to chlorosis is usually less in American vines than in native vines and their hybrids, and depends on the extent of the secretion of acid substances; those species and varieties with most acidity in the roots are least resistant to chlorosis and vice versa.

Moreover, this character is connected with the presence in the soil of certain substances such as iron and, it would appear, magnesia, which neutralise the injurious action of the calcium carbonate and are necessary to the formation of chlorophyll.

As regards *adaptation*, the authors noticed that certain Franco-American hybrids (Aramon  $\times$  Rupestris G. No. 1, and Mourvèdre  $\times$  Rupestris 1202) were subjected by the changes in environment to marked variations from the characters observed in France. Especially have they shown a rather low resistance to drought, by reason of a climate much warmer than that of their native country, particularly when grafted on plants such as Cataratto, Catanese, etc., which are not very drought resistant. They, therefore, require moist, deep, fertile, not over heavy soils, otherwise there is danger of their fading or dying after a few years.

These conditions are particularly indispensable to Aramon  $\times$  Rupestris G. No. 1, the more so because it is a very productive stock.

Berlandieri R. Nos. 1 and 2, and their hybrids 420 A, 157-II, 34 E. M., 17-37, 319 A., 301 A., 301 B. and 41 B. usually do very well whether grafted or ungrafted, and are very tolerant to lime, even when it is present in a very assimilable form, as in the Spagnola experiment field, more especially so considering the wetness of the soil. Those which proved most resistant to drought under the conditions considered were Berlandieri Nos. 1 and 2, 157-II, 34 E. M., 301 A. and B. and 41 B. Nos. 420 A., 17-37 and 219 A. showed weak growth, especially when grafted on Cataratto, whether in the Casa Bianca experiment field, in calcareous sandy loam, ferruginous, light, stony, shallow, but with a permeable sub-soil, in the demonstration vineyard of Casa Bianca, or that of Misilla, in soil not very different.

The most productive stock are, in decreasing order, Aramon  $\times$  Rupestris G. No. 1, Berlandieri R. Nos. 1 and 2, 34 E. M. and 41 B. Those which showed greatest uniformity in this respect were Berlandieri Nos. 1 and 2, 41 B., 34 E. M., and 157-II. Production with the different stocks was usually more uniform in dry than in wet years.

The *affinity* of all these stocks for the native vines usually proved excellent. Only in rare cases did the plants die through lack of affinity, as happened with Mourvèdre  $\times$  Rupestris and 420 A. grafted with Catanese in the Casa Bianca experiment field, but everywhere else its condition was normal.

Affinity does not depend only on the nature of the stock and the scion, or on their specific differences, but also on their individual differences and the functions they are called upon to fulfill as stock or scion.

To counteract fading due to lack of affinity it suffices to use a stock which is a good conductor and has strong tap roots. This removes, or at least greatly decreases the obstacle arising from pressure at the point of grafting, which if not the actual cause of the phenomenon, hinders at any rate the material exchange and the circulation of sap between the stock and the scion. As a rule it is best to use stock the functional capacities of which are superior to those of the scion, or to use as scion a native variety with limited requirements, the development and production of which are not excessive (e. g. Grillo), so that even if the symptoms characteristic of want of affinity do not disappear completely, they at least become much less serious and frequent than is usually the case.

There are marked differences in development and production according to the native varieties grafted.

Aramon  $\times$  Rupestris G. No. 1, for example, is killed by serious phylloxera lesions when grafted with Cataratto, but continues in very good condition with Pignatello, Damaschino, Grillo and Grecanico, in the same soil. This fact had been remarked previously and was confirmed at Misilla and Casa Bianca. Aramon  $\times$  Rupestris G. No. 9, however, shows no sign of fading under identical soil conditions, and is in an excellent state of vegetation in the experimental vineyards. The same may be said of No. 2, and these two stock may be compared with Rupestris du Lot..

Very serious wilting due to *bramble-leaf disease* occurred in the Spagnola vineyard on plants of Aramon  $\times$  Rupestris grafted with Pignatello (a variety very subject to the disease), and on those of Mourvèdre  $\times$  Rupestris grafted on to Catanese (also very subject) from the first year after planting. The cuttings, however, came from a suspected locality. Only material known to be free from disease should be used.

One of the most brilliant results of grafting is that *it has made it possible to grow outside their zone of adaptation certain vines which in the past required special conditions*. Thus, Catanese, which ungrafted only does well in moist deep soils, when grafted with Sicilian-American hybrids of the Casa Bianca vineyards, proved strong and productive, even in dry, stony shallow soil.

The growth and yield of Zibibbo and Pignatello in the Misilla and Casa Bianca vineyards are very different from when they were ungrafted under similar conditions.

Mourvèdre  $\times$  Rupestris, which in its natural state suffers much from drought, grafted with Grillo has a very fine vegetation, even in the dry soil of the Casa Bianca experiment field.

Finally, the really exceptional fertility of certain scions which have attained a productivity hitherto unknown in these soils must be noted. Among these should be mentioned Damaschino on Aramon  $\times$  Rupestris G. No. 1 in the Casa Bianca and Misilla vineyards, Cataratto and Grillo on Berlandieri  $\times$  Röss Nos. 1 and 2, in the Misilla and Spagnola vineyards, Periconne, Catanese and Grillo on 157-11 and 34 E. M., in the Misilla and Spagnola vineyards, and Cataratto, Pignatello and Grillo on 41 B. in the Casa Bianca and Spagnola vineyards.

This leads to other, more important considerations. It is known that in dry soils vines are very subject to great irregularities in yield because they respond more to the atmospheric variations of different years. In the case of well-chosen American vines, however, this occurs more rarely and to a slighter degree, because certain stock counteract the failings of the soil so as to make it comparable to moist soils of similar composition. It is, therefore, a great advantage of grafting and the new methods of vine cultivation that they have removed, at least to a great extent, the dangers arising from a crisis due to an excess or a failure in yield.

The system which has given the best results is that of cleft grafting, on account of the greater uniformity of development and the higher yield

(as average per stock and per surface unit) obtained. This is very marked when comparison is made between two demonstration vines at Casa Bianca, one of which had been cleft-grafted, and the other grafted in the vineyard. The same result is observed in the experiment field at Spagnola, where the rows planted with cleft-grafts were much more uniform and productive, and, in some cases (31 B. and Berlandieri Ress. No. 2) earlier, than those which were grafted in the vineyard.

English grafting in the vineyard is, moreover, insufficient to obtain uniform and regular rows without gaps. This makes it necessary to adopt other auxiliary systems of grafting, such as the English herbaceous graft and the flute graft, with which good results may be obtained by grafting in the vineyard, results which in many cases are not inferior to those obtained by cleft-grafting.

Among the hybrids obtained in Sicily and planted in the experimental vineyard of Casa Bianca, there are some which are really *remarkable and well worth propagating*, by reason of their vigour, their resistance to drought and lime, their affinity to the French vines, and their yield. Tests have shown the most satisfactory to be Paulsen Nos. 473, 509, 779, 1043, 1064, 1077, 1103, 1119, 1120, 1254, 1321, 1323, 1362, 1381, 1437, 1447, 1548, 1583, 1837, 1901, 1902, and Ruggeri Nos. 48, 70, 77, 110, 128, 140, 143, 152, 162, 180, 198, 252, 253, 298, 300.

The greatest affinity was found among the Paulsen hybrids, Sicilian-American or  $\frac{3}{4}$  American, all of which are excellent from this point of view, with the exception of a few in which the authors noted cases of "folletage" (apoplexy).

The Ruggeri hybrids, nearly all Americo-Americans have not, as a rule, given good results with Catanese, a plant already known for its slight affinity for American vines and their hybrids. This seems to support the hypothesis that Vinifera hybrids have a greater affinity for French vines than pure American ones.

On the other hand there are among the old Franco-American stock many examples which prove the contrary. Thus Mourvèdre  $\times$  Rupestris 1202, Colombeau  $\times$  Rupestris (Gamay Coudere), Bourrisqou  $\times$  Rupestris, Aramon  $\times$  Rupestris G. No. 2 and No. 9, to mention only the principal ones, and a large number of direct hybrid bearers, have often shown a lesser affinity for French vines than many Americo-Americans. Also Grimaldi 188 (Calabrese  $\times$  Rupestris), when grafted with Catanese, dies in the third or fourth year. Other Sicilian  $\times$  American hybrids which, during the first years after grafting appeared very strong, suddenly died after from "folletage" in the Casa Bianca experimental vineyard. Death by "folletage" is but a particular case of lack of affinity.

The hypothesis laid down after a study of "folletage" in France (according to which the disease is caused by the action of strong dry winds over a prolonged period thus causing excessive transpiration by the leaves as compared with the amount of water absorbed by the soil) is in no way justified. The authors' observations show that the hybrids obtained and selected in Sicily usually have a greater affinity to Sicilian

vines than have the old stocks, besides being extremely resistant to drought. This is very promising for vine-growing in this district, for which, in view of its almost tropical climate, the investigations described are of the greatest importance.

It is still necessary to select these vines further for resistance to bramble-leaf disease, in order to choose stock possessing to a high degree the quality of adapting themselves to local conditions as well as all the other characteristic good qualities, so that the vines may become continually more profitable. In other words, it is necessary to choose the stock which is most satisfactory in all respects and will prove most valuable to Sicilian vinegrowers.

653 - Studies in Forage Poisoning (1). — GRAHAM, R.; BRUECKNER, A. L. and PONTIUS, R. L. I. — A Preliminary Report on an Anaerobic Bacillus of Etiologic Significance. *University of Kentucky, Agricultural Experiment Station, Bulletin No 207*, pp. 49-113. 36 Figs. II. — An Anaerobic Organism Isolated from Ensilage of Etiologic Significance. *Ibid.*, *Bulletin No. 208*, pp. 117-133, 7 Figs. Lexington, Ky., June and July, 1917.

HYGIE

I. — Forage poisoning has long been known in the United States, where it has caused serious loss in cattle, but more particularly in horses and mules. Previous experiments have already proved that *B. botulinus*, which causes botulism or meat poisoning in man, is pathogenic to horses and donkeys, producing symptoms closely resembling those of forage poisoning. The authors were able to confirm these results by experiments with horses and mules. In very acute cases the animals died without showing any previous symptoms, but, as a rule, the characteristics of the disease were loss of appetite, stupor, rapid breathing, subnormal or normal temperature, paralysis of the tongue and pharynx, salivation, slight watery discharge from nostrils, difficulty in feeding, muscular weakness, obstinate constipation, incoordination in walking, decumbency, decubitic ulcers accompanied by secondary infection, rapid horizontal movement of the fore feet as in running, intervals of coma until death. The incubation period may last from a few hours to a few days. Guinea-pigs are also very susceptible to infection by *B. botulinus*. Chickens are highly resistant, but it is interesting to note that the faeces of chickens fed *B. botulinus* are capable of infecting horses and mules given food contaminated with these faeces. This shows that fowls may be a factor in spreading the disease.

In order to study this question more fully further experiments were made with oat hay which had caused an outbreak of forage poisoning in 1915. The pathogenic factor in this hay proved to be water-soluble, and, after the forage had been stored for 22 months, fatally infected a horse which was given water in which it had been immersed. From the caecum of the

(1) See also R. November, 1917, No. 1032. (*Ed.*)

horse was isolated an anaerobic organism which was slightly motile, spore-forming, Gram positive and easily stained with the ordinary aniline dyes; the bacilli were single, but may occur in short chains. In its morphological characters this organism closely resembled *B. botulinus*.

The bacillus isolated from the caecum of the horse, when administered by the mouth, proved fatal to horses, mules, and guinea-pigs, causing symptoms indistinguishable from those caused by *B. botulinus*.

A thorough examination of the oat hay water in question led to the isolation of an organism which resembled closely that isolated from the caecum of the fatally infected horse; this organism, when administered by the mouth, caused death in horses, mules, and guinea-pigs, accompanied by symptoms identical with those caused by *B. botulinus*.

Antitoxic goat, sheep and cow sera, prepared against *B. botulinus*, proved efficacious against lethal amounts of a homologous toxin. The antitoxic serum afforded protection in horses when administered subcutaneously and intravenously, and in guinea pigs when administered intraperitoneally, against: 1) a fatal amount of homologous toxin by the mouth; 2) infection by the mouth with a lethal amount of the organism isolated from the caecum of the horse and against lethal amounts of the broth culture filtrate of this organism; 3) the bacilli isolated from the oat hay water.

The whole series of experiments seems to prove that *B. botulinus*, which is known to be capable of developing in forage, is the pathogenic agent in forage poisoning.

II.—Further experiments carried out on a farm, where there had been a natural outbreak of forage poisoning among mules, confirmed the results previously obtained. Agglutination tests with serum highly immune to *B. botulinus* and the organism isolated from the ensilage which caused the outbreak were positive, but normal sera of different animals agglutinated neither of the organisms. Sheep and horse sera immune to the organism isolated from the ensilage gave positive agglutination results with *B. botulinus* and the pathogenic organism isolated from the horse which died as a result of drinking water from infected oat hay.

654 — The Toxic Action of *Thlaspi alliaceum* and the Active Principles of Some Poisonous or Suspected Cruciferae. — BEGUINOT, AUGUSTO, in *Atti dell'Accademia Veneto-Trentino-Istrian*, Vol. X, pp. 90-110 Padua, 1917

In May, 1917, the author (Director of the Royal Garden of the Botanical Institute of Padua) examined some fresh fodder cut at Pettorazza (province of Rovigo). It had been asked whether such fodder could have caused the death of oxen (8 out of about 40 which had shown signs of poisoning) on a farm at Pettorazza. The author noted that the fodder consisted largely of the Crucifer *Thlaspi alliaceum* L., in an advanced stage of fructification, most of the seed being ripe.

Cruciferae cannot be considered as poisonous in the strict sense of the word, *i. e.*, capable of causing poisoning, fatal even in small amounts and at any period of development, but some can cause serious illness, often even followed by death, when eaten by cattle in large quantities during the advanced flowering stage or when ripe. The species most commonly held to

be dangerous are: *Brassica nigra* Koch, *Br. Sinapistrum* Boiss., *Br. campestris*  $\alpha$  *pleifera* D. C., *Eruca sativa* Mill, *Lepidium Draba* L., *Erysimum cheiranthoides* L., etc.

*Thlaspi alliaceum* is fairly rare in Italy, and very rare in Venetia. Neither this variety nor *Thl. arvense* should be given to cattle; when cows eat it their milk assumes a disagreeable garlicky smell. On the Pettorazza farm mentioned above the first fatal case occurred 5 or 6 hours after the last meal, the other cases after about 20 hours. The oxen were from 9 to 15 months old. The clinical symptoms were convulsions, shivering, weakness, etc. An examination of the blood showed the absence of pathogenic microorganisms. The post-mortem showed effects different from those generally observed in the case of poisoning in that the breathing tubes and stomach were very slightly affected. According to the author this is due to the rapidity with which the blood absorbs the poison (allyl sulphocyanate) thus causing death before the pathogenic effects could manifest themselves.

As in the Rovigo province the district infested with *Thl. alliaceum* is limited by the lower course of the Adige and the Bianco canal, the author believes it would be possible to exterminate the plant completely by a systematic destruction before the seed are ripe.

- 655 - Researches on the Malady "Trembles" or "Milk Sickness", Caused by *Eupatorium ageratoides* in North Carolina, U. S. A. (1). — CURTIS, R. S. and WOLF, F. A., in the *Journal of Agricultural Research*, Vol. IX, No. 11, pp. 397-404 + 2 Figs. Washington, June 1, 1917. — WOLF, F. A., CURTIS R. S., KAUPP, B. F. (Agricultural Experiment Station of North Carolina), in the *Journal of the American Veterinary Medical Association*, Vol. LII, New Series, Vol. V, No. 7, pp. 820-827 + 2 Figs. Ithaca, N. Y., March, 1918.

Of late years the authors' attention has been directed to a serious disease of domestic animals, including horses, cattle, sheep and hogs, which is commonly called trembles. This disease is transmissible to man through the milk of animals affected with trembles, and thus physicians call it "milk sickness". It has been known to be endemic in Tennessee, Kentucky, Ohio, Indiana, Illinois, Missouri and Georgia, since their first settlement and in North Carolina since the American Revolution. It was first described in 1810, but there is considerable confusion as regards the etiology of the disease, the etiological factors usually considered being 1) poisonous minerals (arsenic, copper, mercury, cobalt, lead, and aluminium); 3) a microorganism (*Bacillus lactimorbi*); and 3) a poisonous plant. The first 2 theories are not well supported by facts, whilst the third has 2 important points in its favour: - a) the malady disappears when the natural vegetation is replaced by cultivated plants; b) it is limited to the grazing season. A number of species of plants have been considered as causing "trembles", *Eupatorium ageratoides* (= *urticaefolium*) being most commonly held to be the cause.

Work published by MOSELEY, in 1906, confirms the opinion, held since 1840, that this plant, known as "white snake root", is the cause of the disease. The authors have adduced further proof by obtaining the disease in sheep, pigs, and guinea pigs fed with concentrated foods and white snake root.

(1) See also R., February, 1918, No. 179. (Ed.)

The symptoms include : — nervous spasms followed by paralysis of the limbs ; congestion of the brain, liver, heart and kidneys ; hyperaemia of the lungs ; mucoenteritis.

The incubation period of the disease varies from 3 days to 12 weeks or more ; the period between the appearance of the symptoms and the death of the animal (only a small proportion recovers) is from 12 hours to 3 or 4 days.

There is no certain method of treatment ; the only preventive measure consists in ploughing the areas infested by *E. ageratoides*, which is a perennial, and sowing them to cultivated forage plants. Timber land infested with the plant, and which cannot be ploughed up, should be fenced in, to keep the stock out.

Mr. MOSELEY's work is confirmed by the authors' experiments with sheep fed on green " white snake root " plants from June to October, 1916. Out of 18 experimental animals, 15 showed signs of trembles, while 14 died and 1 recovered. It is possible that one of the fatal cases was due in part to an infestation of stomach worms. Death ensued from 5 to 27 days after the animals had commenced to eat white snake root. Considerable variation existed in the several ewes, also, with reference to the quantity of weed ingested before trembles appeared. Indirect evidence against the infectious nature of the disease was secured by failure to communicate trembles from sheep characteristically affected to healthy sheep when they were confined and fed together in a small lot. Common stock salt (8 oz. and 12 oz. per head in 11 and 18 days) and baking soda (30 oz. per head in 19 days) given together with a mixed ration of *E. ageratoides* and grain were without apparent antidotal effect.

It has been claimed that aluminium phosphate causes a disorder similar to that following the feeding of white snake root, but the authors found no harmful effect to follow the feeding for 69 days of aluminium phosphate mixed with grain and supplemented with alfalfa hay.

656 — **Investigations on the Etiology and Control of Infectious Abortion in Mares, in Kentucky, U. S. A.** — GOOD, E. S. and SMITH, W. V., in *Kentucky Agricultural Experiment Station, University of Kentucky, Bulletin* No. 204, pp. 337-395 + 18 Tables, Bibliography of 29 works, + 13 Pl. Lexington, 1916.

In 1907 the Department of Animal Husbandry of the University of Kentucky equipped a bacteriological laboratory for the study of infectious abortion in cows and mares at the Kentucky Agricultural Experiment Station. At that time it was generally supposed that this disease in both these species of animal was caused by the same organism. Furthermore, the fact had not been established that the organism causing abortion abroad and in the United States was the same.

In 1896, Dr. BANG isolated *Bacillus abortus*, an organism now conceded to be the cause of abortion in the cow. Although he never isolated the organism from an aborting mare, he produced cases of abortion in mares experimentally by infecting them with the bacillus and concluded that the bacillus caused the disease in the mare as well as in the cow.

In 1911, the Kentucky Laboratory isolated *Bacillus abortus* Bang from aborting cows. At the same time, a number of cases of abortion in

mares were examined, but no causal organism could be found. The cause of the disease in cows being well established, the Laboratory concentrated its efforts on isolating the germ causing abortion in the mare, and succeeding in isolating a microorganism called *Bacillus abortivo-equinus* from the uterine exudates and foetuses of aborting mares. The experiments described in the Bulletin in question prove that this bacillus is the causal agent of abortion in mares.

During the experiments numerous studs and cases were investigated by the Laboratory, and studies were made regarding: — the morphological, cultural and physiological characteristics of the bacillus; the agglutination and complement fixation tests; inoculation experiments; the production of a hyperimmune serum; immunization tests with a bacterin made from *Bacillus abortivo-equinus*; the effect of methylene blue, hexamethyleneamine, carbolic acid, and potassium permanganate on the organism.

RESULTS OF THE EXPERIMENTS. — In confirmation of their previous experiments, the authors continue to find a bacillus belonging to Subgroup II of the *Colon-typhi* group as the etiological factor of infectious abortion in mares and jennets; they propose the name of *Bacillus abortivo-equinus* for the organism.

By cultural, agglutination and complement fixation tests, the organism is found not to be identical with other pathogenic organisms of Subgroup II of the *Colon-typhi* group, such as *Bacillus suispestifer*, *B. paratyphosus A*, *B. paratyphosus B*, *B. paracolon*, *B. enteritidis* Gaertner and *B. typhi-murium*.

The *Bacillus abortivo-equinus* varies in its physiological property of splitting lactose and saccharose, for it produced approximately 2 % of gas and 2.5 % of acid in 1 % lactose broth in 86 % of 116 trials and no gas in 20 % of these trials, while in 1 % of saccharose broth slightly less than 2 % of gas and about 0.2 % of acid were produced in 50 % of 56 trials, and no gas with this sugar in 50 % of the trials. It was found that *Bacillus enteritidis* Gaertner, belonging to the same subgroup of the *colon-typhi* group as *B. abortivo-equinus*, contrary to the generally accepted literature, produced 2 % gas in lactose in 75 % of the trials and in saccharose broth a small amount of gas was produced in 1 out of 7 trials.

The disease of infectious abortion in mares may be diagnosed by the isolation of *Bacillus abortivo-equinus* and by the agglutination and complement fixation tests.

A one-tenth of 1 % solution of potassium permanganate destroys *B. abortivo-equinus* in 1 minute. A 1 % solution of carbolic acid also destroys it in 1 minute. A 1 per 1000 solution of methylene blue destroys the organism in 5 minutes, while a saturated solution of boric acid destroys the germ in 3 hours. All these solutions in the strengths mentioned can be used as douches and not injure the mare. The water used should first be boiled, the chemicals added and cooled to body temperature before injection.

Subcutaneous injections of *B. abortivo-equinus* produced abortion in guinea pigs and rabbits, and an intravenous injection of the organism produced abortion in the hog and sheep. The feeding of large amounts of the

germ to a pregnant sow produced no injury whatever, and the subcutaneous injection, also the feeding of the organism to pregnant ewes did not produce abortion.

The intravenous injection of small amounts of the bacillus in hogs resulted only in lassitude for a few days, while a large dose given intravenously and repeated produced death, with the recovery of the organism from the internal organs of the animal.

An intravenous injection of 2 cc. of physiological salt suspension of *B. abortivo-equinus* in a pregnant mare produced abortion in 10 days, and the organism was recovered from the uterine exudate of the aborting mare and from the internal organs of the foetus. An injection of 1 cc. produced abortion in 12 days.

The growth of *B. abortivo-equinus* on large agar tubes flooded with sterile water, mixed with grain and fed to a pregnant mare produced a persistent diarrhoea which would not yield to medical treatment, resulting in the death of the mare 20 days after. Streak dilutions made of the internal organs of the mare and foetus on plain agar revealed the presence of *B. abortivo-equinus* in the heart blood of the mare and liver of the foetus, thus showing that the bacillus had passed through the intestinal walls to the blood stream of the mare and foetus and would have caused abortion had the mare lived.

A bacterin made by growing the organism on plain agar, flooded with physiological salt solution and heated to 60°C. for 2 hours protected rabbits against 10 times the lethal dose of the organism.

The subcutaneous injection of quite large doses of bacterin (killed organism), in pregnant mares, produced no ill effects, save an occasional abscess at the seat of inoculation. The injected mares produced live, healthy colts.

A mare receiving a bacterin in increasing doses, subcutaneously, and afterwards injected subcutaneously with increasing doses of the live organism, delivered a live, weak colt which soon developed into a strong individual. The treatment greatly depressed the mare. Soon after delivering the foal she began to mend, and, 4 months after, was in excellent condition. It is quite probable that the treatment with a bacterin had protected her from aborting when later quite large doses of the live organism were injected subcutaneously.

Increasing doses of a bacterin, followed by an intravenous injection of 2 cc. of a suspension of the live organism in physiological salt solution did not give a pregnant mare sufficient protection to deliver a healthy foal. While the colt came alive, it was a "sleeper" and died 22 hours after delivery.

A hyperimmune serum for infectious abortion in mares was produced that had marked bacteriolytic properties in vitro. This serum protected rabbits from the lethal dose of the organism. In one case, it protected from 5 times the lethal dose. The serum did not protect a mare from an artificial infection, the mare aborting 12 days after receiving the live organism intravenously. The amount of the germ given, however, was vastly

in excess of an infection which could have been obtained naturally. The serum may prove of value in a stud where infection is known to exist.

From these investigations it is concluded that a bacterin made of *B. abortivo-equinus* injected subcutaneously will, if given to a pregnant mare in proper and increasing doses, do no harm and will, in all probability immunise her against the disease of infectious abortion if the bacterin be administered before the disease is contracted in a natural manner. In the production of this bacterin, the bacillus is grown on agar slants and the culture then washed 3 times with normal salt solution in a centrifuge.

657 - **The Amino-Acid Minimum for Maintenance and Growth, as Exemplified by Further Experiments with Lysine and Tryptophane.** — OSBORNE, THOMAS B. and MENDEL, LAFAYETTE B. with the Cooperation of FERRY, EDNA L. and WAKEMAN, ALFRED J. (Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXV, No. 1, pp. 1-12, 14 Diagr. Baltimore, Md., May, 1916.

FEEDS  
AND  
FEEDING

Additional experiments are reported in this paper to show the part played by tryptophane and lysine in the metabolism of maintenance and growth. The quantity of these amino-acids available in the diet can be made the limiting factors which determine the nutritive equilibrium and possibilities for increment of size in an individual. They afford an important illustration of the "law of minimum" applied to essential nitrogenous components of the food supply.

658 - **The Effect of the Amino-Acid Content of the Diet on the Growth of Chickens (1).** — OSBORNE, THOMAS, B. and MENDEL, LAFAYETTE B. (Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXVI, No. 2, pp. 293-300 + 1 Plate. Baltimore, Md., September, 1916.

Experiments on the feeding of albino rats have shown that for adequate growth a suitable supply of certain amino-acids must be available in the diet. Conspicuous among them are tryptophane, lysine and cystine. A ration which fails to yield these in reasonable abundance cannot promote growth but, if the other (non-protein) dietary factors are suitable, increment of weight can promptly be brought about by the addition of these essential amino-acids. BUCKNER, NOLLAU, and KASTLE have attempted to test the validity of the conclusions just expressed, in a series of feeding experiments on young chicks, by using grain mixtures which they believed to exhibit a low and high lysine content respectively. The outcome was interesting in showing unmistakable differences in the growth of the birds in the two groups.

Believing that the conclusion of BUCKNER, NOLLAU and KASTLE in respect to the relative amounts of lysine yielded by their foods was in the main correct, although unproved, the authors have concluded to attempt the application to the chick of the methods of feeding mixtures of more definitely known lysine content. The plan of the experiments was to compare the growth of chicks (Rhode Island Reds) fed on diets which, in one case contained "corn gluten", the mixed proteins of which yield about 1 per cent of lysine, and in the other case contained equal parts of "corn gluten"

(1) See also R., April 1918, No. 442. (Ed.)

and lactalbumin, a protein yielding about 10 per cent of lysine. The food mixtures contained, aside from the protein ingredients the essential substances including inorganic salts, fat-soluble and water-soluble hormones, which experience with rats has shown to be required for perfect growth.

Two types of food were employed. One, the "fat food", was made in the form of a paste by grinding the ingredients together with a sufficient quantity of lard and butter fat; the other, the "starch food", was made in the form of a coarse meal by substituting starch for a large proportion of the fat in the "fat food". In one experiment the total gain of body weight in 55 days was 52 gm. for the chick on corn gluten food; 283 gm. for the chick on corn gluten + lactalbumin food; in another a chick at the age of 81 days had gained 322 gm. in a period of 53 days, on the corn gluten + cottonseed flour ration, while at the same age a chick on the corn gluten food had increased in weight only 44 gm.

These results are in agreement with the writers' observations upon rats receiving similar diets. We thus see that corn gluten permits a very slight growth of chickens as well as of rats, because it contains some maize gluten — a protein which yields tryptophane as well as a little lysine. With chicks, as with rats, lactalbumin, rich in both tryptophane and lysine, is an efficient adjuvant to the proteins of corn gluten.

Therefore these observations corroborate, for the chick, the experience which the authors have previously published regarding the unlike value of different proteins in the nutrition of growth.

In further accord with the observations on the growth of rats, cottonseed flour also forms a suitable adjuvant for the proteins of corn gluten, whereby in the presence of "protein-free milk", butter fat, etc., satisfactory increments of growth can be obtained. Two chicks beginning at the age of 28 days on a corn gluten + cottonseed flour ration gained 450 gm. and 556 gm. respectively in 79 days.

The results confirm the conclusions drawn by BUCKNER, NOLLAU, and KASTLE respecting the effect of foods high and low in lysine on the growth of chickens. The assumption is justified that chickens, as well as rats, require a sufficient amount of lysine in order to make normal growth and that will doubtless be found true for other species.

659 — **Studies on the Nutritive Deficiencies of Wheat and Grain Mixtures and the Pathological Conditions produced in Swine by their Use.** — HART, E. B., MILLER, W. S. and MC COLLUM E. V. (Departments of Agricultural Chemistry and Anatomy of the University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXV, No. 2, pp. 239-259. 9 Diagr. + 5 Plates. Baltimore, Md., June, 1916.

In earlier studies on the influence of restricted natural feeds on growth and reproduction it was observed that a ration from the wheat plant — wheat grain plus wheat straw — was wholly inadequate with heifers for reproduction and in some instances for continued growth. With swine, confined to the wheat grain and a suitable salt mixture, growth soon ceased and the animals passed into a poor condition, while a maize and salt mixture ration was at least sufficient for slow growth and continued well-being. Similar results are on record with rats, and only when a liberal supply of

casein and fat-soluble *A* was added to a wheat grain and salt mixture was growth continuous and, in the case of rats, reproduction possible.

In earlier papers the authors have expressed the view of the possibility of inherent toxicity in the wheat kernel, a view now made probable by the fact that the wheat embryo yields by ether extraction an oil of distinct toxicity and a residue far more innocuous than the embryo itself. That this embryo carries a considerable quantity of a toxic substance is further shown by the fact that, on increasing the mass of embryo in the rations of herbivora, earlier abortions are produced than when the ration carries the whole wheat grain only. When the diet of swine consisted of whole wheat gluten plus a suitable salt mixture the individual soon failed to grow and passed into a pathological condition. Loss of weight, rough coat, emaciation, lack of muscle coordination, laboured breathing, and even blindness manifested themselves. Experiments with rats showed that with abundance of better proteins from milk powder or casein, a more efficient salt mixture and the addition of fat-soluble *A*, and with whole wheat constituting approximately 65 per cent of the ration, the depressing action of this toxicity could be overcome.

With swine receiving similar additions to the wheat grain, but not in the same quantitative order, growth was normal but reproduction failed. It is important in this connection to call attention to the fact that when the additions to wheat were only salts and butter fat but without casein, the curve of growth was improved, but ultimately these animals failed with symptoms similar to those shown on the wheat, salt mixture diet. It became evident as this work with swine progressed that these pathological conditions manifested by swine are, as far as the histological picture of the spinal cord is concerned, analogous to, if not identical with, the pathological condition recorded for polyneuritis in fowls, but here induced by an inherent toxicity and not by a deficiency. Therefore malnutrition, histologically characterized by nerve degeneration, may result from the absence of certain factors in the diet as in the case of beri-beri. A similar condition may likewise arise from the presence of toxic materials in apparently normal food products, and in the presence of all known factors essential for continued growth and well-being.

With a large mass of wheat in the ration of swine toxicity will follow even in presence of all the recognized factors for growth. Only in the presence of very liberal quantities of all these factors can the effect of the toxicity be overcome. No one important factor for growth, such as better proteins, salts, or fat-soluble *A*, appears able to act as a complete corrective for this toxicity.

It also appears possible to produce similar pathological conditions in swine in the absence of all known toxic material and in the presence of a fair quality of protein, a plentiful supply of fat-soluble *A*, and water-soluble *B*, but a poor salt mixture; namely, that natural to the grains used.

Excellent supplementary materials to the grains even in the presence of the toxicity of the wheat products, have been found in alfalfa and commercial meat scraps. Probably milk, if used in sufficient quantity, would

also serve this purpose admirably. The factors introduced by alfalfa are undoubtedly an abundance of fat-soluble A and a better salt mixture. Its richness in calcium may be important. With commercial meat scraps the factors for improvement are undoubtedly better proteins, more fat-soluble A, and a liberal supply of calcium phosphate resident in the bone material it carries.

660 — **The Stability of the Growth Promoting Substance in Butter-Fat.** — OSBORNE, THOMAS B. and MENDEL, LAFAYETTE B. with the cooperation of FERRY, EDNA L. and WAKEMAN, ALFRED J. (Connecticut Agricultural Experiment Station and Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXIV, No. 1, pp. 37-39. Baltimore, Md., 1916.

A considerable number of observations are now on record to show that certain mixtures of isolated food substances furnishing a ration upon which animals (albino rats) decline or cease to grow can be converted by the addition of some of the natural "fats" into a ration adequate for growth. The authors have found that the inefficiency of lard and some other fats in this respect is not due to the destruction of the growth promoting factor by heat, since these fats fail to promote growth adequately even when they are prepared at low temperatures in the laboratory. Furthermore they found that butter fat does not lose its growth-promoting potency by treatment with live steam; and the yolk extracts of heated eggs have also been reported as effective. From such facts it seems unlikely that the explanation of the ultimate failure of growth when certain of the natural fats supply the fat component of the diet is to be found in some destructive reaction brought about by preliminary heating. MC COLLUM and DAVIS believe that the substance which exerts a stimulating action on the growth of rats is sufficiently stable to withstand conditions of saponification which they have employed.

The authors have found that by fractional crystallization from alcohol it is possible to concentrate the growth-promoting factor present in butter-fat and beef fat. It remains in the mother liquor or "oil" fractions, whereas the fractions containing the fats with high melting points are ineffective. In order to learn whether the growth-promoting substance retains its physiological potency when kept for long periods, samples of butter fat and butter "oil" were stored: 1) at 18°C., in the light; 2) at 18°C. in the dark; 3) at 8° C. in the dark. Their efficiency in restoring growth, etc., was subsequently tested on animals that had failed on the "lard diets". The results indicate the pronounced stability of the growth-promoting substance as contained in butter fat under ordinary conditions of storage. However, in the butter "oil" gradual deterioration occurred, so that within a year its characteristic growth-promoting potency was eventually almost completely lost.

The feature here involved has a practical bearing in relation to the storage of butter and other fat products.

661 — **A Vitamine Favouring Growth, Isolated from the Pancreas of the Sheep.** — EDDY, W. H. (Chemical Laboratory of the New York Hospital), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 1, pp. 113-126 + 9 Diagrams. Baltimore, 1916.

By treating the water-soluble part of the alcoholic extract of the sheeps' pancreas with Lloyd's reagent, the author isolated a substance which, when fed to rats, was found capable of aiding their growth.

This substance, which is separated from the extract as a phosphotungstic precipitate, is neither a protein, nor a fat, nor an amino-acid combination.

**662 — The Nature of the Dietary Deficiencies of the Wheat Embryo (1).** — MC. COLLUM, E. V., SIMMONDS, NINA and FITZ, WALTER (Laboratory of Agricultural Chemistry of the Wisconsin Experiment Station, Madison), in *The Journal of Biological Chemistry*, Vol. XXV, No. 1, pp. 105-131, 19 Diagr. Baltimore, Md., May, 1916.

The experiments reported in this paper reveal the fact that the wheat embryo contains qualitatively all the factors essential for the promotion of growth and well-being in an animal, but these are not so proportioned that it can serve as a satisfactory diet without several modifications.

The mineral content must be modified in certain respects before growth can proceed at all.

The character of the proteins is excellent; no other proteins from plant sources which the authors have studied are superior to them. Rations containing but 10 per cent of these proteins are wholly adequate for growth at the maximum rate.

Both the fat-soluble *A* and the water-soluble *B* are present; the first, in moderate concentration; the second, in very high concentration as measured by the needs of the growing animal. Two per cent of wheat embryo supplies enough of the water soluble *B* to promote growth at the normal rate for several months.

There is contained in the wheat germ a substance which is distinctly toxic to animals. This is in great measure removed by extraction with ether, and is found in the fat fraction. The writers have not yet determined whether the toxicity is due to peculiarities in the chemical nature of the fats themselves or to something which is associated with the fats.

**663 — Studies of Cotton-seed as Food (2).** — I. WELLS, C. A. and EWING, P. W., Cottonseed Meal as Incomplete Food (Georgia Experiment Station), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 2, pp. 15-25, Bibliography of 8 publications. Baltimore, Md., 1916. — II. OSBORNE, THOMAS B. and MENDEL, LAFAYETTE B., The Use of Cotton Seed as Food (Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven), *Ibid.*, Vol. XXIX, No. 2, pp. 289-317, 5 Diagr. Baltimore, Md., March, 1917.

I. — The results of former experiments (WELLS and EWING, Acidosis and Cotton-seed Meal Injury, *Georgia Agricultural Experiment Station*, Bulletin 119, 1916) had indicated that in feeding cotton-seed meal to pigs to ascertain the injury said to result from this it is necessary to balance the ration, not so much as to the nutritive ratio, determined by the amounts of fats, carbohydrates, and protein present, but rather as to the so-called accessory food factors. The present paper relates the writers' further experiments bearing upon this phase of the question. They were carried out on Duroc Jersey pigs; the conclusions arrived at are as follows: —

Cotton-seed meal is an incomplete food. This is true even when it is fed with sugar and starch to a wide nutritive ratio.

(1) See *R.*, January 1918, No. 2. (*Ed.*)

(2) See also *R.*, January 1918, No. 64; March 1918, No. 306; April 1918, No. 443. (*Ed.*)

Pigs upon an absolute maintenance diet ate in addition only small quantities of cotton-seed meal and were not greatly injured by it.

So called cotton-seed meal injury is due in large part to inadequate diets.

II. — Cotton-seed meal is one of the most valuable feedstuffs at the command of the American stockman. After the animal has digested it, the value of the residue as fertilizer is about three-fourths the original value of the meal. The United States uses only part of the cotton-seed meal which it produces and one of the reasons which prevent a larger domestic consumption of this by-product of the cotton industry is the danger that sickness and death may follow its use. Cattle fed for more than 90 to 120 days on a heavy cotton seed meal ration (6 pounds or more per head daily) become lame, and their eyes discharge freely, blindness often resulting. Deaths may occur, especially in young animals. Pigs are peculiarly susceptible to the effects of cotton-seed meal, possibly because they are usually fed a larger quantity of the meal in proportion to their body weight. In feeding pigs, symptoms of sickness may appear at any time after 3 weeks of feeding, and deaths frequently occur with little warning. Various systems of feeding cotton-seed meal to pigs have been devised. Some of them appear to minimize its danger somewhat, but none of them prevent it entirely. This product, therefore, can not be regarded as a safe feed for pigs in the combinations in which it has heretofore usually been fed. (ROMMEL, G. M., and VEDDER, E. B., *Journal of Agricultural Research*, Vol. V, p. 489, 1915).

Referring to the experiments in feeding cotton-seed meal which have been made by various agricultural station workers, WELLS, C. A., and EWING P. V. (*Georgia Agricultural Experiment Station, Bull.* 119, 1916) state that the results of such experiments do not entirely agree and few absolute conclusions can be drawn from them. They indicate, however, that swine (particularly young pigs), calves, sheep, horses, cows, steers, dogs, cats, guinea pigs, rabbits, fish, poultry, and other animals may be injured by eating cotton-seed meal. Some of the smaller animals, such as pigs and calves, seem to be more susceptible to its injury than cows, steers, and similar animals. This, however, may have been due to their youth, or, more probably, to a consumption of larger quantities of meal in proportion to their live weight. When the meal was fed in connection with pasturage, or when it had been steamed, boiled or fermented, or when fed with mineral matter, particularly iron compounds, it often seemed to exert no apparent injury to pigs even when fed in rather large quantities. The injury resulting from the feeding of cotton-seed meal to stock has been attributed to : a) the oil in the meal ; b) its crude fibre ; c) excesss of nitrogen and perverted metabolism ; d) the action of bacteria and moulds ; e) presence of betain, cholin, or other alkaloids, and to gossypol ; f) to injurious phosphorous compounds ; g) to a protein group containing loosely bound sulphur, which interferes with normal iron metabolism ; g) to worms and certain other causes of minor importance .

Cotton-seed products for feeding purposes are available in several commercial forms. Cotton-seed *kernels* are obtained when the whole cotton-

seed is decorticated and freed from most of the hulls. Cotton-seed *meal* is the term applied to the ground cotton-seed cake from which most of the oil has been pressed. Cotton-seed *flour* is prepared by finely grinding and sifting the meal, whereby the lint, etc., are removed more completely than from cotton-seed meal.

Two processes are commonly employed in preparing cotton-seed meal. In the first process the seeds are decorticated, ground, and then steamed for about  $\frac{3}{4}$  of an hour. The hot mass is freed from most of the oil by means of hydraulic presses and the resulting press cake is then ground to a meal. In the second process the oil is expressed from the seeds by means of Anderson expellers whereby the meal becomes heated. The residue is then ground as in the first process. The second procedure is frequently called the cold process. Nearly all of the mills in the United States use the method employing live steam.

MARCHLEWSKI, L., (*Journal für praktische Chemie*, Vol. LX, p. 84, 1899) isolated from the "foots" from cotton-seed oil a substance which he named gossypol. WITHERS, W. A. and CARRUTH, F. E. (*Journal of Agricultural Research*, 1915, Vol. 261) (1) have isolated this from cotton-seed *kernels*, by extraction with fat solvents and they report it to be highly toxic to rabbits, guinea pigs, rats, and pigs. They state that the ether-extracted *kernels* are rendered non-toxic by removal of gossypol. According to WITHERS and CARRUTH, "cotton seed meal and flour were found toxic to rabbits but the flour produced no ill effects on rats". The unlike toxicity to rats is explained by the variation in alteration or removal of gossypol in the manufacture of the *meal* from the *kernels*.

To ascertain whether the cotton-seed proteins are, like some proteins from maize, notably deficient for the purposes of nutrition the authors have conducted feeding experiments on white rats for which cotton-seed proteins furnished practically all of the food nitrogen and for which the other essential dietary components were supplied by adding to the products to be tested a suitable mixture of protein-free milk, butter fat, and starch which, with the addition of adequate protein, is sufficient for perfect growth. In this way they have found that satisfactory growth can be made by rats when either cotton-seed *globulin*, or the total cotton-seed protein precipitated from alkali extracts of cotton-seed meal, is employed without significant amounts of other protein in the mixture.

The facts now available are briefly summarized below:

Cotton-seed *kernels* are unsatisfactory for nutrition. Cotton-seed *meal* and *flour* are valuable foods for growing rats, both when used as the sole source of protein in the food, or when used in smaller quantity to supplement other less efficient protein concentrates. The excellent "quality" of the cotton-seed proteins as a whole is attested by the satisfactory growth made on diets furnishing the equivalent of only 9 per cent of protein (N  $\times$  5.4); even with 6 per cent of the protein considerable growth ensued. Cotton-seed *flour* gave good results when used as a supplement to such deci-

(1) See also R., January 1918, No. 64; March 1918, No. 306. (Ed.)

dedly inferior protein concentrates as "corn gluten", distillers' grains, and "vegetable albumin flour".

The injurious substance in the *kernels* can be removed by extraction with ether and, according to WITHERS and CARRUTH, by extraction with carbon bisulphide, chloroform, benzene, or alcohol, but not with petroleum ether or gasoline. The ether soluble material is deleterious, either because it contains some toxic ingredient or because it renders the food containing it so unpalatable that the animals refuse to eat it. This agrees with the results obtained by WITHERS and CARRUTH and by MC COLLUM, SIMMONDS, and PRITZ.

Foods containing cotton-seed oil prepared by pressing the kernels in the cold, or furnished as the crude unbleached commercial oil prepared by heating the kernels before pressing them, are eaten without detriment by rats.

By treatment with steam under suitable conditions the *kernels* lose their deleterious effect on rats. The variations in the results of feeding different samples of cotton-seed meal, which have been reported, may be due to differences in the mode of heating which the products have experienced in their preparation.

As regards the question as to whether so called "cotton-seed injury" in the feeding of domestic animals can be classed with the deficiency diseases, it is quite possible that, as ROMMEL and VEDDER maintain, food mixtures lacking some of the now recognized essential ingredients of an adequate diet have been employed in the past. The authors' experience with rats successfully grown on cotton-seed rations excludes the probability that there is ordinarily any lack of the water-soluble vitamine. Whether the quota of inorganic salts furnished in agricultural practice is always sufficient the writers are unable to answer. It is noteworthy, however, that they have induced young rats to double their weight at a normal rate of growth on a food mixture containing nothing except cotton-seed *meal*, starch, and lard. The deleterious effects of unheated cotton-seed *kernels* cannot be denied. Whether the reputed detrimental effect after feeding some of the commercial cotton-seed meals is associated with a failure to destroy a deleterious constituent or is attributable to unsuitable methods of feeding in some cases is still debatable.

**664 - Test of Three Protein Concentrates and Two Leguminous Roughages in Milk Production.** — HUNZIKER, O. F. and CALDWELL, R. E., in the *Purdue University Agricultural Experiment Station Bulletin* No. 203, pp. 1-20. Lafayette, Indiana, August, 1917.

Results of an experiment designed to give directions to feeders of dairy cows, regarding the type of protein-carrying concentrates and leguminous roughages best adapted for maximum and economical milk yield.

The three protein-carrying concentrates under test were cottonseed meal, linseed meal and gluten feed, and the hays fed were alfalfa hay and soybean hay; ground maize and maize silage were included in all rations.

The experiment covered a period of 180 days and was divided into six periods of 30 days each, 15 cows being used, divided into 3 lots of 5 cows each.

The rations used in the experiment are given in the following schedule :

1. Ground maize, cottonseed meal, alfalfa hay and maize silage.
2. Ground maize, cottonseed meal, soybean hay and maize silage.
3. Ground maize, linseed meal, alfalfa hay and maize silage.
4. Ground maize, linseed meal, soybean hay and maize silage.
5. Ground maize, gluten feed, alfalfa hay and maize silage.
6. Ground maize, gluten feed, soybean hay and maize silage.

The cows used were : 13 pure bred Jerseys and 2 pure bred Ayrshires fresh approximately 75 days before they were placed in the experiment.

The average daily feeds consumed during the entire experiment are shown in Table I.

TABLE I. — *Showing Average Daily Feeds consumed — Entire Experiment.*

Ration	Ground maize lb.	Cottonseed meal lb.	Linseed meal lb.	Gluten feed lb.	Alfalfa hay lb.	Soybean hay lb.	Maize silage lb.
1	7.88	0.49	—	—	8.52	—	24.50
2	7.44	0.78	—	—	—	7.43	25.07
3	7.66	—	0.55	—	8.54	—	25.00
4	7.40	—	1.06	—	—	7.65	24.81
5	7.24	—	—	0.90	8.27	—	25.10
6	6.02	—	—	1.61	—	7.62	25.24

The average daily production of milk for each of the 6 periods of the experiment was not especially high, averaging 19.64 lb. for all cows when receiving alfalfa hay and 18.41 lb. for all cows when receiving soybean hay. The low daily milk production may be accredited to the fact that the cows were mostly pure-bred Jerseys, having a rather high fat content.

Table II shows the amount of dry matter required to produce a unit of product.

TABLE II. — *Showing the Amount of Dry Matter Required to Produce a Unit of Product.*

Ration	Average daily milk produced lb.	Average daily butter fat produced lb.	Average daily dry matter consumed lb.	Dry matter required per 100 lb. milk lb.	Dry matter required per pound butter fat lb.
1	20.18	0.9224	22.899	113.42	24.76
2	19.93	0.9346	22.901	121.99	25.88
3	19.85	0.9064	22.605	114.92	24.47
4	17.31	0.8161	21.120	113.75	24.35
5	18.89	0.8822	21.483	113.85	24.94
6	17.98	0.8246	20.817	115.74	25.25

The cost of the product, considering feed cost alone (1), is given in Table III together with the value of the product, calculating all butter fat at 30 cents per pound and the skim milk at 25 cents per hundred pounds.

TABLE III. — *Showing Cost of Product.*

Ration	Average daily cost of feed	Average daily value of product	Cost per 100 pound milk produced	Cost per pound butter fat produced	Production per \$ 1.0 worth of feed
1	\$ 0.1925	\$ 0.32	\$ 0.98	\$ 0.216	\$ 1.605
2	0.1901	0.28	1.10	0.234	1.464
3	0.1997	0.32	1.00	0.213	1.602
4	0.1990	0.30	1.05	0.226	1.523
5	0.1968	0.31	0.99	0.218	1.589
6	0.1895	0.28	1.05	0.229	1.498

The average daily cost apparently was not influenced by the type of protein-carrying concentrates used. The variation in cost was doubtless influenced chiefly by the roughage fed. The type of roughage used produced an average variation in the total value of the product from \$9.52 when alfalfa hay was fed to \$8.67 when soybean hay was fed, or about 4 cents per day.

The conclusions drawn as a result of the discussion of the data presented in the foregoing tables may be summarized as follows :—

A ration used in milk production, which contains ground maize, maize silage and a leguminous hay, requires a very limited amount of protein-carrying concentrates in order that it may be properly balanced. The three protein-carrying concentrates used in the experiment affected the cost of the ration less than any of the four feeds of which the ration was composed.

When fed in connection with alfalfa hay, cottonseed meal was the most economical source of protein, gluten feed ranking second and linseed meal standing third, using prices as shown in the note (1).

Alfalfa hay was 12 % more economical as a milk producing roughage than soybean hay, both selling at the same price per ton, and without taking into account the greater quantity of soybean hay refused, due to its unpalatable character. The cost of milk was affected to the greatest degree by varying the price of maize. Hay ranked second, maize silage third and the protein-carrying concentrates fourth. The hay and maize exert practically the same influence upon the cost of milk.

The use of soybean hay caused an increase in body weight and a decrease in daily milk and butter fat production.

Properly balanced rations were, approximately, equally efficient in the production of milk and butter fat per unit consumption of dry matter.

(1) Prices of feeds used were as follows : Cottonseed meal \$ 30 per ton ; linseed meal \$ 36 per ton ; gluten feed \$ 28.50 per ton ; ground maize \$ 0.60 per bushel ; alfalfa hay \$ 15 per ton ; soybean hay \$ 15 per ton ; maize silage \$ 3.50 per ton.

665 - Feeding with Maize Silage and Ground Cotton Cake : Its Influence on the Composition and Quality of the Butter. — See No. 696 of this Review.

666 - The Role of Water in a Dairy Cow's Ration; Investigations made in U. S. A. — LARSEN, C., HUNGERFORD, E. H. and BAILEY, D. E., in *South Dakota State College of Agriculture and Mechanic Arts, Agricultural Experiment Station, Bulletin No. 175*, pp. 648-691 + 16 Tables. Huron, April, 1917.

CATTLE

Some dairymen claim that if the amount of drinking water given to a cow is limited, the body temperature is raised and the composition of the milk modified, the percentage of fat especially being increased. In order to verify this assertion the authors undertook a series of experiments (1) on the effect of watering cows at different intervals with varying quantities of water on the following factors: — amount of food consumed, digestibility of food, quantity and composition of faeces and urine, quantity and composition of milk, composition and quality of butter fat, body temperature and physical condition of the cow. Data on the mineral metabolism of the cow were also obtained. The experiment, carried out on four animals, was divided into three periods, separated by a period in which the ration was normal. In the first period the animals were watered every 24 hours (an average of 61.65 lb. per head), in the second period every 60 hours (an average of 51.20 lb. per head), in the third period with half the normal ration of water (40.00 lb. per head).

A series of tables gives: — Composition of feed and water; weight of animals, amount of food consumed and daily milk yield, coefficients of digestibility of the rations, amount of water drunk and food digested daily, daily amount and composition of the faeces, relation of amount of water to dry matter consumed, average daily amounts and composition of the urine and the milk, analysis of butter fat, average temperature of the shed and cows, effect of room temperature on the total amount and percentage of fat in the milk; food constituents digested per 1000 lb. of live weight daily, daily energy

(1) The effect of varying quantities of water in the ration on the composition of milk has been studied by many authors. TURNER, SHAW, MORTON and WRIGHT compared experimentally: — 1) a full allowance with a limited allowance of water; 2) a heavy ration of turnips with a dry roughage ration; 3) wet beet pulp with dry beet pulp; 4) green clover with cured hay. They proved that, though individual cows produced milk with an abnormal fat content, the different rations did not as a rule influence either the quantity or the composition of the milk.

GILCHRIST (Variations in the Composition of Milk and their Probable Causes, *Durham County Council Education Committee Reports, Dairy Investigations, Offerton Hall*, pp. 7-27: 1909) found little or no difference in the quantity and quality of milk produced by cows either on pasture or a heavy mangel ration and that produced by cows on a ration of hay and grain.

ARMSTRONG found that cows drink more when fed a heavy protein ration than when fed a low protein ration, and that cows fed dry roughage drink about 40 lb. more water per day than those fed green hay. (*Authors.*)

See also the summary of the results obtained by various workers in experiments on the influence of the composition of the ration on milk secretion, read by KELLNER at the International Dairy Congress held at Budapest, June, 1909, in the *Journal of the Board of Agriculture*, Vol. XVI, No. 8, pp. 649-654, London, November, 1909; the author proves the influence to be very slight. See also *B.* 1912, Nos. 150 and 682; 1916, No. 885; 1917, No. 347; 1918, No. 63. (*Ed.*)

requirement per 1000 lb. live weight, distribution of water in the cow's body, average daily rations and balance of food nutrients in the three periods of the experiment.

RESULTS. — 1) *Food consumed.* — When the cows are watered once in 24 hours instead of two or three times there is a slight decrease in the total amount of food taken and in the quantity of milk produced, but this second decrease is not proportionate to the first. During the 30 days of the experiment the animals lost an average of 11 lb. per head. This loss was much greater during the second test (17 lb.) and the third (95 lb. per head on an average).

During the periods in which the cows received a full ration of water at long intervals, the expected decrease in milk production was not obtained. If the slight decrease in the amount of food consumed and the loss in weight be considered it must be concluded that cows can utilise the water stored in their systems for milk production and other functions. When the cows only received half the normal quantity of water (test 3) there was a marked decrease in the amount of hay consumed, milk produced and in body weight.

2) *Digestion of rations.* — The coefficient of digestibility was increased in each of the tests in which the intervals between watering were lengthened and in those in which the cows only received half the normal ration of water. This increase in the coefficient of digestibility is particularly marked in the case of crude fibre. Cows watered once in 24 hours digested 55 % of crude fibre as compared with 54 % digested by the control animals watered three times a day; cows watered once in 60 hours digested 71.07 % of fibre as against 55.7 % by the control animals, and those receiving half a ration of water digested about 2 % more than the control animals.

The increase in the digestibility of the nitrogen free extract and of the protein is not regular and is less marked.

As regards the actual amount of crude fibre digested, the cows in test 1 digested about 0.09 lb. per head daily, and those in test 2 only 1.26 lb. more than the control animals, those of test 3 digested 1.125 lb. less than the control animals.

Numerous investigations have led to the general acceptance of the theory that the digestibility of crude fibre depends largely on the active bacteria present in the intestinal tract and the action of the digestive juices. It is probable that an increased amount of water retards bacterial action in digesting crude fibre, and that a decreased amount leaves the digestive juices more concentrated and, therefore, more efficient and makes the chyme firmer and slower in moving through the digestive tract so that it is exposed for a longer period to the action of the secretions in the tract.

These results show that to obtain the most efficient digestion of food it is wise not to water the animals too abundantly at feeding time or immediately before or after a heavy meal.

3) *Effects of the quantity of water ingested on the composition of the excreta.* — The percentage of water in the faeces and the urine varies but little with the different quantities of water ingested; there was almost no difference between the faeces of the control animals and those in tests 1 and 2;

in test 3 there was a decrease of about 2 %. Frequent watering seems to have no appreciable effect on the composition of the faeces except that lengthening the intervals between drinking slightly reduces the crude fibre. When the cows only received half the normal ration of water there was an increase in the protein, nitrogen-free extract and crude fibre contained in the faeces.

When the cows received an unlimited supply of water three times a day they drank 3.5 lb. for every pound of dry matter consumed, when watered once in 60 hours they drank 2.38 lb. per pound of dry matter, and when receiving half the normal ration of water every 24 hours they drank 1.8 lb. per pound of dry matter.

4) *Effect of the quantity of water ingested on the quantity and composition of the milk.* — In all the tests the composition of the milk and butter fat remained absolutely unchanged. It is for this reason that a cow receiving insufficient water goes dry without there being any modification in the composition of her milk. Frequent watering has little influence on the quantity of milk produced. When the normal water ration was reduced by half the milk yield was reduced a little at the beginning, this reduction increasing as the experiment continued till it was about  $\frac{1}{4}$ . There is no doubt that the cows would have gone dry if this ration had been continued.

5) *Effect of water on the body temperature of the cow.* — When the cows were watered every 24 hours the body temperature was lowered by the fraction of one degree Fahrenheit 15 minutes after watering. With intervals of 60 hours the temperature dropped 2° F. The minimum was obtained 1 to 1½ hours after watering (130 lb. of water per head). The temperature of cows receiving half the normal ration of water was 1° F. higher than when they received a normal amount, but there was no increase in the fat content of the milk.

During a special experiment the cows were exposed to room temperatures varying from 51 to 104° F. It was found that the fat content tends to increase with the body temperature, though the increase is but slight; about 4.4% for 69° F. and 5.04% for 104.8° F. Since, however, high temperature slightly reduces milk secretion, the total amount of fat increases in inverse ratio to the percentage, in the case quoted from 11.2 lb. to 10.2 lb. per head daily. In conclusion it may be said that keeping dairy cows in milk in hot sheds, blanketing them and withholding water in order to raise the fat content is very dangerous to their health.

6) *Physical condition of the cows.* — The abnormal conditions brought about by withholding water were nervousness, gauntness and high body temperature. When the animals were watered every 60 hours and when they received half the normal ration of water a larger amount of energy was required to accomplish the body functions.

7) *Chief functions of water in a dairy cow's ration.* — The results of their experiments led the authors to the following conclusions: — A good dairy cow probably requires more water than any other domestic animal. Water dissolves food (for this reason the more food an animal eats; the more drink it requires), distributes it to the different parts of the body and removes the

waste products. The authors showed that more than 12 % of the total water drunk is eliminated through the skin in winter in the shed, and 27 % in August ; 56 % of the water drunk is eliminated in the faeces and 15 % in the urine. On an average, 15 % of the water drunk passes into the milk (in good milkers this percentage is higher; in one of the experiment animals, among which there were no choice cows, this percentage was 24 %). Water regulates the body temperature ; the loss of water through the body was twice as great in August as in January.

**667 - The Influence of Parturition on the Composition and Properties of the Milk and Milk Fat of the Cow.** — ECKLES, C. B. and LEROY, S. PALMER (Department of Dairy Husbandry, University of Missouri, Columbia), in *The Journal of Biological Chemistry*, Vol. XXVII, No 2, pp. 313-326. Baltimore, Md., 1916

The general opinion prevails that cows' milk is not suitable for human food for a period of time after parturition. Opinion varies as to the length of time the milk is unfit for use, as low as 2 days and as high as 15 days being stated as the proper period by different authorities. The methods and standards for certified milk adopted by the American Association of Medical Commissions place the figure at 7 days after parturition. The basis for the exclusion of cows' milk immediately after the birth of the calf is that its composition or constituents give rise to intestinal disorders. The evidence upon which this conclusion is based is, however, extremely difficult to find.

The data which are offered in the present paper indicate that colostrum milk is subject to variations in composition, or in other words that the effect of parturition on the composition of cows' milk may be greatly influenced by other factors. Data are presented on two questions: 1) the effect of milking the cow up to the time of parturition ; 2) the influence of the length of the period the cow is dry before parturition.

The conclusions which the authors have drawn from these data are the following :—

Parturition in the case of the cow is normally accompanied by the production of milk of extremely abnormal composition, called colostrum.

When cows are milked up to parturition, however, the colostrum milk and milk fat are much less abnormal in composition and follow closely the composition of the milk and milk fat given before parturition.

The chief characteristic of the milk as the cow approaches parturition in these cases is the marked increase in the content of heat-coagulable proteins, which reach their maximum in the first milk following parturition, that is, the true colostrum milk. This would indicate that a high content of heat-coagulable proteins is the chief, if not the only, real effect of parturition on the milk.

The length of time the cow is dry before parturition is a factor influencing the composition of colostrum milk, but does not influence the composition of colostrum milk fat. The shorter the time the cow is dry the less abnormal will be the composition of the colostrum milk.

668 — **Winter Steer Feeding in Indiana, U. S. U.** — SKINNER, J. H. and KING, G. F., in the *Purdue University, Agricultural Experiment Station, Bulletin No. 191*, Vol. XIX, pp. 1-35. Lafayette, Indiana, September, 1916.

The experiments described were undertaken to determine: — 1) the comparative value of leguminous hay alone and in combination with maize silage as roughage for fattening cattle; 2) the comparative value of clover hay and alfalfa hay as roughage for full-fed cattle; 3) the value of feeding molasses and mixed molasses feeds for fattening cattle; 4) the comparative value of a limited feed of maize with maize silage and a full feed of maize for finishing steers.

For the purposes of the experiment 70 medium feeding cattle were used. These were divided into seven lots of 10 steers each, as far as possible equal in size, condition, breeding, etc., and kept under similar conditions. The experiment lasted 150 days. With each lot of cattle were 10 good quality hogs, with an average weight of 105 lb. each when the experiment started. In addition to droppings from the cattle all the hogs received as much maize as they could eat; in addition five hogs in lots 2, 3 and 4 also received a small quantity of shorts and kitchen waste.

*Maize silage and leguminous hay v. leguminous hay (Lots 2, 4, 3 and 7)* — The rations were composed of shelled maize, cottonseed meal (2.5 lb. daily per 1000 lb. live weight), clover or alfalfa hay, with and without maize silage.

The table shows that the addition of maize silage to the ration reduced the maize required and practically replaced hay. It also shows the average daily gain, cost of gain per 100 lb., and profit per steer with and without pork. It is seen that the addition of maize silage to a ration of shelled maize, cottonseed meal and clover had very little effect on the gains made by the cattle, whereas when alfalfa hay was substituted for clover hay the difference in gain was marked. Although the additions of maize silage to the ration with clover hay slightly reduced the gain (0.07 lb.), it also reduced the cost of gain by 94 cents per 100 lb. In the ration with alfalfa hay the addition of maize silage both raised the gain (0.29 lb.) and reduced the cost of gain (\$ 2.30 per 100 lb.)

*Limited feed of maize v. full feed of maize (Lots 1 and 4).* — During the five months of the experiment Lot 1 received a ration of maize silage, clover hay and cottonseed meal, with maize in the following varying amounts daily per steer — 1st month, none; 2nd month, 5 lb.; 3rd month, 7 lb.; 4th month, 8 lb.; 5th month, 9 lb. Lot 4 received a ration of cottonseed meal, clover hay, maize silage, and as much maize as the animals would eat after having been gradually worked on to a full feed.

From the table it is seen that the steers on a limited feed of maize ate larger quantities of both clover hay and silage than those on full feed. The average difference in maize consumption was 4.01 lb. daily throughout the whole period.

The table also shows that the average daily gain per steer was  $\frac{1}{10}$  lb. in favour of an unlimited maize supply, but the gain was less economical, costing 84 cents per 100 lb. more than when limited maize was fed. The

Ration	Lot 1 Cottonseed meal, clover hay, maize silage limited shelled maize lb.	Lot 2 Shelled maize, cottonseed meal clover hay lb.	Lot 3 Shelled maize, cottonseed meal alfalfa hay lb. Profit per steer without pork . . . . .	\$ 14.63	\$ 9.55	\$ 10.59	\$ 17.61	\$ 11.52	\$ 9.24	\$ 17.61

profit from full-fed cattle was \$ 1.66 less than that from those given limited maize.

*Clover hay v. alfalfa hay as roughage* (Lots 2, 4, 3 and 7) When hay was the only form of roughage the cattle receiving clover ate the same quantity of maize but slightly more hay (0.7 lb. daily) than those receiving alfalfa. When, however, silage was added, those receiving alfalfa ate slightly less grain and hay but more silage than those receiving clover. The average amount of food consumed daily is shown in the table.

When clover or alfalfa were fed as the only roughage there was practically no difference in any of the principal factors influencing profit or loss; the rate and cost of gain were practically the same in each case. When, however, silage was added to the ration the cattle receiving alfalfa hay surpassed those receiving clover hay in every factor except pork production, their rate of gain was more rapid and more economical, their finish was better and the profit per steer higher. It is difficult to account for this marked superiority by the slight difference in the rations consumed; it was more likely due to a difference in the individuality of the cattle, although such a difference was not evident. It is notable that in all the trials comparing the value of clover hay and alfalfa hay with maize silage, the cattle which most nearly replaced hay by silage made the most rapid and economical gains. The average results of this experiment are given in the table.

*Cane molasses v. molasses feed* (Lots 4, 5 and 6). — The rations fed were composed of shelled maize, cottonseed meal (2.5 lb. daily per 1 000 lb. live weight), maize silage, and clover hay, varied with either cane molasses or molasses feed. If feeds containing molasses improve the appetites of cattle they may clearly be of great value. The table shows the effects of the different rations on the appetites of the cattle. It will be seen that the addition of molasses to the ration increased the appetites of the cattle, the increase being shown more particularly by the amount of silage consumed. The molasses feed was much relished by the animals.

The addition of molasses to the ration increased the rate of gain, whereas when molasses feed was substituted for cottonseed meal the rate of gain was reduced. The addition of molasses made very little difference in the cost of gain, but the use of molasses feed instead of cottonseed meal materially increased this cost. It should be noted that the most efficient ration from the point of view of gain and the finish of the cattle was that composed of shelled maize, cottonseed meal, molasses, clover hay and maize silage, but the most economical ration was that composed of shelled maize, cottonseed meal, clover hay and maize silage.

A detailed financial statement of the experiments is appended to the bulletin.

669 — **Fattening Western Lambs in U. S. A.** — SKINNER, J. H. and KING, F. C., in the *Purdue University Agricultural Experiment Station, Bul. div. No. 192. Vol. XIX, pp. 1-26.* Lafayette, September, 1916.

SHEEP

The object of the experiment was to compare the feeding values for fattening lambs of : — 1) clover hay and maize silage alone and in combination : 2) maize silage alone and in combination with dry roughage ;

3) clover hay and alfalfa hay; 4) cottonseed meal as a supplement to rations of maize, clover hay and maize silage; 5) cottonseed meal and ground soy beans as supplements to rations; 6) molasses. The influence of shelter on fattening lambs was also studied.

Two hundred and twenty-five choice improved Mexican lambs were used. They were of excellent quality and remarkably uniform in size, type, quality and condition. The lambs were divided into 9 lots of 25 each. Eight of these lots were placed in an open shed and fed different rations, the ninth lot was fed in a barn upon a ration similar to that of Lot 6 in the open shed. The experiment lasted 100 days.

*Maize silage and clover hay* (Lots 3 and 6). — Both lots of lambs were started with a ration of 14 lb. of oats daily for 25 lambs. At the end of the 7th day maize was added to the ration and oats gradually eliminated till, by the 17th day, each lot was receiving the experimental rations only. It was only after the 17th day that more than 1 lb. of silage daily per lamb was consumed, but at no time was less than 1 lb. of hay eaten daily per lamb. The appended table shows the results obtained.

It is seen that the difference in daily gain is practically negligible. There was a saving of 81 cents in the cost of 100 lb. gain when silage was used, and an increased profit of 29 cents per head.

*Maize silage v. maize silage and dry roughage* (Lots 1, 5, and 7). — All the lambs received a grain ration of 7 parts shelled maize and 1 part cottonseed meal. At the end of 80 days, the lambs of Lot 1, receiving only silage as roughage, went off very badly and their ration had to be materially reduced and one feed of clover hay given to make them eat well again.

The table shows that the elimination of dry roughage from the ration decreased the grain consumption and increased the silage consumption, but not in proportion to the dry matter removed by the elimination of clover hay. The elimination of clover hay also decreased the profit per lamb and the rate of gain. The rate of gain and profit per lamb was lowest when oat straw was added to the silage. The finish on the lambs was much the best when clover hay and silage were fed.

*Clover hay v. alfalfa hay* (Lots 3 and 4). — The only difference in the rations fed was that one lot received clover hay, the other alfalfa hay. It will be seen from the Table that the grain consumed was the same in both cases, but that more hay was eaten when clover was fed. The best results, however, as regards gain, profit and finish, were obtained with alfalfa. These results do not agree with two similar trials made at Purdue; this is probably due to the fact that, though the best clover hay procurable was used, it was only of medium quality and not entirely free from mould, whereas the alfalfa hay was of excellent quality and well cured.

*Cottonseed meal as a supplement* (Lots 6 and 7). — At the end of 12 days 1 lb. of cottonseed meal for 25 lambs was introduced into the ration, and gradually increased till, at the end of 20 days Lot 7 was receiving 3 lb. of cottonseed meal and 21 lb. of maize, as compared with 24 lb. of maize given to Lot 6. Both lots were then given all the grain, hay, and silage they would eat, the cottonseed meal being kept in the proportion of 1 lb. to 7 lb. of

maize. At no time was there any difference in the quantity of food eaten by the two lots. The table shows that, though the addition of cottonseed meal to the ration increased the cost, it also increased the rate of gain and the profit. This is in accordance with previous trials which showed the great merit of cottonseed meal to lie in the improved finish it gave the lambs.

*Molasses* (Lots 2 and 7). — The only difference in the rations of the two lots was that Lot 2 was given 4 lb. of cane molasses daily in place of 4 lb. of maize. The amount of food eaten was almost the same in both lots, though the addition of molasses slightly increased the appetite of the lambs. The rate of gain was slightly higher when molasses was fed, but, owing to the high price of the molasses, the profit was less; this was also partly due to the fact that the finish on the lambs in Lot 2 was less good than those on Lot 7.

*Ground soybeans v. cottonseed meal as a supplement* (Lots 7 and 8) — The only difference in the rations was the substitution of ground soybeans for cottonseed meal. The table shows the daily food consumption to be practically the same in both cases. The small difference in the rate of gain, the cost of gain and the profit made were in favour of cottonseed meal.

*Open shed v. barn as shelter* (Lots 6 and 9). — Lot 6 was fed in an open shed containing a space 14 × 16 ft. under cover and 14 × 14 ft. in the open. Lot 9 was fed in a barn 36 × 44 ft. with three windows in the north, one in the south, and one in the east, all of which were kept open. The lambs, the only animals in the barn, were confined in a space of 14 × 24 ft.

Both lots were fed similar rations composed of shelled maize, clover hay, and maize silage. The results given in the appended table show that the grain and hay consumed was the same in both cases, but that Lot 6 ate more silage. This was because the lambs in the barn did not eat silage as early as those in the open; when they had learnt to eat it well, the amount consumed was about equal in both lots. The lambs in the open shed made more rapid and economical gains than those in the barn, but the finish was the same in both cases. These results confirm those obtained in previous trials.

670 - **The Wintering of Bees in Ontario, Canada.** — PETTIT, MORLEY, in *Ontario Department of Agriculture, Bulletin* No. 256, pp. 24 + 11 FIGS. Toronto, Ontario, October, 1917.

The beekeepers of Ontario lose each year from 10 to 50 % of their colonies through winter and spring losses.

American bee literature is full of theories on the wintering of bees and on the causes of the losses therefrom. Many of these theories have been rejected or ignored. As the result of numerous experiments and a free interchange of ideas, however, successful beekeepers have evolved methods of wintering based on principles which recent scientific research has on the whole proved to be correct,

Beekeepers in Ontario adopt two methods of wintering. Some place their hives in a cellar and attempt to keep the bees inactive by controlling the environmental factors, such as light, temperature, ventilation, etc., till the weather permits the bees to renew their summer activities. Others protect the hives on the summer stands, leaving the bees free to go out and to fly whenever the weather permits them to do so. Both of these methods, if intelligently carried out, give good results.

For outdoor wintering the hives are placed in collapsible wooden boxes the sides of which are joined by cleats. Many beekeepers place one hive in each box, others two and others four per box. In this last case two hives are placed facing west and the two others facing east. Between the box and the hive is a space of 3 inches, and between the roof of the hive and that of the box a space of 8 or 10 inches is left. The box is placed on a solid stand 8 inches high which prevents draught of air underneath.

The entrance holes are cut in the side of the box so that the bees may go out in suitable weather. The hives are packed for winter as soon as possible after the supers have been removed, and in October the bees are given an abundant supply of maple sugar. The author gives the measurements of the different parts used for constructing wintering boxes, the size of which depends on that of the hives.

Till a few years ago the most common method of wintering in northern climates was that of keeping the hives in a cellar. Most beekeepers in Ontario and the northern States found that their bees wintered better in cellars than out of doors. Since the improvement of the method described above, however, outside wintering is generally preferred even as far north as New Ontario. Nevertheless, many still prefer cellar wintering. The general conditions required for cellar wintering are:— 1) total darkness, 2) a uniform temperature between 40° to 45°F. The conditions are obtained most satisfactorily in cellars which are almost entirely underground as they are less subject to changes in outside temperature. The air of the cellar must be kept pure by a suitable system of ventilation, and must be neither too dry nor too damp.

The hives themselves must have good ventilation; this may be obtained by removing the summer covers and placing on the top a layer of felt, a cushion of chaff, etc. The hives are placed one above the other, those in the bottom row resting on a stand at least 1 foot above the cellar floor.

The hives are placed in the cellar before the frosts, in southern Ontario in the last days of November, and earlier in the northern districts.

Judgement must be exercised in the removal of the hives from the cellar, the date depending on the condition of the bees and on the season. The best time for setting them out is the evening before or the morning of a day which promises to be fine and calm, but not too hot (60 to 70°F.) When such a day is expected the doors and windows of the cellar are opened at sunset.

Directions are given for the protection of the hives in spring and for feeding the bees. There should be an ample supply of food to avoid any danger of starvation. Autumn is the best time for feeding bees for the following spring.

671 — **Bottini, Colantoni, "Subalpina", and "Sughera" Bee Hives.** — *L'Apicoltura italiana*, Year XIV, No. 3, pp. 29-31 + 1 Fig. Ancona, March, 1918.

The **BOTTINI** hive is made of cement with an "Eternit" cover. The cement is mixed with ingredients which make it a bad conductor of heat so that the bees may be protected from cold in winter as much as possible; this would not be the case with ordinary cement. It has the advantage of lasting for a very long time and of being easy to disinfect thoroughly.

The **COLANTONI** hive only has one medium-sized frame. It combines the advantages of the hive with a moveable top with those of the hive opening at the back. The frame has an opening  $9 \times 13\frac{3}{4}$  inches and may be used both as a brood box and a super. The brood box, which has an opening at the back fitted with glass, makes it possible to estimate the number of young bees, clean the floor easily by raising the shelf, and to place a feeder on the floor. The brood box may even be examined if the super is left in place and the shelves be removed with tongs so long as they are parallel to the entrance.

The "Subalpina" hive, which is an improved **DADANT BLATT** pattern, includes the following parts: — 1) a floor board on two slide-bars which support, at a height of about 16 inches, four strong legs, slanting and hinged in front. At the back there is a movable ledge (which is fixed temporarily when the hives are moved) which closes the opening between the bottom and the brood box. This ledge is used to clean the hive, introduce disinfectants, queens, etc., for transferring, feeding, etc.; 2) a brood box and super, surrounded at the top by a band which serves as a holder and support to the roof; 3) a floor in two or three pieces, the largest of which is double-walled and forms a very practical feeder; it is composed of two cups for the honey or syrup and a third in the centre which has a hole allowing the passage of the bees which may be stopped when the feeder does not work; 4) an "Eternit" roof. The brood box and super are fitted with holes for a ventilation regulator. The nest and honey store may be arranged either parallel or perpendicular to the entrance.

The "Sughera" hive is not of a single pattern; the name is used only to designate the material of which it is made (cork crushed and united by a paste insoluble in water, or by tar, which is not injurious to bees and prevents their being attacked by *Tinea* larvae). Any kind of hive may be built with this material (1).

## SERICULTURE

673 — Can the Action of Cold Decrease Mortality among Silkworms Suffering from "Flacherie"? — LOMBARDI, LORENZO P., in *Informazioni seriche*, Year V, No. 2, pp. 19-20. Rome, January 20, 1918.

In the Bulletin No. 1, 1916, of the Agricultural Experiment Station of Crema, an article appeared under the title of "Intestinal Fermentations of the Silkworm", in which it was stated that when silkworms suffering from "flacherie" were subjected to a temperature of 12°C. mortality ceased, and the worms spun their cocoons. The worms were subjected to the low temperature for 48 hours, without food. When replaced in their normal surroundings food was withheld for another six hours.

The author (of the Royal Bacteriological Institute of Portici) was not convinced by these experiments, and in order to verify them, made several tests with silkworms of various breeds.

From the results he concluded that a temporary lowering of the temperature does not definitely improve the condition of silkworms attacked by "flacherie". The disease is only temporarily arrested, and later regains its virulence, causing losses equal on an average to those among the control lots.

674 — On the Discovery of a Plant Suitable for Feeding Silkworms. — I'UJIMA, DAIJIRO in the *Bulletin de l'Association séricicole du Japon*, Year II, No 12, pp. 1-16. Tokio, December 25, 1917.

As it is not uncommon in Japan for the young mulberry leaves to suffer from drought and frost the author has sought for plants suitable for feeding silkworms while resisting frost (other than *Cudrania triloba* [silkworm thorn]; *Broussonetia Kazinoki* Sieb., black goat's-beard, dandelion, plants already known to be utilisable for this purpose).

The author lists 13 plants that seem to be eaten readily by the silkworm; he has classified them according to his experimental results in the following manner:

a) Plants of no practical value:— 1) *Phragmites communis* Trin.; 2) *Lactuca Thunbergii* Maxim; 3) *Campanula punctata* Mig.; 4) *Lampsana apogonoides* Maxim.; 5) *Lampsana humilis* Makino; 6) *Crepis japonica* Benth; 7) *Pieris hieracioides* L. var. *japonica* Bgl.

These plants might furnish good food but their leaves are too scanty.

b) Plants of uncertain practical value:— 8) *Lactuca denticulata* Maxim; 9) *Codonopsis lanceolata* B. and H.; 10) *Papaver somniferum*.

c) Plants fairly useful for feeding the larvae:— 11) *Sorghus oleraceus* L.; *Adenophora verticillata* Fisch. var. *typica*.

d) A plant worth using:— 13) *Lactuca brevirostris* Champ. (1). This plant starts growing early in spring and by autumn reaches a height of 6 or 7 ft. If it is cut in summer, it puts forth buds and grows rapidly, so that the leaves can be removed continuously from spring to autumn. Silk-

(1) See R., January 1918, No. 77. (Ed.).

worms fed on this plant until their first moult and even the second one, gave excellent results, actually better than those given by mulberry-fed larvae. Larvae fed on this plant up to the third moult gave results slightly inferior to the preceding ones; but experience has shown that *L. brevisrostris* is perfectly suitable for feeding silkworms.

675 - **Production of Silkworm Eggs of the Annual Breed, in Japan, in 1917.** — *Informazioni seriche*, Year V, No. 6, pp. 89-90. Rome, March 20, 1918.

According to the Japanese Ministry of Agriculture and Commerce the quantity of silkworm eggs produced in 1917 was estimated at 292 347 533 layings of eggs in frames and 765 050 boxes of commercial eggs, or a total of 3 688 525 boxes (100 layings in frames make a box), an increase of 5 % on the production for 1916.

The seed was produced by the different breeds in the following manner: 1 448 623 boxes of Japanese breeds, or 39.3 % of the total production; 2 239 902 boxes of foreign breeds, or 60.7 %. In the foreign races there were 3.5 % of yellow cocoons and 46.5 % of white ones. The Sino-European hybrid is the most numerous (58 %) in the eggs giving yellow cocoons; then come the Nippo-European hybrids with 17.7 % and the European races with 11.2 %. Amongst the eggs giving white cocoons, the Sino-Japanese hybrid forms 58.9 %, the Sino-Nippo-Europeans 15.9 % and the Chinese races 19.2 %.

676 - **Development of the Silkworm industry in Cambodia.** — DE FLACOURT, MARTIN, in *Bulletin Economique de l'Indochine*, Year XX, New Series, No. 127. pp. 649-661. Hanoi-Haiphong, November-December, 1917.

Cambodia has a hot and fairly dry climate and a fertile soil in which the mulberry tree grows remarkably well. Silkworm breeding there is very popular and very widely practised. Information gathered at the silkworm centres, as well as in certain other districts of the country, shows, not only the present possibilities of production, but also a great promise for the future development of the industry. Special attention should, therefore, be given to this country, which is perhaps the only one of French Indo China combining such conditions so favourable to an assured intensive development of silkworm breeding.

As things are at present its capacity of production makes it possible to consider with confidence a perfected spinning industry which will henceforth be assured of obtaining locally a sufficient quantity of good quality raw material to supply over 500 to 600 pans. The undeniable influence of the industry on the production of the country may be easily foreseen.

On the other hand the local Government, by the action it has exercised so far on the most important silkworm breeding centres and could extend to the other districts of Cambodia, and by the great encouragement it has given to the industry, has favoured and prepared the way for the establishment of steam silk spinning mills, which form the basis of a perfected silk industry, and appear at an eminently favourable moment.

It falls to private initiative and the French consumers to profit by the situation by founding spinning mills and thus contributing to the development of the local silk production

- FISH CULTURE 677 — **The Raising of Leather-Carp and Black-Bass in Sologne, France.** — ROULE, LOUIS, in the *Bulletin de la Société Nationale d'Acclimatation de France*, Year LXVI, No. 2, pp. 33-35. Paris, February, 1918.

M. BRUNET has carried out successful acclimatisation experiments on his property at Mouteaux, Sologne.

Leather-carp (notable for their rapid growth, hardiness, small bones and good quality flesh) were imported from central Europe some 10 years ago. The acclimatisation was perfect, M. BRUNET has had no need for further importation and he now stocks his ponds with fry of his own rearing.

The black-bass (*Micropterus salmoides* Lac.) has been imported into Europe from the United States. It was known that it could live under French climatic conditions, but it was not certain if it could breed there, as it does in upper Italy. M. BRUNET imported 30 black-bass fry from Italy in April, 1914, and distributed them in his ponds; they were taken out in October 1914 and gave not only fine young fish weighing about 2.2 lbs., but also about 4 000 fry. The black-bass had reproduced, therefore, and were completely acclimatised.

## FARM ENGINEERING.

- AGRICULTURAL MACHINERY AND IMPLEMENTS 678 — **British Agricultural Tractors.** — *The Engineer*, Vol. CXXIV, Nos. 3233, 3234, 3235; Vol. CXXV, Nos. 3236, 3237, 3238, 3239, 3240, 3241, 54 Fig. London, December 14, 1917-February 8, 1918.

According to the President of the Board of Agriculture, 1 400 tractors had, by October 6, 1917, ploughed 14 500 acres of land for next year's harvest. Three years ago there were probably not 100 tractors in use in the United Kingdom. This progress, though considerable, has not been as rapid as it might have been owing to the objections raised by farmers against mechanical traction chiefly with regard to compressing the soil and the provision of inadequate power. In some recent models the latter defect is obviated by providing a 30 HP. engine which should suffice for 3-furrow ploughs doing fairly deep work under favourable circumstances. British tractors are usually strongly built, and they are therefore very lasting. In time, standardisation will be probably arrived at in the various types of tractors, but the final type has not yet been decided upon. There are still numerous problems that remain to be solved by British makers, who are at present occupied in delivering the machines that are required for bringing large areas under cultivation.

British agricultural tractors may be divided into 2 classes, those that are propelled by a) steam and b) by internal combustion engines. Contrary to the internal combustion engined machines, the steam driven ones follow, save in one or two cases, very closely the design of road locomotives, except they are lighter, the question of weight being of great importance.

STEAM TRACTORS. — The agricultural tractor made by AVELING & PORTER, of Rochester (fig. 1) resembles the road locomotives and rollers made by that firm, but it is smaller and lighter (5 tons). The driving wheels, which

are 5 ft. in diameter, are 12 in wide, but for working on soft ground detachable extension rings 6 in wide with the necessary spuds are provided.

The engine is of the compound type with 2 cylinders. The boiler has 27 tubes and is fitted with a fire-box of the Belpaire type. The normal speed of the engine is 225 revolutions per minute, and at that speed 21 brake-h.p. is developed at the fly-wheel. The engine is mounted on laminated steel springs fitted to both back and front axles. There are 2 speeds : — 2  $\frac{1}{2}$  and 5 miles per hour respectively.

Fig. 1. — AVELING & PORTER steam tractor.

This serviceable little engine will haul a 3-furrow plough under normal conditions. It can cover from 40 to 50 miles per day on the road, with an approximate cost of from 15s. to 16s. Coal, or more preferably coke, is the fuel employed.

The tractor (fig. 2.) built by C. BURRELL & SONS, of Thetford, has an overall length of 14 ft. 3 in., a width of 5 ft. 8 in., and a height to the top of the fly-wheel of 6 ft. 8 in. ; it weighs 6 tons 18 cwt. The boiler is of the locomotive type and has 25 tubes. The engine is compound with cylinders 4  $\frac{1}{2}$  in. and 7  $\frac{1}{2}$  in. in diameter by 8  $\frac{1}{2}$  in. stroke. It runs at 230 revolutions per minute, developing 20 B. H.P. at the fly-wheel. It has either 2 or 3 speeds, the 3 speeds being 2, 3 and 5 miles per hour. The tractor is furnished with a winding drum which is operated by the engine and carries 60 yards of steel wire rope. It is specially built for farm work.

Amongst the various engines built by W. FOSTER & Co., of Lincoln, the 1909 model of the "Wellington" tractor, shown in Fig. 3. may be referred to.

The tractor is of 14-18 HP, very well built and designed, and can tow

an 8-ton load over good roads with gradients up to 1 in 20, while on the slow speed gear it will haul the same load up gradients of 1 in 8. The tender contains a water tank of 80 gall. capacity and a coal bunker holding 3  $\frac{1}{2}$  cwt.

Fig. 2. — BURRELL & SONS steam tractor.

Additional tanks are fitted that bring up the total water capacity to 153 gall., which suffices for a journey of some 18 miles under normal conditions.

It is possible that, on account of the limitations of weight, the machine

Fig. 3. — "Wellington" steam tractor (W. FOSTER & Co.)

requires replenishing with coal and water too frequently to suit farming conditions; the tractor has, however, been successfully used for hauling 3-furrow ploughs.

The same firm also builds a larger steam tractor, specially designed to

suit agricultural conditions in the Argentine. The boiler is designed for burning straw ; it will haul a plough, serve as a road tractor or drive a FOSTER threshing machine. The firm of FOSTER also builds a 40 B. H.P. petrol tractor for use as a general purpose machine. It weighs about  $4\frac{3}{4}$  tons and gives an effective draw-bar pull of 4 000 lb.

The "Suffolk Punch" steam tractor built by R. GARRETT & SONS, of Leiston, is of the horizontal compound type (1). It is intended to perform any agricultural work (Fig. 4) as well as hauling a 10-ton load at 5 miles an hour over fairly good roads. The fire-box is placed in the front of the motor, while the smoke-box and funnel are in the rear, so that the driver is very well placed for controlling the vehicle. The boiler is designed so that an inferior quality of coal may be used ; the steam is superheated. The engine develops from 37 to 40 B. H.P.

Fig. 4. — "Suffolk Punch" steam tractor (R. GARRETT & SONS) drawing a plough.

According to the makers, the average cost of hauling a 4-furrow plough, ploughing to a depth of 6 in. to 7 in., is from 3s. 6d. to 4d. 6d. per hour, the time taken being from  $1\frac{1}{2}$  to 2 hours per acre.

The engine normally runs at 325 revolutions per minute, and there are 2 speeds, namely, a slow speed of 2 miles per hour for ploughing and a higher speed of 5 miles for road work, the engine running at normal speed in both cases. The tractor in full working order weighs about  $5\frac{1}{2}$  tons.

The MANN'S PATENT STEAM CART AND WAGON CO., of Leeds, have designed a tractor specially for farm and estate work. This tractor (Fig. 5) has 3 speeds, varying from 2 to 6 miles per hour. The lowest speed is for ploughing in strong land ; the intermediate speed for light or medium

(1) See R., 1916, No 331. (Ed.).

land, as well as for pulling self-binders, etc., and the quick speed for travelling on the road.

The engine is of the horizontal type, with cylinders 4 in. and  $6\frac{3}{8}$  in. in diameter by 7 in. stroke. The governor is set to run the engine at 300 revolutions per minute, the speed required for driving ordinary threshing machines. The tractor itself weighs about  $4\frac{1}{4}$  tons, but detachable sideboards are provided so that an extra weight of about a ton can be carried for road work.

On ordinary roads this tractor can haul a 6-ton load; it will easily pull a 4-furrow plough in strong clay land. A fair average days' ploughing is 5 acres.

Fig. 5. — MANN steam tractor, drawing a plough.

In the tractor made by Messrs. J. and H. McLAREN, of Leeds (illustrated in Fig. 6), the boiler is of the usual traction engine type, with a compound engine, with cylinders  $4\frac{1}{2}$  in. and  $7\frac{1}{2}$  in. diameter by  $8\frac{1}{2}$  in. stroke. There are 3 speeds, namely, 5,  $2\frac{1}{2}$  and 2 miles per hour. When running on the road at 5 miles per hour the speed is 314 revolutions per minute, but when ploughing at 2 miles per hour, the speed is 355 revolutions per minute. The machine weighs under 5 tons and is built so as to have a long life. This tractor, provided with a trailer, gained the Royal Agricultural Society's Gold Medal in 1910.

The compound steam tractor made by RANSOMES, SIMS AND JEFFERIES, of Ipswich, weighs about  $4\frac{3}{4}$  tons. It is of the road locomotive type, and is more especially intended for hauling loads of from 5 to 7 tons on ordinary roads with moderate gradients than for ploughing and similar farm work. The high-pressure cylinder is  $4\frac{1}{2}$  in. in diameter and the low-pres-

sure cylinder  $7\frac{1}{2}$  in. in diameter, the stroke of both cylinders being 8 in. A by-pass is provided so that high-pressure steam can be admitted to the low-pressure cylinder to provide increased power for starting or emergencies. The engine develops 16-20 HP. For travelling, 2 speeds, namely, 3 and 5 miles per hour, are provided. The engine is mounted on helical springs to the main axle and laminated springs to the front axle.

Fig. 6. — MACLAREN steam tractor.

The tractor made by ROBEY & CO, of Lincoln, can haul from 6 to 8 tons on ordinary roads, plough from 10 to 15 acres of average land per day of 10 hours and will drive such machinery as a 4 ft. 6 in. threshing machine.

It is of the usual road locomotive type, but in miniature (Fig. 7). The engine is compound with cylinders 5 in. and 8 in. in diameter by 9 in stroke. There are 2 travelling speeds, *i. e.*,  $2\frac{1}{2}$  and 5 miles per hour.

It is impossible to give any exact figures as to costs of working these tractors, but approximately it may be said that, taking coal at £2 per ton, the total cost (wages, fuel, oil, interest, etc.) of ploughing 60 acres in 5 days of 10 hours each is £12. 5. 6, the acre, therefore, costing 4s.  $1\frac{1}{2}d.$  per acre.

W. TASKER & SONS, of Andover, make a series of tractors specially designed for agricultural work. The most important model (Fig. 8) — the "Little Giant" — is a gear-driven steam-tractor; another type is chain driven. Another type has a winding drum for double engine ploughing.

These machines are of the road locomotive type. The engine is of the compound type with cylinders 5 in. and  $7\frac{3}{4}$  in. in diameter by 8 in. stroke, and develops 25 B. H.P. When the machine is to be used for driving fixed machinery, a high-speed governor of the Pickering type is provided. There are 2 speeds, *i. e.*, 3 and 6 miles an hour. The main gearing runs in an oil bath. The mounting is on the Hoare's spring system.

WALLIS & STEEVENS, of Basingstoke, make the "Wallis" steam motor tractor for universal service. The model (Fig. 9) has been greatly perfected since it was first produced in 1900. It can haul a 6-furrow plough in most soils, and on medium land as many as 9 furrows have been cut with it.

Fig. 7. — ROBEY & Co steam tractor.

The tractor has a locomotive-type boiler with the 2-cylinder engine mounted on top of it. When running at its normal speed of 400 revolutions per minute it develops 24 B. H.P. The working parts are enclosed in a

Fig. 8. — "Little Giant" steam tractor (W. TASKER & SONS).

splash oil-bath, and are therefore protected from dirt and dust, while being easily accessible to the driver. Gear changing is easy and the main axle is fitted with a differential motion. The hind axle is fitted with a slip-winding drum. The tender contains a coal bunker and a water tank. The tractor burns coal or coke, but wood may be used.

Fig. 9. — WALLIS & STEEVENS steam tractor.

According to the makers the cost of ploughing an acre works out at just under 11s., while the machine can plough 5 acres a day on the average.

INTERNAL COMBUSTION TRACTORS. — BUMSTED & CHANDLER, of Hedgesford, Staffordshire, make the "Ideal" (1) tractor (Fig. 10) for general farm use: — ploughing, harvesting, road hauling, and as a power plant.

It is driven by a vertical 4-cylinder engine, which develops 35 HP. There are 2 speeds forward of 3 and 6 miles per hour and a reverse speed of 3 miles per hour. The hind wheels are furnished with self-cleaning spuds. With a 4-furrow plough, the machine weighs 4  $\frac{1}{2}$  tons. It is 20 ft. long with the plough attached, and 6 ft. 6 in wide. On average land it ploughs one acre per hour.

A long and interesting description is given of the Crawley "Agrimotor", which has been dealt with previously (2).

Motor ploughs of two sizes are built by J. FOWLER & Co., of Leeds. In one the engine has a single cylinder, while in the other there are 2 cylinders.

(1) See B., 1914, No. 558. (Ed.) — (2) See R. 1917, No. 942. (Ed.)

These machines embody the Wyles' patents and also the subsequent inventions and improvements of J. FOWLER & Co. The first type, of 10 HP. (1), can do the work of 4 horses and is very suitable for work among drilled crops, vineyards, hop gardens, colonial crops, etc.

Fig. 10. — BUMSTEAD & CHANDLER motor tractor, hauling a plough.

The 2 cylinder plough (Fig. 11) with a single speed of  $1\frac{3}{4}$  miles per hour, weighs about 21 cwt. It can be fitted with 2 forward speeds of 2.2 and 1.5 miles per hour respectively, and a reverse speed of 1.5 miles per hour. It is slightly longer and wider than the single-cylinder machine.

Fig. 11. — JOHN FOWLER & Co. motor plough.

Its cylinders have a 4 in. bore and 5 in. stroke; it develops 13-14 B. H. P., with the engine running at from 1 000 to 1 100 revolutions per minute.

It can either cut one or two furrows; if 2, the width and depth cut is slightly less.

(1) See *R.*, 1916, No. 897. (*Ed.*)

The "Ivel-Hart" tractor, built by the IVEL AGRICULTURAL MOTORS, Limited, is driven by an engine which will work with paraffin, petroleum and other low grade fuels, after starting on petrol. One of its chief features is (Fig. 12) that it only has one driving wheel, and hence differential gearing is not required.

Fig. 12. — "Ivel Hart" motor tractor, drawing a plough.

The engine is of 2-cylinders, cast in one piece, with  $5\frac{1}{2}$  in. bore and 7 in. stroke, and the normal speed is 600 revolutions per minute (varying from 500-750). At the normal speed the brake horse-power is 22, and the draw-bar horse-power 15. There are 2 forward and 2 reverse speeds, obtained by a total of 7 gear wheels and pinions, 5 of which run in an oil bath. Lubrication is of the force feed type. The total weight is 59 cwt, and the length is 12 ft. 8 in.

The machine is self-steering when ploughing. The draw-bar can be adjusted in position. Under average conditions the tractor can haul a 3-furrow plough at a depth of from 6 in. to 8 in., while in heavy soils it will haul a 2-furrow plough cutting from 6 in. to 10 in. deep. It will plough an acre with a 3-furrow plough to a depth of from 6 in. to 7 in. in from  $1\frac{3}{4}$  to  $2\frac{1}{4}$  hours, depending on the nature of the soil and the length of the field. To plough an acre takes from 4 to 5 gallons of paraffin according to the soil.

The motor plough made by MARTIN'S CULTIVATOR COMPANY, Limited, of Stamford, is of the caterpillar type. It is a 3-furrow plough (Fig. 13) and

does all the work that can be done by horse ploughing ; it can be manipulated by one man.

It can plough 5 or 6 acres a day with a consumption of  $2\frac{1}{4}$  to 3 gall. of petrol. The whole of the plough frame can be detached and its place taken by a wheeled undercarriage, the machine then becoming an agricultural tractor suitable for working cultivators, drills, harrows, mowers, etc. A pulley for driving machinery can also be attached.

Fig. 13. — MARTIN motor tractor, drawing a plough.

The engine is of the 4-cylinder, 4-cycle type, similar to that used in heavy motor lorries. The cylinders have a bore of  $3\frac{3}{4}$  in and a stroke of 5 in. At 1000 revolutions per minute the engine develops 25 B.H.P. There are 2 "Zenith" carburettors. The engine is started on petrol and run on paraffin. There is a Dixie magneto and lubrication is effected by a gear-driven wheel pump.

The chain tracks are constructed in accordance with recent patents. Each can be separately adjusted so as to act as land or furrow wheels respectively and also to regulate the depth of ploughing. They distribute the weight over a large area of soil, and since the total weight of the motor with a 3-furrow plough is only about 30 cwt., the weight per unit of area in contact with the soil is by no means high.

The "Universal" tractor(1), made by the SAUNDERSON TRACTOR AND IMPLEMENT CO, is well known, but the present model (Fig. 14) is much more simple. The makers have paid great attention to the accessibility of the parts, ease of renewals and increase of bearing surfaces to give longer life. Before this improved model was placed on the market it was tested for 12 months on some of the heaviest clay in England. The machine proved itself capable of doing the entire work on a 240-acre farm, no horse labour whatever being required.

(1) See *B.*, 1914, No. 558, and *R.*, 1916, No. 897. (*Ed.*)

The "Universal" tractor is of 20-25 B.H.P. It can haul a 3 or 4-furrow plough or other implement, and drive a 4 ft. 6 in. thresher with elevator and chaff-cutter attached. It will haul 5 or 6 tons on the road at a speed of 5 miles per hour. By means of a special coupling it can haul 3 mowing machines, or 2 self-lift binders.

All the working part of the tractor are covered in; the control mechanism is very simple: the movement of one single lever in front of the driver forwards or backwards controls everything by acting on the governors. The tractor is completely standardised, so that the firm will soon be producing a large number of these British-built machines.

Fig. 11. — SAUNDERSON TRACTOR AND IMPLEMENT Co. motor plough.

With the object of providing an equipment less costly than the usual steam plant, WALSH & CLARK, of Guisely, near Leeds, make a ploughing set operating on the cable system, but driven by internal combustion engines, which are started on petrol but run on paraffin. Each engine (Fig. 15) weighs about 6 tons, and is rated at from 30 to 55 B.H.P. at an engine speed of 600 revolutions per minute, and when travelling or ploughing, and 22 B.H.P. on the driving belt.

The engine is of the horizontal type, with 2 cylinders, and gives a continuous pull on the rope of 3500 lb. It will haul a 4-furrow plough on medium or light land, and a 3-furrow plough on heavy land. A pair of engines can plough from 7 to 10 acres per day of 10 hours, according to the nature of the land, and with rope speeds of from 250 ft. to 350 ft. per minute. They will also cultivate from 14 to 20 acres per day. The machine can be employed as a tractor for road or field work.

Messrs. W. WEEKS & SON, of Maidstone, make the WEEKS DUNGEY "New Simplex" tractor (Fig. 16), intended for all-round farm work. It starts on petrol, but runs on paraffin; there are 3 speeds, *i. e.*, 4  $\frac{1}{2}$ , 2  $\frac{1}{2}$  and 1  $\frac{3}{4}$  miles per hour. It has cut 24 acres of corn per day with an ordinary 5 ft. binder, and 27 acres with a 6 ft. machine.

The "New Simplex" tractor has 4 wheels and weighs 35 cwt. It is 8 ft. long, 4 ft. wide and 5 ft. 6 in. high and develops 25 B.H.P.

Fig. 15. — WALSH & CLARK cable motor tractor.

The machine is very well constructed and fitted with all the latest improvements. In Kent, it has ploughed from  $2\frac{1}{2}$  to 3 acres per day, at a cost of about 12s. per acre.

Fig. 16. --- "New Simplex" motor tractor (W. WEEKS & SON).

The WYLES motor plough has been described in this *Review*, March 1918, No. 332. Fig. 17 shows it hauling a mowing machine.

The latest tractor built by Messrs. CLAYTON & SHUTTLEWORTH, of Lincoln, is of the chain track type, and a woman can manipulate it, with a

plough attached. The tractor develops 35 HP and it can haul a 3- or 4-furrow plough.

The engine has 4 cylinders, each of 120 mm. bore and 140 mm. stroke. Petrol is used for starting and paraffin for running. The mechanism is easily accessible. Two forward speeds of  $1\frac{3}{4}$  and 4 miles per hour and a reverse of 3 miles per hour are provided, while the necessary mechanism is actuated by straight-through lever control. The chain tracks have received a good deal of attention. The weight of the tractor is carried on each side by 4 rollers.

The draw-bar pull is 2 tons in slow gear. For the driving of machinery there is a belt pulley. The tractor weighs 2 tons 16 cwt. It is 11 ft. long, 5 ft. 4 in. wide and 5 ft. 6 in. high. The British Government has ordered large numbers of these tractors.

Fig. 17. — WYLES motor tractor, hauling a plough.

The ALLDAYS & ONIONS PNEUMATIC ENGINEERING Co. make a tractor carried on special springs for road work, the springs being clamped down for field work.

Fig. 18. shows the tractor, which is for all-round work. It has 3 speeds forward and a reverse ; the highest road speed is 5 miles per hour and the slow speed is  $1\frac{1}{2}$  miles per hour for difficult ploughing and  $2\frac{1}{2}$  for ordinary ploughing.

The engine is vertical, 4-cylinder, and runs at 1000 revolutions per minute. A Zenith carburettor, arranged to work with paraffin is provided.

The "New Simplex" tractor has 4 wheels and weighs 35 cwt. It is 8 ft. long, 4 ft. wide and 5 ft. 6 in. high and develops 25 B.H.P.

Fig. 15. — WALSH & CLARK cable motor tractor.

The machine is very well constructed and fitted with all the latest improvements. In Kent, it has ploughed from  $2\frac{1}{2}$  to 3 acres per day, at a cost of about 12s. per acre.

Fig. 16. — "New Simplex" motor tractor (W. WEEKS & SON).

The WYLES motor plough has been described in this *Review*, March 1918, No. 332. Fig. 17 shows it hauling a mowing machine.

The latest tractor built by Messrs. CLAYTON & SHUTTLEWORTH, of Lincoln, is of the chain track type, and a woman can manipulate it, with a

plough attached. The tractor develops 35 HP and it can haul a 3- or 4-furrow plough.

The engine has 4 cylinders, each of 120 mm. bore and 140 mm. stroke. Petrol is used for starting and paraffin for running. The mechanism is easily accessible. Two forward speeds of  $1\frac{3}{4}$  and 4 miles per hour and a reverse of 3 miles per hour are provided, while the necessary mechanism is actuated by straight-through lever control. The chain tracks have received a good deal of attention. The weight of the tractor is carried on each side by 4 rollers.

The draw-bar pull is 2 tons in slow gear. For the driving of machinery there is a belt pulley. The tractor weighs 2 tons 16 cwt. It is 11 ft. long, 5 ft. 4 in. wide and 5 ft. 6 in. high. The British Government has ordered large numbers of these tractors.

Fig. 17. — WYLES motor tractor, hauling a plough.

The ALLDAYS & ONIONS PNEUMATIC ENGINEERING Co. make a tractor carried on special springs for road work, the springs being clamped down for field work.

Fig. 18. shows the tractor, which is for all-round work. It has 3 speeds forward and a reverse ; the highest road speed is 5 miles per hour and the slow speed is  $1\frac{1}{2}$  miles per hour for difficult ploughing and  $2\frac{1}{2}$  for ordinary ploughing.

The engine is vertical, 4-cylinder, and runs at 1000 revolutions per minute. A Zenith carburettor, arranged to work with paraffin is provided.

The crank shaft is carried in 3 bearings lined with anti-friction metal. There is a high-tension Dixie magneto, and steering is by the Ackermann system. The tractor will turn in a circle having a diameter of 28 ft. It is provided with a winding drum, carrying 50 yards of steel wire rope. The present wheel base of the tractor is 7 ft. 10 in., but it is to be reduced to 7 ft.

The tractor has been tested in Scotland and also at Birmingham where it drew a 3-furrow HOWARD gang plough. The draw-bar pull was about 1100 lb. on the average.

For use in driving machinery, an 18 in. pulley is provided; it can drive a 4 ft. 6 in. threshing machine.

Besides the detailed description of the various British tractors, an account is given of the "Tracford" (1) appliance, intended to convert a FORD or other car into a 20 HP agricultural tractor. There are 3 steel land wheels, provided with detachable spuds.

Fig. 18. — ALLDAYS & ONIONS motor tractor.

679 — **Ploughing with Government Tractors in England.** — *Mark Lane Express Agricultural Journal*, Vol. CXIX, No. 4507, p. 141, and No. 4510, p. 228. London, February 11 and March 4, 1918.

In Herefordshire, 3 "Titan" tractor units ploughed over 520 acres in the last week of January, the division being: Hereford, 170 acres; Leominster, 142 acres, and Ross, 208 acres.

The Ross team's work, which was accomplished with 7 tractors, gave an average of  $29 \frac{5}{7}$  acres per tractor; 9 tractors were used in the Hereford and Leominster units, which makes the work done by the Ross unit all the more creditable; the work done by the Ross tractors varied from 26 to 32 acres each, ploughed in from 53 to  $68 \frac{1}{2}$  hours.

(1) See R., April 1918, No. 455. (Ed.)

In Surrey, a Titan tractor ploughed 51 acres in a single week at Redhill. The county average for the week was 12 acres per tractor.

In Lancashire a tractor towing a 3-furrow RANSOME plough did 52  $\frac{1}{4}$  acres during the week ended February 23. No special provision was made for record breaking. The ploughing was 8 in. deep and 2.54 gallons of fuel were consumed per acre.

In 5 weeks this tractor has performed the following work (including that described above): — during the week ended January 25, 27  $\frac{1}{2}$  acres were ploughed, 103 gall. of fuel; from January 25 to February 15, 21 acres were ploughed on an average per week, with an average consumption of 66 gall. of paraffin; the total consumption for the week February 15 to 22 for ploughing 52  $\frac{1}{4}$  acres was 133 gallons.

680 — **The Use of Coal Gas for Ploughing Tractors.** — *The Implement and Machinery Review*, Vol. XLIII, No. 516, p. 1289 + 2 Figs. London, April 1, 1918.

As petrol is unobtainable and paraffin is both scarce and costly, it is of interest to note the use of coal gas for ploughing tractors.

Messrs. BARTON BROS, of Beeston, England, make a flexible gas container to be placed above the tractor. This system, already adopted for many commercial and pleasure vehicles, is the most economical as it does not require the gas to be compressed and only gives a slight loss in calorific efficiency. For farm work there is no objection to the use of a container, save that of its voluminous appearance. It is carried on a tray supported by wooden uprights bolted on to the tractor frame.

The container's capacity is 250 cu. ft., and, it is reported that 500 cu. ft. of gas suffice to plough half an acre of level land.

The system can be employed to advantage by farmers within reasonable distance of a supply station. In England, as the companies usually give special conditions to users of gas for power purposes, the cost of ploughing by this means is very low. In the case mentioned in the article the container is mounted over a Whiting-Bull tractor and the gas is brought to the field in a portable holder carried on a trailer and containing sufficient to charge the bag on the tractor three times, or enough to plough about three-quarters of an acre. To the cost of the gas must, therefore, be added the expense of the journeys with trailer between the field and the supply station.

The distance over which the owner can afford to transport the gas will probably be found to be fairly large considering the present price of other fuels.

TILLAGE MACHINES AND IMPLEMENTS. — *France*: 486337 Fixing device, for plough shares and other similar cultivating tools; 486445 Motor plough.

*United Kingdom*: 113029 Motor driven endless track machine for levelling ground and for extracting steel and iron scrap therefrom in view of reclaiming land.

*United States* : 1254817 Harrow ; 1254985 Plough coulter ; 1255035 Self cleaning harrow and cultivator ; 1255420 Combined tractor, roller and harrow ; 1255442 Detachable share for cultivator and scarifier implements ; 1255509. One wheel harrow cart ; 1256225 Detachable V shaped packing band for fitting on a harrow-disc ; 1256349 Traction gang plough ; 1256632 Agricultural machine ; 1256984 Disc-plough ; 1257127 - 1257818 Ploughs ; 1257236 Tractor plough ; 1257407 Riding attachment for harrows and the like ; 1257446 Gang plough.

MANURES AND MANURE DISTRIBUTORS. — *United States* : 1255052 Straw-spreader ; 1256190 Spreading machine ; 1256196 Straw conveyor and spreader ; 1256854 Fertilizer distributor ; 1256459 Fertilizer attachment for maize planters.

DRILLS AND SEEDING MACHINES. — *Canada* : 180769 Land packer and seeder.

*United Kingdom* : 112976 Potato planter.

*United States* : 1254859 Drill ; 1255055 planter ; 1255532 marker for maize planter ; 1256083 Rotary marker device for actuating the rock shaft of a maize planter ; 1256292 Potato planter ; 1257839 Maize planter ; 1257928 Attachment for maize planter.

VARIOUS CULTURAL OPERATIONS. — *United States* : 1254687 Weeder ; 1254999 Cotton chopper ; 1256473 Cultivator fender.

CONTROL OF DISEASES AND PESTS OF PLANTS. — *France* : 486296 Application of calcium sulphide to the treatment of fungous diseases of the vine and other plants.

*United Kingdom* : 113121 Reciprocating pump for spraying apparatus.

*United States* : 1254649 Boll weevil exterminator ; 1255131 Insect destroyer.

REAPERS, MOWERS AND HARVESTING MACHINES. — *France*. 486230 Circular platform harvesting machine with curved cutting knife for various heights.

*United Kingdom* : 113117 Mechanism of side-delivery rake and swath turning machines.

*United States* : 1255209 Combined harvester ; 1255365 Hay sweep ; 1255520 Hay rake ; 1255914 Pea picker ; 1255930 Harvester and elevator combined ; 1255982 Harvester-crop curing chamber and baler ; 1256178 Side-delivery rake ; 1256347 Maize harvester ; 1256390 Vegetable gatherer and loader ; 1256410 Bundle carrier attachment for harvester ; 1256438 Vacuum cotton picking machine ; 1256683 - 1247403 Ensilage harvesters ; 1256700 Grass guard for mowers ; 1256776 Corn harvesting attachment for farm wagon ; 1257269 Bean harvester ; 1257304 Adjusting mechanism for grain shocking machine ; 1257386 - 1257387 Mowers.

MACHINES FOR LIFTING ROOT CROPS. — *Switzerland* : 77479 Forkhead for potato diggers.

*United States* : 1255051-1256713 Vegetable harvesters ; 1255302-1256182 Potato digging machines ; 1256119 Front auger support and bearing for beet harvester ; 1257081 Beet harvester and topping machine ; 1257168 - 1257953 Beet harvesters.

THRESHING AND WINNOWER MACHINES. — *Canada*: 181020 Grain grader.

*United States*. 1254817 - 1257592 - 1257802 Threshing machines; 1256120 - 1256506 Feeders for threshing machines; 1256585 Bean separator; 1257115 Pea and bean separator.

MACHINES AND IMPLEMENTS FOR THE PREPARATION AND STORAGE OF GRAIN, FODDER, ETC. — *Canada*: 181041 Drying kiln.

*United States*: 1255041 Hay press; 1257466 - 1257474 Bale forming presses; 1257510 Feeding device for hay baling presses.

STEERING AND TRACTION OF AGRICULTURAL MACHINERY. — *Canada*: 181061 Tractor.

*France*: 486455 Agricultural tractor.

*United Kingdom*: 113016 Apparatus for power cultivation of land; 113102 Endless track vehicle.

*United States*: 1254819 Endless automatic track laying and ground treading power operated traction engine; 1255404 - 1255530 - 1256651 Tractors; 1256113 Tractor wheel; 1257416 Tractor or truck; 1257589 Tractor connection.

FEEDING OF LIVESTOCK. — *United States*: 1254937 Hog watering apparatus.

POULTRY FARMING. — *United Kingdom*: 113159 Feeding trough for poultry.

INDUSTRIES DEPENDING ON PLANT PRODUCTS. — *United Kingdom*: 113042 Bakers' oven.

DAIRYING. — *Canada*: 180828-180970 Desiccated milk; 180829-180830 Milk condensation, process and apparatus; 180831 Buttermilk powder; 181131 Milk concentrating apparatus; 181133 Process of condensing and desiccating buttermilk; 181134 Condensed buttermilk.

*Switzerland*: 77531 Churn mechanism; 77532 Milk skimming device.

*United States*: 1255186 Milking machine cluster; 1255239 - 1256793 Milking machines.

VARIOUS. — *Switzerland*: 77478 Hydro-electrical installation for operating agricultural machinery.

*United Kingdom*: 112987 Humidifier.

*United States*: 1255055 Hydraulic pump.

## RURAL ECONOMICS.

683 - **Organization of Ten Dairy Farms in the Bluegrass Region of Kentucky.** — ARNOLD, J. H., in *U. S. Department of Agriculture Bulletin* No. 548, (Office of Farm Management), pp. 1-12. Washington, D. C., May 24, 1917.

This bulletin presents a brief analysis of the organization of 10 dairy farms selected and studied during 1914 in Mason, Scott and Madison Counties, in the bluegrass region of Kentucky.

The adaptation of the soil to bluegrass pasture is the distinctive natural advantage which these localities have for this type of farming. The

climatic factors, however, partly offset this advantage, especially for the production of cheese and butter. The long summer months are warm, with a lower rainfall than the winter months, while in the extensive dairy sections of Wisconsin and New York the highest rainfall is during the summer months which average 7 to 8 degrees F. cooler than in Kentucky. These adverse conditions have not interfered with the increased production of market milk where there is a demand at good prices, but they are a handicap, especially in the production of cheese, which is produced to best advantage in a climate that is relatively cool.

*Receipts from Dairy Products, together with Labour Incomes of Each of Ten Farms.*—The business of each of the 10 farms studied may be summarized briefly as follows:—

TABLE I. — *Size of farms, with number of cows and with receipts from labour income and dairy products.*

Farm No.	Size of farm acres	Number of cows	Labour Income	Gross receipts from milk	Receipts from cream	Receipts from butter	Gross receipts per cow	Receipts from dairy	Receipts from tobacco
1 . . .	400	75	\$ 1 466	\$ 5 315	\$ 2101	—	\$ 98.88	% 80	% 10
2 . . .	290	30	3 654	4 500	—	—	150.00	67	13
3 . . .	247	19	1 739	3 066	730	—	199.78	82	2
4 . . .	150	50	6 408	6 768	1128	\$ 25	158.00	72	0
5 . . .	51	15	3 201	2 920	225	260	227.00	85	9

9 . . .	134	12	287	—	624	—	52.00	49	15
10 . . .	120	12	— 1 521	—	104	780	73.60	51	0
Total Average	163	27	* 1 773	2 561	689	106	126.16	71	5.8

The market price of milk distributed to customers ranged from 7 to 10 cents per quart, and cream 60 cents to \$ 1 per gallon. When the milk was re-tailed in larger cities through local distributors the farmer received 15 to 20 cents per gallon and paid 1 ½ to 2 cents per gallon to ship it 30 to 50 miles.

The labour incomes on most of the farms were large as compared with those of successful farms of other types in this region. The average labour income on 187 farms was \$ 750, while the average of these ten dairy farms was \$ 1 773. On the ten farms studied those which sold market milk and which had high receipts per cow made the largest labour income.

*Seven Successful Dairy Farms Analyzed and Compared.* Table II shows the capital invested and the receipts and expenses on seven successful dairy farms.

(1) Animal unit — the equivalent of 1 cow, horse, or beef animal; 2 heifers, 4 calves, 7 sheep, 5 hogs, 14 pigs, or 100 chickens are counted as equivalent to an animal unit.

(2) Total capital includes investment in land, buildings, machinery, live stock, feed supplies, and cash to run the business.

(3) Working capital includes all items of capital except land, buildings, and other improvements usually included in real estate.

(4) Expenses include a charge for unpaid family labour, depreciation, and 5 per cent interest on total capital besides money actually paid out in conducting the farm business.

(5) Farm income is the total receipts less expenses.

(6) Labour income is farm income less 5 per cent interest on invested capital.

Farm 1 is the largest of the ten in question and is valued at \$ 125 per acre. It is well situated near a market point. While it is somewhat rolling the soil is of good quality and nearly all of it tillable. If properly organized, this farm should have made the largest labour income of the group; instead it is among the lowest of those which were only fairly successful. In the first place receipts per cow are low as compared with those of the more successful farms. Half this acreage could easily be made to support this herd. With a higher degree of diversity and by handling other live stock, the gross income of this farm should be increased considerably without much more expense. The average expenses of the ten farms are about 45 per cent. of the receipts, while on this farm they are about 75 %, showing that the business was too expensive for the income received. This farmer housed his cows in a \$ 7 000 dairy barn, an investment of nearly \$ 100 per cow, while his nearest competitor, one of the most successful farmers of the group, had but one third of this amount invested. This farm, although large, failed to produce as much feed for dairy stock as the average farm (\$ 18) and expended for purchased feeds \$ 20 per cow.

Farm 2 is one of the most efficiently organized larger sized farms. The diversity is much larger than that of farm No. 1. About 46 per cent of the receipts were from sources other than dairying, mainly wheat and tobacco. Sales of live stock amounted to \$ 1 200 above purchases.

The operator owned 132 acres and rented 158 additional ones for which he paid \$ 800 a year. All the feed except concentrates was raised on the farm. Only one man was hired, the operator and his family doing most of the dairy work; 33 acres of maize for grain, 12 acres of silage maize, 50 acres of wheat, 25 acres of meadow hay and 5 acres of tobacco were raised, by his own and hired labour; 11 acres of tobacco and 10 acres of maize were raised by a cropper.

Farm 3 had 10 acres of maize for grain, 8 acres for silage, 10 acres in rye which was grazed, and 20 acres in hay. There were 153 acres in pasture, 2 acres in garden and orchard, and the remainder, 44 acres, was considered waste land. The topography was hilly and not well adapted to cultivated crops. The land was valued at \$ 40 per acre, though the more level land in the community was valued at \$ 100 to \$ 150 per acre. Three year-hands were employed on this farm and seven head of work stock were kept. Both man-labour and horse-labour were poorly utilized. A better utilization could have been achieved and the income considerably increased if a few acres of tobacco had been raised. There were no receipts from crops and diversity was low.

Farm 4 may be classed as the best dairy farm of the ten. While the receipts per cow were considerably above the average, others had higher receipts per cow, but in the expenses this farm showed high efficiency in the economy of the labour and feed, two most important factors. Operating expenses were only about 35 per cent of receipts as compared with 45 per cent, the average for the ten farms. The land area (150 acres) was small as compared with the number of stock units kept on the farm. These numbered 98, or about 1.9 acres for each animal unit. Of this number of animal units 50 were dairy cows. The food purchased amounted to about \$ 10 per cow. About 50 per cent of the farm area is in bluegrass pasture. About \$ 1 000 of the total receipts represented breeding fees. During the last two years (1915-1916) hemp has been substituted for tobacco, and yields 1 700 lbs per acre which, at 10 cents per pound, represents \$ 170 per acre. The expense of growing an acre of hemp is about the same as that of tobacco (\$ 50 to \$ 60 exclusive of rent), and the average rent for the land is figured at \$ 30 to \$ 50 per acre. This farm, operated by a graduate of an agricultural college, is rated among the best dairy farms in the State. The work of milking, bottling and distributing is done by the operator with the help of a man and a boy.

Farm 5 shows the possibility of profitable dairying on a small farm with a small amount of capital invested on which almost all the labour is done by the operator and his family. Operating expenses were but 33 % of receipts and the labour income was among the highest of the group. The receipts per cow were unusually high and allowed an expense of \$ 25 per cow for purchased feed. This farm produced \$ 500 of tobacco on 3 ½ acres, \$ 80 of poultry and \$ 115 of increase in value on colts raised. The farmer owns 40 acres and rents 11 acres in addition for hay; 25 acres are devoted to permanent bluegrass pasture.

Farm 6 was only moderately successful. Profits could have been in-

creased greatly if the business had been made larger by increasing the income from cows. If the operator had hired a man he could have increased his herd to 20 or 25 cows and besides could have raised 5 to 6 acres of tobacco instead of 2. There were no receipts from hogs and only \$75 worth of skim milk was sold.

Farm 7 was operated by a tenant who had a half interest in the working capital of the farm. Business expenses were shared equally, as were also receipts. The tenant with the help of two year-hands and some extra labour, performed the work; 45 acres of the farm were in maize for silage, 33 acres in pasture, 2 acres waste and 1 acre for garden. Receipts from sources other than dairy cows were mainly from young stock. There were no receipts from crops.

*The Farms that Failed.* — The three unprofitable farms of the ten were inefficiently organized and operated. Apparently these farmers depended mainly on dairy products for an income, but each was operating a small-sized business on a fair-sized farm. It does not pay a farmer to give special attention to the dairy business unless there is a sufficient number of cows to warrant special equipment, the application of most of his time, and the development and maintenance of a profitable market.

*Comparison of the Seven More Successful Dairy Farms with the Average of Ten.*—Table III compares the average of the seven successful dairy farms with the average of the whole group, with respect to the more essential factors.

*Comparison of the Seven More Successful Dairy Farms with  
the Average of Ten.*

	<hr/> Per cent, net earnings on investment	<hr/> 10
		14

These comparisons illustrate many of the points discussed for the different farms. For instance, the average successful farm had the largest business, as shown by the size of farm, the number of dairy cows, and the working capital. On the average successful farm there were more receipts from crops and miscellaneous sources than were shown for the average of the ten farms. The most important comparison is that shown for the receipts per cow: \$ 164 on the average of the successful farms and \$ 126 on the average of the whole group.

### AGRICULTURAL INDUSTRIES.

INDUSTRIES  
DEPENDENT  
ON PLANT  
PRODUCTS

684 - **Wine Making With Foxy Grapes** (1) — CADORET, ARTHUR, in *Le Progrès agricole et viticole*, Year XXXV, No. 12, pp. 274-275. Montpellier, March 24, 1918.

A method is described (derived from the work of the late Prof. BOUFFARD and of PIERRE ANDIEUX and used for about 15 years by an agricultural syndicate) by which the foxy flavour of Clinton wine may be removed. The process consists of: —

- 1) harvesting shortly before complete maturity;
- 2) fermentation for 24 hours;
- 3) treatment with 9 gm. of sulphite for red wines;
- 4) strengthening for 2 or 3 days.

The method is still more satisfactory if the selected or natural yeasts of the country are utilised in combination with the sulphurous acid.

Quite recently the author obtained good results with Noah grapes which had not been treated in the vat by the following method: —

- 1) treatment with 1 % of oil;
- 2) repeated stirring for 48 hours;
- 3) decanting;
- 4) filtration through wood charcoal;
- 5) clarifying with 1 % unskimmed milk.

He intends to adopt the first method with his Noah grapes at the next harvest, and believes he will thus free them from all foxy flavour.

(1) Cf. R. May, 1916, No. 555 and Feb., 1917, No. 183. (Ed.)

685 — **Cupreous White Wines with Extreme Delayed Thickening.** — CARLES, P., in the *Annales des Falsifications et des Fraudes*, Year XI, No III-III, pp. 43-48 Paris, January-February, 1918.

For about twelve years there have been brought from time to time to oenological chemists, white wines of strange appearance, bad keeping qualities and, sometimes, doubtful hygienic value. These wines show nothing abnormal during the time they are treated as usual in the casks, but turn leaden when bottled, then become gradually thicker till they are eventually unsaleable. The rate of the thickening ("louche") varies according to the season and the composition of the wine, and is more rapid in proportion as the weather is hotter and there is less air between the liquid and the cork. Thickening stops suddenly when the wine come into contact with the air by being poured into a cooler, or if a few drops of hydrogen peroxide are added, and may be stopped from one day to another simply by removing the cork and leaving the bottle standing up. If the wine is poured back into a corked bottle the thickness reappears, though, beyond a certain limit, this re-starting is no longer possible. These phenomena are obviously due to a chemical reducing agent and an oxidising agent both acting on an unknown factor the proportions of which are minimum, as is very evident.

Wines behaving in this manner have the ordinary composition of white wines, but contain a few grams of fruit sugar, and are relatively rich in sulphurous acid; they are white wines sweetened by a sweeter one or with sugar and treated with sulphurous acid (anti-ferment). It is the small amount of sugar which is the principal reducing agent.

The unknown factor is copper, and the precipitate is red oxide of copper, caused by reduction by the grape sugar and sulphurous acid. There is no doubt that at least part of this copper comes from anti-cryptogamic sprays the bases of which are copper salts. Wines subjected to mutage contain very little tannin and their degree of acidity, sugar content and newness, in general, do not help to free them from metals. They thus take up the copper with which the grapes have been treated and keep it to an excessive extent.

There are many ways of testing whether white wines will thicken late. The method given is based on the capacity of tannin to make the copper dissolved in the wine insoluble and the capacity casein then has to remove the copper tannate in the lees.

Into 1 litre of wine is poured 1 cc. of  $\frac{1}{10}$  clear solution of tannin, or 0.10 gm. The whole is mixed and, after a few minutes, 10 cc. of skim milk are added (or, per hectolitre, 10 gm. of pure tannin and 1 litre of skim milk at the most). The mixture is well shaken, left for at least 24 hrs., then filtered. If copper is present it is contained in the deposit. The liquid is filtered, air-dried, and burnt. It is easy to dissolve everything in the ash with hydrochloric acid and to separate the copper by simply filtering with an excess of ammonia. The estimations may be made electrolytically or colorimetrically, since the original quantity was 1 litre.

In order to make sure that the treated wine no longer contains copper the clarified litre is evaporated in a porcelain dish, a little acid magnesium

nitrate added, and the residue burnt ; this may be done easily and completely with successive additions of fresh dilute nitric acid. It is essential to burn even the very smallest particles of carbon. The process is then continued as described above with hydrochloric acid, ammonia in excess, etc., or by any other method for separating copper from an inorganic mixture.

From an hygienic point of view, the amount of crystallised copper sulphate contained in such wines — according to the author, 0.015 gm. per litre — if taken at meals by healthy adults is not injurious to the health, but may be so if drunk between meal times. Invalids, old people and those suffering from liver complaints should not use these wines as a daily drink, the more so as similar quantities of copper may be contained in certain chocolates and even in native dwarf beans. In such cases, however, the consumption in weight of food is less than in the case of wine, and the food is not taken daily, with all meals, and between meals, as is wine. Finally there is no doubt that, by passing through the roots of the cacao tree and bean plant, the copper has been made innocuous, but this is not so with wines because the greater part of the copper has been deposited on the grape in the form of copper mixture and is found in this state in the must.

686 — **The Mycoderms of Wine.** — DE ROSSI, G., in *Le Stazioni sperimentali agrarie italiane*, Vol. IV, Pt. 11-12, pp. 529-562, Bibliography of 20 publications, 2 Pl. with 15 Fig. Modena, 1917.

The author has found at least 4 different species of mycoderms capable of acidifying wine, each with clearly different physiological aptitudes. These species are : — *Mycoderma vini*, which causes a very weak consumption of both the alcohol and the total acidity of the wine, while it does not produce volatile acids in sufficient quantity to influence the organoleptic properties ; *M. acidificans* which produces a large amount of volatile acids and thus even seriously changes the wine ; it ceases growth at 32-33° C. ; *M. duplex* and *M. tenax*, much more suited than the others to live in an acid medium, attack the acids very actively at a temperature above 15° C., but not destroying the alcohol vigorously ; *M. duplex* grows well in the presence of 9-10 % alcohol ; *M. tenax*, on the contrary, cannot support more than 4 to 5 % of alcohol.

687 — **Cement Vats.** — MATHIEU, L., in the *Revue de Viticulture*, Year XXV, Vol. XLVIII, No. 1241, pp. 230-233. Paris, April 11, 1918.

Owing to the war there is a shortage of casks, and it has been necessary to use all sorts of second-hand barrels, which sometimes give the wine a foreign taste ; in some cases cement vats are used and the question has arisen as to whether such vats are as serviceable as those of wood. The vat may be used for two distinct purposes — for fermentation, in which case the wine only remains in it during the process, or for storing the wine.

The material of which the sides are made, if well fired, can have no influence even on the finest wines, during the few days fermentation lasts.

For keeping wine, however, the wood is of great importance, so much so that for certain choice wines new oak of good quality is absolutely necessary for the long fermentation of white wines and for keeping the wine

after the first tunning. New oak imparts to the wine a taste due to its soluble substances, so that the use of choice oak has become necessary, as it is also for refining the alcohols of wine.

Oak chips, which would give up their useful substances, can be added to wine in a cement vat. Small wooden casks are, however, favourable to slow oxidation by reason of their porosity, thinness, and the large surface in contact with the air. From this point of view cement vats would be more suitable for wines the aging of which should be retarded, as oxidation is the essential factor of this process. The impermeability of the sides of cement vats to oxygen may be counteracted by periodical injections of air into the wine, which may then be left to oxidise.

Great care must be taken with choice wines, and no modification in the method of making or keeping them should be introduced till repeated tests have shown that the taste will not be modified thereby.

Cement vats should have no cracks, and the sides, joints, iron-work of the cover, and pipe connections (if red copper or bronze are replaced by brass) must not be subject to attack by acids. The absence of cracks results from the composition of the material used, which must be resistant to all surface contraction. Resistance to the acids of the wine may be obtained by direct treatment of the cement with tartaric, sulphuric solutions or silicate, by lining with glass, etc.; the joints also should be treated.

Another danger of cement vats for keeping wine in summer is the formation by drops in temperature of a free surface which may give rise to an excess of air and acetification; as acetic acid is denser than wine it diffuses rapidly. This may be prevented by a slanting bottom, but preventative measures are often useful.

**688 — A Method for the Separation of Protein from Non-Protein Nitrogen in Wheat Flour.** — BLISH, M. J. (Montana Agricultural Experiment Station, Bozeman), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 3, pp. 551-559 + 2 Tables. Baltimore, 1917.

Previous to investigating the biochemical changes in frosted wheat, and their relation to bread-making value, and in order to study the effect of premature freezing on the nitrogen compounds of the wheat kernel, the author found it desirable to develop a satisfactory method for the separation of protein from non-protein nitrogen in wheat flour.

None of the separation methods used for biological products seem to be satisfactory for use with cereals, since these contain alcohol-soluble proteins that do not occur in any other plant or animal tissues. Reagents ordinarily used for precipitating proteins, such as alcohol, acetic acid, trichloroacetic acid, colloidal iron, phosphotungstic acid, tannic acid, etc., are unsatisfactory for removing gliadin from water extracts of flour. The method of RITTHAUSEN (1872), which consisted in alternately adding to the protein in solution dilute copper sulphate and potassium hydroxide until the copper precipitate would no longer dissolve, was found to be the best available by OSBORNE and LEAVENWORTH in their researches on copper-protein compounds; the value of the method can be seen by comparing the

amounts of total nitrogen not precipitated found by using 50 cc. portions of extract :— colloidal iron method (at room temperature), 0.00266 gm.; same method, at boiling temperature, 0.003 gm.; phosphotungstic acid method, 0.0010 gm.; tannic acid method, 0.0012 gm.; copper sulphate method, 0.0008 gm.

The following details of the copper method as used on flour extracts are given below :— 1) *proportion of flour to water in the extract* : the best is 20 parts of distilled water saturated with toluene to 1 part of flour ; 2) *duration of the extraction* : the quantity of nitrogen found in different extracts was the same for extractions lasting 2, 3, 4, 5, 6, and 12 hours respectively ; a minimum extraction period of 2 hours (during which the extract is shaken vigorously every 15 minutes) was adopted ; 3) after filtering the extract, the proteins are precipitated by treating 50 cc. of the filtrate with 15 cc. of N/10 NaOH, followed by 16 cc. of N/10  $\text{CuSO}_4$ . The amount of  $\text{Cu SO}_4$  used should be slightly greater than the equivalent quantity of NaOH. The nitrogen content can be afterwards determined in the filtrate separated from the cupric precipitate by the usual Kjeldahl method and the amino-acids by Van Slyke's microchemical method.

The effectiveness of the test was examined by ascertaining the chemical nature of the nitrogen compounds that remained in solution after the copper proteins precipitation, and it was concluded that the *true proteins were almost completely precipitated* ; only (and other authors confirm this), traces of peptide linkings still remain in solution.

Normal patent flour contains but about 2 mgm. of amino-acid nitrogen for every 100 gm. of flour, and about 3 times as much nitrogen in free acid amide form.

There is probably a considerable amount of *non-protein nitrogen* not precipitated by the copper method which is neither amino-acid nitrogen nor is it in the form of peptide complexes ; its nature is not known.

659 — The Milling Value of the Wheats "Aurore" and "Blé des Alliés". — See No. 650 of this Review

691 — A Comparison of Linseed Oil and Lumbang Oil as Paint Vehicles. — AGUILAR, R. H., in *The Philippine Journal of Science*, Vol. XII, Sec. A, No. 5, pp. 235-243 : Fig. Manila, September 1917.

"Lumbang bato" (*Aleurites moluccana*) is of very wide geographic distribution extending from India through Malaya to Polynesia. In the Philippines it is common and widely distributed both as a native and as a semicultivated tree. "Lumbang banucalag" (*A. trisperma*) is confined to the Philippine Islands and less common than the preceding species. The seed of *A. moluccana* yields from 60 to 65 per cent oil by extraction with solvents and 55 per cent by hydraulic expression at 500 kg. per square centimetre ; the seed of *A. trisperma* yields about 43 per cent by hydraulic ex-

pression at 310 kg per square centimetre. (The per cents are calculated on the kernel weight).

The lumbang oils are possible substitutes for linseed oil, and they have been much studied, but little has been reported concerning their behavior with different pigments or the quality of the resulting paints. For this reason the author carried out a series of tests on the properties of linseed, lumbang bato and lumbang banucalag oils described in the article under consideration, experiments which gave the following results:—

The drying properties of lumbang bato and lumbang banucalag oil are comparable with those of linseed oil.

Lumbang bato oil is very similar to linseed oil in its properties as a paint vehicle, and like linseed has certain disadvantages for use in red paints.

Lumbang banucalag oil cannot be used as a paint vehicle, especially with red lead; it dries into a paste. This is also true with lumbang bato containing 75 and 90 per cent lumbang banucalag. Lumbang banucalag containing between 50 and 75 per cent lumbang bato will make a good vehicle for red lead.

692 - The Use of *Bacillus felsineus* in Retting Various Textile Plants (1). — CARBONE, D., in the *Bollettino di Studi ed Informazioni del R. Giardino coloniale di Palermo*, Vol. IV, Pt. 1-2, pp. 3-9. Palermo, 1917.

The author has found that *Bacillus felsineus* rets the following textile plants:— nettle; ramie (*Boehmeria nivea*); Spanish broom (*Spartium junceum*); *Agave americana*, *A. Zapupe*, *A. sisalana*, *A. Candelabrum*, *A. yuccaeifolia*, *A. Rumphii*; *Furcraea gigantea*, *F. altissima*; *Sansevieria cylindrica*, *S. zeylanica*; *Yucca gloriosa*; *Sphaeralcea angustifolia*, *Grevia oppositifolia*, *G. orientalis*, *Sida Avicennae*; mallow; bark of mulberry branches; Jerusalem artichoke tubers.

693 - The Protein of Cow's Milk. — OSBORNE, T. B. and WAKEMAN, A. J., with the Collaboration of LEAVENWORTH, C. S. and NOLAN, O. L., (Connecticut Agricultural Experiment Station, New Haven), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 1, pp. 7-17, No. 2, pp. 243-251. Baltimore, January and February, 1918.

In all attempts to discover the nature of the water-soluble vitamins in milk it is essential to know the properties and proportion of protein that remains in solution after removing the casein and heat coagulable proteins. This question was very thoroughly studied by the authors. They separated: 1) *lactalbumin*, the composition of which, when ash- and moisture-free, after drying at 110° C., was:— C, 52.51; H, 7.10; N, 15.43; S, 1.92; P, traces; O, 23.04; it was present at the rate of about 2.4 gm. per litre of the original whole milk; 2) *lactoglobulin*, present at the rate of about 0.2 gm. per litre of original whole milk and with the following composition:— C, 51.88; H, 6.96; N, 15.44; S, 0.86; P, 0.24; O, 24.62; 3) an *alcohol soluble protein*,

INDUSTRIES  
DEPENDENT  
ON ANIMAL  
PRODUCTS

(1) See R., October 1917, No. 956. (Ed.)

obtained from the alcoholic washings of the casein precipitate and present in very small amount.

Long and repeated attempts to find if there are any *proteoses* present in the milk, gave no definite results.

SIEGFRIED obtained a product from cows' milk which he called "nucleon", and the authors have concluded that this substance is probably a mixture of uncoagulable protein and some still unidentified organic substance which yields phosphoric acid on hydrolysis.

In the second work, the authors describe their researches on the alcohol-soluble protein, which has the composition:—C, 54.91; H, 7.17; N, 15.71; S, 0.95; P, 0.08; O, 21:18. On analysis 100 gm. of the protein gives:—arginine, 2.92; histidine, 2.28; lysine, 3.98; tyrosine, 2.47. It is an acid compound and gives strong tryptophane, Millon's and buret reactions.

694 — **On the Thermo-Resistance of Non-Sporogenous Bacteria in Milk.** — GORINI, C., in *Reale Istituto lombardo di Scienze e Lettere, Rendiconti*, Vol. XLVIII, Pt. 18 pp. 956-961. Milan, 1915.

A contribution to the study of the thermo-resistance of sporogenous bacteria, which emphasises the principle: — that species or races endowed with exceptional thermo-resistance should be accepted with great caution and it must be ascertained whether such a property is really a character that is *permanent and common* to the generality or at least to the majority of the individuals of a given race of bacteria or whether, on the contrary, it is a case of a protective influence similar to that found by the author in milk. In fact, the author's researches on the survival of non-sporogenous bacteria in sterilised milk, show that it is due, not to the existence of species or races having exceptional thermo-resistance, but rather to the protecting influence of caseous envelopes that form round the organism, apparently due to the life-activity of the germs themselves before and after sterilisation.

695 — **New Contribution to the Commercial Sterilisation of Milk.** — GORINI C., in *Rendiconti del Reale Istituto Lombardo di Scienze e Lettere*, Series II, Vol. LI, Pt. 1-2, pp. 135-140 Milan, 1918.

The sterilisation of milk has already passed through two successive phases of technical progress. The first succeeded in preserving the milk from *rapid and violent changes*, the second from *retarded and slow changes*. By his present studies the author proves that if it be possible to say that this latter problem has been satisfactorily solved by means of improvements in technical methods, there remains yet a third, and perhaps final, obstacle to be overcome. This is the *insidious change* of sterilised milk which can be recognised only after the vessel has been opened and by heating. This change differs from the others in that it is often very difficult to ascertain the bacterial cause, so that mistakes may be made by attributing it to a purely chemical cause.

It is caused by the "acid-rennet producing" bacteria proved by the author to be present in the cow's udder, especially under conditions of in

flammation, even when physiological, because the bacteria survive sterilisation owing to protective coverings which form in the udder or during heating. Moreover the milk may leave the udder containing already enough of this "rennet" enzyme to undergo the insidious change in question by the sole effect of heating even if the organisms are largely dead or inactive. Finally this change differs from the others in that preventative measures cannot be adopted against it in the dairy; they must be applied directly in the *shippon and on the dairy cows*. Methods must be used which will inhibit the abnormal development of the bacterial flora of the udder (careful and complete milking, discarding of the first streams of milk, exclusion of all milk left stagnant in the udder or from inflamed udders even under slight, temporary physiological conditions, etc.) and *dairy cows should be selected according to the bacterial flora of the udder*, as proposed by the author in a previous paper (1). If these principles, as has been the case with the previous ones, are adopted practically in the industry, the remaining difficulties attending the sterilisation and preservation of either sterilised or condensed milk may be eliminated.

696 — **The Composition and Market Qualities of Butter when Corn Silage is Fed with Cottonseed Meal.** — PALMER, L. S. and CROCKETT, D. T., in the *Journal of Dairy Science*, Vol. I, No. 3, pp. 235-245. Baltimore, September, 1917.

One of the most important facts brought out in a recent bulletin (2) regarding the effects which the feeding of cottonseed products exerts upon the composition and properties of butter, was the tendency for certain roughages to counteract in large measure the usual results which follow the use of cottonseed meal. Attention was directed particularly to the counteracting influence of corn silage, but a somewhat limited amount of data were presented by ECKLES and PALMER with regard to the extent to which corn silage counteracts the peculiar market qualities of cottonseed meal butter, just described. As this phase of the question is of considerable practical importance, a more extended study of this point was made by the writers and the results of their experiments are here presented.

Twelve pure-bred cows were selected from the University herd and divided into two groups of six cows each.

The general plan of the experiment, together with the average ration consumed by each group in each period, and the duration of each period is shown in Table I.

(1) GORINI, C., *Rend. R. Ist. Lomb. Sc. Lett.*, 49, 1916.

(2) ECKLES, C. H. and PALMER, L. S.: *Effects of Feeding Cottonseed Products on the Composition and Properties of Butter*. Missouri Agr. Exp. Station Research Bulletin 27, pp. 44, Figures 3, 1916. See R., July, 1917, No. 651. (Ed.)

TABLE I. — *Plan of experiment and average ration consumed in each period,*

Period	Date	Group I.		Group II.	
1	Nov. 5 to Nov. 23, 1916	Silage	lb. 29	Silage	lb. 28
		Hay (1)	9	Hay	9
		Grain (2)	8	Grain	9
2	Nov. 23 to Dec. 15	Silage	29	Silage	18
		Hay	9	Hay	7
		Grain	6	Cottonseed meal	3
		Cottonseed meal	3		
3	Dec. 15, 1916 to Jan. 1, 1917	Silage	29	Hay	18
		Hay	9	Grain	4
		Grain	4	Cottonseed meal	5
		Cottonseed meal	5		
4	Jan. 1 to Jan. 21	Silage	29	Silage	28
		Hay	9	Hay	10
		Grain	7	Grain	9

(1) The hay fed to both groups throughout the entire experiment was a mixture of equal parts alfalfa and timothy.

(2) The grain fed to both groups throughout the entire experiment was a mixture of maize meal two parts, distillers grains one part, wheat bran one part.

### *Results of experiment.*

*Composition of butter.* — An examination of the figures given for the analyses of the different churnings of butter for moisture, fat, curd, ash and salt shows no differences in the composition of the different samples of butter which can be attributed to the changes in the ration.

*Score of butter.* — On examining the data concerning the market quality of the various samples of butter, as shown by the usual method of scoring, it is seen that all the samples of butter were of good quality, the only defect from a commercial point of view being in flavour. Certain slight defects in body were noted in some cases but these were not sufficiently pronounced to lead to a deduction in the score. For example, the butter from three of the churnings of period 2 was characterized as hard and brittle; similarly the body of both churnings of group I in period 3 was stated to be hard, although not objectionably so, while no note was made with regard to the body of either churning from group II in this period. With regard to the oily flavour which frequently characterizes cottonseed meal butter, this was noticed only in the case of the two churnings from group I in period 3.

The results of these experiments on the market qualities of the butter may be, therefore, summarized as follows :

1) Cottonseed meal, when fed in quantities of 3 to 5 pounds imparted a slight oily flavour and harder body to the butter, but these defects were not sufficiently pronounced to detract materially from the market value of the butter.

2) The effects of the cottonseed meal feeding were fully as pronounced when fed with maize silage, as when a mixture of alfalfa and timothy hay constituted the only roughage.

*Keeping quality of butter.* — Previous experiments have been uniform in showing that butter made when cottonseed meal forms a part of the ration retains its original flavour appreciably longer than when no cottonseed meal is fed. The general result of the study was to confirm the former results showing a superior keeping quality of butter made on a cottonseed meal ration over that made when the ration contains no cottonseed meal. The feeding of cottonseed meal materially retarded the rate of deterioration of butter kept at 8° to 12° C. This effect was secured when the cottonseed meal was fed with maize silage as well as when it was fed with hay.

*Chemical and physical constants of butter fat.* — The results of the analyses of the butter fat are shown in Table II.

TABLE II. *Chemical and physical constants of butter fat on different rations.*

Period	Group	Saponification Value	Reichert-Meissl Number	Iodine-Value Hubl	Melting Point °C	Standing-up Temperature °C
1	I	234.9	31.66	28.10	32.90	34
2	I	232.9	30.95	29.01	34.18	34-35
3	I	233.4	31.03	28.88	34.10	35-36
4	I	232.2	29.63	30.22	33.03	34
1	II	236.8	33.27	29.70	32.38	33
2	II	229.2	29.63	34.69	34.35	34-35
3	II	227.4	30.01	34.42	33.98	35-36
4	II	232.5	30.73	32.11	32.45	33

Abnormally high saponification and Reichert-Meissl values and an abnormally low iodine value are the striking features of the fat constants during liberal silage feeding. The melting point of the fat was increased slightly by the cottonseed meal in periods 2 and 3, and this effect was also noticed in the increased standing-up temperature of the butter.

Very different results characterized the feeding of the cottonseed meal in periods 2 and 3 in the case of group II, in which the roughage was also changed to one of hay only. A marked depression of the saponification and Reichert-Meissl value and increase in the iodine value and melting point characterized the fat constants in these periods in comparison with the constants of the fat in the basal periods. The standing-up temperature of the butter was also increased. Such effects are characteristic of cottonseed meal feeding when dry roughage is fed.

One or two other features of the data in Table 2 may be mentioned. It is noticed that the fat constants of group II were not abnormal in any of the periods, even in period 3 when 5 pounds of cottonseed meal were fed with a dry roughage of hay only. These results are probably due, in part at least, to the fact that the fat constants were already abnormal in the opposite direction from those which usually characterize cottonseed meal feeding, when the ration was changed to include the cottonseed meal. Another feature of the data was that no greater effects were secured when 5 pounds of meal were fed to group II than when 3 pounds were fed.

Very great difficulty is also experienced in attempting to explain why the addition of cottonseed meal to a ration containing of a liberal portion

of silage fails to affect any of the fat constants except the melting point of the butter fat. The results of the present experiment on the chemical and physical constants of butter fat may be summarized as follows : —

The liberal use of maize silage in a ration counteracted all the effects which 5 pounds of cottonseed meal usually exert upon the chemical constants of butter fat in that the addition of the cottonseed meal to a ration containing a liberal amount of maize silage was without effect upon the fat constants.

697 — **The Determination of Fat in Certain Milk Products.** — FRANCIS, C. K. AND MORGAN, D. G., in the *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station Bulletin No. 114*, pp. 1-4. Stillwater, Oklahoma, April, 1917.

A method for determining fat, including treatment of the samples, in such dairy products as ice cream (requiring 14 % fat content by law), evaporated milk, malted milk, dried skim-milk and similar milk products, is described. The procedure is similar to that followed when using the Babcock test, but in place of sulphuric acid, mixtures of glacial acetic, sulphuric and nitric acids are prescribed. The fat is separated and read in a Babcock bottle.

698 — **Wool Studies. — Washing Sheep Before Shearing; Time of Shearing.** — HAMMOND, J. W., in the *Ohio Agricultural Experiment Station Bulletin No. 294*, pp. 309-322. Wooster, Ohio, April, 1917.

This experiment was undertaken for the purpose of securing data on the following points :— 1) The influence of washing sheep on the yield of grease and of scoured wool and on the rate of gain made by the sheep ; and 2) the influence of the time of shearing on the yields of grease and scoured wool and on the rate of gain made by the sheep.

*Plan of the Experiment.* — One hundred lambs, practically purebred Merinos, born in 1910, were divided into four lots as nearly alike as possible with respect to sex, weight and conformation. The experiment extended over a little more than 2 years, so that during its progress three clips of wool were removed.

The treatment of the lots with respect to washing and time of shearing was as follows :—

*Lot 1:* Washed; shorn about April 12.

*Lot 2:* Unwashed; shorn about April 12.

*Lot 3:* Washed; shorn about June 1.

*Lot 4:* Unwashed; shorn about June 1.

*Washing and shearing.* The sheep were washed by hand in a stream 7 to 10 days before shearing with power-driven clippers.

*Scouring the wool.* — The scouring was done by the emulsion process, similar to that used commercially. The wool was put through three scouring liquors containing potash, soap and potassium carbonate of gradually diminishing strength, and finally through a rinse of clear warm water. The wool was dried to a constant weight at a temperature of 150° F. both before and after scouring to overcome any differences in moisture content.

From the results presented it appears that the washed sheep produced

1.49 pounds less grease wool per head when shorn April 12, and 2.64 pounds less per head when shorn June 1, than did unwashed sheep shorn on the same dates. Washing the sheep had practically no effect on the amount of scoured wool produced or on the rate of gain made by the sheep.

Wool shorn June 1, both washed and unwashed shrank more in scouring than did wool shorn April 12.

The results of this experiment also indicate that, in many cases at least, not sufficient premium is paid for washed wool to cover the cost of washing and for the loss in weight of the wool.

Since washing sheep does not improve the quality of the wool fibre and does not diminish the cost of scouring; the practice is not beneficial to the manufacturer.

Washed sheep shorn April 12 produced more grease wool than did washed sheep shorn June 1, while unwashed sheep shorn April 12 produced less grease wool than did unwashed sheep shorn June 1. This indicates that between these two dates there was an increase in weight of fleece due to the accumulation of a greater proportion of yolk or other foreign matter in the wool. Sheep shorn April 12, both washed and unwashed produced slightly more scoured wool than did sheep shorn June 1. Sheep shorn April 12 made slightly greater gains than did sheep shorn June 1.

**699 — The Indian Hide and Leather Trade.** — LEDGARD HENRY (Late President, Upper India Chamber of Commerce), in the *Journal of the Royal Society of Arts*, Vol. LXVI, No. 3407, pp. 274-282, London, March 8, 1918.

The quality of the hides from Indian cattle is not so good as that from Argentine cattle, for, while Argentine cattle do no work, the Indian oxen are used for agricultural purposes. Moreover, on the Argentine, branding is used as a means of identification only, in India it is commonly adopted as a cure for various ailments. Fortunately the cows and female buffaloes are rarely worked, so that their hides are generally in good conditions and are even superior to those of Argentine cows. In England the hide of a slaughtered animal is worth in normal times from  $\frac{1}{12}$  to  $\frac{1}{10}$  of its total value, in India, it is worth  $\frac{1}{3}$  of the value of the animal. For this reason, when there is a large demand for hides, the cattle are often slaughtered for the value of their hides alone. The Indian hide trade is of great importance, coming fifth in the value of exports, even preceding tea.

It has been shown that as a result of the increased consumption of meat throughout the world since the war, a great shortage of hides and leather is to be anticipated in the future. It is estimated that the world's meat-producing animals have decreased as follows:— cattle, 28 080 000 head; sheep, 54 500 000 head; hogs, 32 425 000 head; or a total of 115 005 000 head. Before the war the world's supply of hides was barely sufficient, and prices were steadily rising. The above figures show, that after the war there will be a serious shortage of this product.

In those parts of India where the climate is dry the hides are simply cleaned and dried in the sun or shade. Before baling they are dipped in arsenic solution and again dried. This is considered the best method. In the

damp climate of Bengal and during the rainy season in other provinces, drying is difficult, and the hides are usually salted. This system does not always give satisfactory results. Arsenicated hides are sold by weight, salted hides by the piece after selection and classification.

The hides are divided into various classes as follows :

1) " Commissariats " ; these are the best quality hides. The name was derived from the C branded on the neck of cattle bought by the Indian Government to be fed well for about three months and then slaughtered to supply the army with meat. Although this practice has long ceased the term remains and indicates the highest grade of hide ;

2) " Slaughtered ", a term applied to the hides of animals which have been slaughtered to distinguish them from those which have died naturally ; they are the second grade ;

3) " Deads ", the third grade ;

4) " Rejections ", the lowest grade.

These terms are still in use on the chief markets of India.

There are several varieties of goatskins in India. The best, known as " Patnas ", are from the province of Behar, and are excellent for making glacé kid. Further east, in Dinapore, Bengal, and Eastern Bengal, the skins are larger and heavier in grain and texture but still suitable for glacé kid. In the United Provinces and Rajputana the skins are also larger and coarser than " Patnas ", and only the lighter ones can be used for glacé kid ; the heavier ones are suitable for " Moroccos ", but, unfortunately, often have many holes. In the Punjab the goatskins, known as " Amritsars ", are large, strong and heavy, well adapted to upholstery. In the south Hyderabad and Deccani skins are of fair quality and are bought by the Madras tanners.

Before the war 3 million cow, ox and calf hides were tanned in India and exported annually. At the present time this figure is doubled. The tanning industry is of great importance in India and its further expansion is to be anticipated.

The tanning process resembles that which was used in England before the introduction of labour-saving devices. Labour is plentiful in India, and the native tanners still adopt the primitive methods. In Madras and Bombay the tanning material used is the bark of *Cassia auriculata*, which grows in the jungle ; it is a shrub which grows to a height of from 6 to 8 ft., the shoots of which are cut every three or four years. It is an excellent tanning material, making the skins soft and pliable. The hides are often only partially tanned, so that the European currier has to complete the process, often improving the material thereby. At Cawnpore in the United Provinces there are some large tanneries equipped with modern machinery. The first of these factories was erected 40 years ago by the Indian Government and, in normal times, supplied the leather required by the different branches of the army. The chief tanning materials used at Cawnpore are *Acacia arabica* and *Terminalia Chebula*. The former, which is found over a wide area, is not ripe for cutting till ten or twelve years old. Up to the present these plants have not been systematically cultivated. In view of the increasing

demand for tanning material the Indian Forest Department should attempt to produce an ample supply of tanning bark, which will be very necessary in the future, but should not be left to private enterprise.

In addition to the commercial centres mentioned there are still in the villages primitive tanneries for supplying local requirements. Chrome tanning, though adopted only to a limited extent, could be greatly developed.

With reference to the export of goatskins, before the war India exported annually 20 million raw skins and 7 500 000 tanned skins. The United Kingdom purchased most of the tanned skins, about half of which were reexported to the continent, and about a third of the remainder to America.

Of the raw skins, 75 % were exported to America, 10 % to England, 7 % to France, 5 % to Holland and Belgium, and an insignificant quantity to Germany. Since the war America takes 88.5 % and English imports have dropped to 8 %.

Previous to the war 2 200 000 raw sheepskins and about 9 000 000 tanned ones were exported. America took 87 % of the raw skins in 1913-1914, and 96.5 % in 1915-1916. Of the tanned sheepskins, the United Kingdom imported 58.9 % in 1913-1914 and 64 % in 1915-1916, the United States 20.9 % in 1913-1914 and 19.8 % in 1915-1916; Japan 15 % in 1913-1914 and 11.8 % in 1915-1916.

About 160 000 tanned buffalo hides were exported to England. Of the 2 000 000 raw hides one half went to Germany, one third to the United States, and the remainder was distributed between the United Kingdom, Holland and Italy. The export of ox and cow hides reached about 11 million pieces, 3 million of which were tanned; the tanned hides went to England and the raw hides to the Continent.

Figures for the shipments of raw ox and cow hides to Europe and America are given in a table covering the period from 1872 to 1915.

700 - **The Cold-Storage Plant of Lyndiane, Senegal.** — MOUSSU, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 12, pp. 394-400. Paris, March 27, 1917.

The author reviews a study by M. J. DERRÉ who is in charge of the sanitary inspection of the plant of Lyndiane in West Africa. The installation of the Lyndiane plant in Senegal has made possible the exploitation of one of the principal natural resources, hitherto unused but sure to prove of increasing importance as a result of the abundant livestock and immense pasture lands.

To fulfill the requirements of the home country it has been necessary to make use of herds not only from Senegal but also from the whole of French West Africa. The oxen slaughtered at Lyndiane in 1916 came from Senegal, Niger, Mauritania and Guinea; these districts are in order of importance.

The livestock of different breeds from these districts, which form an immense stretch of land, is not all equally suitable for slaughtering. Owing

PRODUCTS;  
PRESERVING,  
PACKING  
TRANSPORT,  
TRADE.

to its extensive breeding and the position of its plant near the centres of production Senegal holds the first place for quality of meat. The oxen of the Zebu breed ("peuhle" variety) of the Senegalese provinces of Cayar, Baol and Sine Saloum, give a much higher yield than all the other cattle slaughtered, no matter where they come from.

Upper Senegal-Niger is the reservoir of Senegal for cattle; 4 238 oxen from the Soudan, Macina, or the north of the Niger bend were slaughtered at Lyndiane in the year 1916.

Unfortunately the remoteness of the breeding centres necessitates long journeys which cause the animals to lose flesh and thus decrease the yield, for the average weight of the stock from this district is only 596 lb. The average weight of the animals from Mauritania is 583 lb., with a yield of barely 45 %. French Guinea, a remarkable breeding centre, supplies cattle with an average weight of 506 lb. with a 47 % yield.

During 1916 the plant bought 27 350 oxen with an average weight of 537 lb. giving, when killed, a 46 % yield. This meat is exported to France in frozen quarters or as preserved, seasoned beef.

The Lyndiane installation can slaughter 200 oxen in 24 hours; this figure was reached in December and January, but has dropped to 110 on account of irregular delivery. The plant, originally built for freezing meat only, has five freezing rooms of a capacity of 200 metric tons, and five storage rooms, of a capacity of 300 metric tons. From May 1 to December 31, 1916, 13 198 quarters weighing 777 metric tons were delivered, and at the present time the storage rooms are full. The offal (heart, liver, brain, tongue, kidney) are also frozen, packed in 100 lb. cases and sent to France. The suet, intestines and bones are treated in a separate establishment. During the year 1916, 130 154 lb. of commercial suet and 5 665 lb. of edible fat were sold. The hides are treated with special care and, owing to the proximity of salt water, their preservation is assured until they are utilised in France.

It is estimated that the Lyndiane plant could deal with 30 000 cattle annually, and perhaps more. Besides the cattle, of which there are more than 5 million, there are other resources which could be profitably exploited. Experiments in pig-breeding are now being carried out at Siné-Saloum, and are likely to give good results. Already a rapid production of as much as 5 000 head a year seems likely. The variety used is related to the Spanish breed. It is very prolific and breeding will probably increase with yet greater rapidity since the cultivation of manioc has spread throughout the villages. There are very few sheep in Senegal and they are kept by the natives for their own food. Those in Mauritania and Macina are too far away from Lyndiane to be delivered in a sufficiently good condition.

Breeding, if well carried out, cannot fail to increase and improve rapidly, bringing to the colony an un hoped for income and to the home country a great simplification of the serious economic problem of its meat supply.

701 - **Enzyme Activity at the Temperatures Maintained in Cold-Stores.** — BLANCHET, A., in *Le Froid*, Year V, Vol. V, No. 1, pp. 6-9. Paris, January-March, 1917.

The investigations carried out by the author in 1913-1914 aimed at estimating the activity of certain enzymes at temperatures slightly below 0°C., generally used in the cold-storage establishments for storing products in which the action of such enzymes or others of the same group may occur.

He studied a lipase to ascertain its action at temperatures corresponding to those used in preserving butter and other fats. The enzyme examined was one existing in the cytoplasm of castor-oil seeds, which is the one best known at the present time; it was the object of a remarkable study by M. NICLOUX. The castor oil seeds were crushed in a mortar and then mixed with castor oil. The mixture was then acidified with acetic acid. The oil, seeds, and acetic acid were previously cooled during 24 hours in cold rooms.

The acidity was estimated with normal soda after the alcohol reaction had ceased. The activity of the lipase at laboratory temperature (17°C.) was also tested.

The results show definitely that, even at - 5° C, the lipase is sufficiently active to cause a fairly rapid saponification of the fats. There is, therefore, no reason why a certain number of the changes fats undergo while in cold-storage should not be attributed to the action of enzymes of this same group.

The fact that the good keeping of butter is in inverse ratio to the acidity of the cream at the time of churning confirms this hypothesis, for the action of lipases is generally favoured by a certain acidity. This was confirmed by the enzyme studied by the author as well as by the sero-lipase.

702 - **Preserving Fish without Ice.** — Abstract from the *Bulletin mensuel de la Chambre de Commerce française de New York*, in *Le Froid*, Year V, Vol. V, No. 4, pp. 157-159. Paris, October-December, 1917.

In British Colombia and in England a new method has been adopted for keeping fresh fish. As ice is no longer necessary the fish can be sold cheaper because the expense incurred through the ice is done away with. The fish keeps its flavour perfectly, and the method may be applied to either fresh or smoked fish, and even to meat.

The whole procedure lasts only three hours. The fish is first placed in a cooling tank containing water at a low temperature. After half an hour the latent heat of the fish has completely disappeared. The fish is then placed in a tank containing sea water or fresh water to which salt has been added. To prevent the water from freezing it is stirred by a pump which sends it into a pipe in which it passes through a filter filled with willow charcoal which kills all bacteria and then passes out again. The extremely cold temperature of the salt solution closes the pores of the skin of the fish, prevents saturation and acts on the exterior as a disinfectant. At the end of three hours the fish is taken out and has the appearance of fresh fish. There is no danger of its going bad for 10 days and it may be kept for months in a cold room. A plant has been set up in Portugal for preserving fresh fish by this method. According to the English engineers who installed the plant the fish keeps fresh and in excellent condition

for about 15 days, even at a variable temperature. The flavour is that of fresh fish. It does not go soft like fish kept in ice, and may be smoked after having been treated. The method is highly recommended by the inspector of the Dominion fisheries.

M. A. CLIGNY, Director of the Marine Station of Boulogne-sur-Mer, France, believes the method to be of the greatest value. It includes two independent parts, the first of which appears the more original, and may be called pre-refrigeration. It is always advisable to wash fish before any freezing procedure, and it would be excellent to wash it in very cold water which would bring it to a temperature of about 0°C. This is an important improvement on the expensive and defective method of covering it with ice or laying it out in cold and relatively large stores for a period of time which must of necessity be very long. Pre-refrigeration by thorough washing in very cold water could be carried out advantageously in fishing boats. It might be of great importance in the mixed installations, proposed by M. CLIGNY for fishing boats (1) in which the use of ice plays its essential part.

The second part of the method consists in freezing the fish previously cooled to 0°C. This second stage may be attained by the use of ice, dry cold or, as the author proposes, soaking in cold brine.

703 - **The Supply of Canned Salmon in the United States** — BRAND, C. J. in U. S. Department of Agriculture, Office of the Secretary, Circular No. 98, pp. 1-16, Washington, D. C., February 28, 1918.

Commercial stocks of canned salmon in the United States on August 31, 1917, amounted to approximately 310 000 000 pounds. Four-ninths of these stocks were located in the State of Washington.

Nearly three-fifths of the total stocks reported were held by canners of sea food. The stocks of these concerns were practically all reported from the states of Washington, Oregon and California, the canners in the first named state reporting more than three-fourths of these holdings.

One-eighth of the total commercial stocks was held in storage warehouses. As in the case of stocks of canners, those in storage were again chiefly located in the state of Washington, this state reporting two-thirds of these stocks. The wholesale stocks, which constituted more than one-sixth of the total commercial stocks, were fairly well distributed in proportion to population. The stocks of retail dealers which constituted about one-eighth of the total, appear to bear a less close relation to population, the stocks of some of the Southern States being relatively small.

The results of the survey indicate further that the stocks of canned salmon in hand on August 31, 1917, were 18.2 per cent larger than those reported for August 31, 1916. The stocks of canners of sea food showed a marked increase, this increase being only partially offset by decreases in the stocks held in storage warehouses and by wholesalers. The stocks of retailers were practically equal in amount on the two dates.

This Bulletin gives detailed information concerning the extent and the distribution of the supply of canned salmon on the date of the survey.

## PLANT DISEASES

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

GENERAL

704 - **Myxomycetes and Fungi of Ceylon.** — FETCH, T., in *Department of Agriculture, Ceylon. Annals of the Royal Botanic Gardens, Peradeniya*, Vol. VI, Pt. 3, pp. 193-256. Colombo-London, June, 1917.

The list includes 6 myxomycetes and 235 fungi collected and identified in the island during the last few years. *Oidium* spp. has also been reported on 27 different plant hosts. Notes have previously been published on some of the species enumerated.

Among the fungi are described as new to science, 46 basidiomycetes (20 hymenomycetes, 2 gasteromycetes, 24 uredinaceae), 18 ascomycetes (all belonging to the pyrenomycetes), 52 deuteromycetes (14 representatives of the order *Sphaeropsidales*, 7 of the order *Melanconiales*, 31 of the order *Hyphales*.

There are very numerous species of fungi either new or already noted, which were found on cultivated plants or on those useful to man in some way or other.

705 - **New Japanese Fungi** (1). — TANAKA TYOZABURO, in *Mycologia*, Vol. X, No. 2, pp. 86-92, Lancaster, Pa., March, 1918.

In this, the fourth paper on the subject, are given in English the descriptions originally published by various authors in Japanese, of the following species new to science.

1) *Botrytis Liliorum* Y. Fujikuro, n. sp. (published in May, 1914); found on *Lilium longiflorum* at the Experiment Farm of Formosa (Taikazeiho, Taihokuchō) among plants from Lûchû Island. The fungus attacks especially the leaves, on which form small spots about 1 mm. in diameter which soon cover the whole leaf, causing the total decay of the host plant; the fructifications of the fungus appear on the decayed part of the plants as a fine, powdery fur.

2) *Phyllosticta (Phoma) kuwacola* K. Hara, n. sp. (May 1917) on living leaves, shoots and twigs of *Morus alba*, at Mino (Gifu-ken) and neighbouring

(1) See R., Jan., 1918, No. 182. (Ed.)

prefectures. The parasite causes the formation of leaf spots which gradually dry up; the leaves tear in dry weather and rot in wet weather. If the spots appear on the edges of the leaves semi-circular holes are often formed. Adjacent spots coalesce, forming irregular spots which often cover a large area of the leaf and cause the whole blade to decay. Young twigs are also attacked, turn brownish, and die, showing on the surface minute black pustules. Hard twigs when attacked have reddish spots which turn blackish after and sink considerably below the surface; they are rough and cracked. The disease causes the death of the upper part of the twig. The new Japanese name of the disease is "Kuwa no Rinmonbyô" (circle blotch of mulberry). Considerable damage is done every year.

3) *Septobasidium Acaciae* Sawada, n. sp. (November, 1911) on trunks and twigs of *Acacia Richii*. The typical locality is Taikoku-chô Shakuko (Formosa). The fungus has been observed on the euphorbia *Glochidion obovatum* on the Experimental Farm of the Agricultural Station of Formosa and on *Citrus* sp. at Taihoku-chô Kiirun; later (February, 1915), SAWADA reported this fungus in Formosa on *Prunus Persica*, *P. salicina*, *Thea sinensis*, *Salix glandulosa* var. *Warburgii* and *Melia Azedarach*. The attack of the fungus is closely related to that of certain scale insects and in many cases the dead insects are found surrounded by mycelial strands. The fungus sometimes kills *Acacia* trees; to control it a 30-50 % wood-ash solution is recommended.

4) *Cercospora Pini-densiflorae* Hori and Nambu, n. sp. (May, 1917) on the leaves of young *Pinus densiflora*, in the nursery of Makago, in the south of Kyushu Island. A great many young plants, mostly two years old, were fatally attacked. According to the reports the disease seems to be limited to the above mentioned locality, but it seems likely to prove serious unless controlled by treating seedlings with Bordeaux mixture.

5) *Helicobasidium Tanakae* Miyabe. This species, also given as *Stypinella Tanakae* Miyabe and *Septobasidium* sp. is very common in Japan on the trunks and branches of *Morus*, *Salix*, *Vitis*, *Juglans*, *Zanthoxylum*, *Prunus Mume*, *P. donarium* (= *P. paniculata*), *P. salicina*, *P. Armeniaca* var. *Ansu*, *Pyrus Malus*, *P. sinensis*, *Ribes Grossularia*, *Kerria japonica*, *Thea sinensis*, *Paulownia tomentosa*, *Firmiana platanifolia* (= *Sterculia platanifolia*) and *Pittosporum undulatum*; most Japanese authors who have described this species have confused it with *Septobasidium pedicellatum* (Schw.) but the real *Sept. pedicellatum* was first discovered by SAWADA in Formosa, where *Helic. Tanakae* does not appear to exist; *Sept. pedicellatum* appears to attack the mulberry only and also to differ in certain morphological characteristics.

6) *Nothopateella moricola* I. Miyake n. sp. (Dec., 1916) on twigs of *Morus alba*; typical locality, Iwate-Ken, Morioka-shi.

7) *Ustilina Mori* R. Hara n. sp. (May, 1917) on trunks of *Morus alba*; typical locality, Mino (Gifu-Ken prefecture), Kawakami-mura.

As regards *Valsa Paulowniae* Miyabe and Hemmi, the author points out that, besides the Japanese description recently translated by him into

English (1), two other descriptions of the fungus have been published by Dr. HEMMI, one of the discoverers of the species; all three descriptions are marked n. sp. The first article, published with the original description of the fungus (in English) appeared on July 31, 1916; it contains a full account in Japanese of the disease caused by the fungus, and compares it with other similar diseases. The third and last of these articles was published in English on September 20, 1916; it also describes *V. Paulowniae* in English. Dr. HEMMI notes that the fungus was first collected in Aomori-ken (N. Honshû), in August, 1913, by T. NAKAMURA and reported as a serious disease of the "kiri" tree. All three articles are important as they throw light on a very destructive disease of *Paulownia* in Japan, a disease analogous to chestnut blight in America, both in its swift destructive action and in the loss it causes of timber much valued for cabinet-making.

706 - **Fungi of the Philippine Islands** (2). — SACCARDO, P. A., in the *Atti dell' Accademia Veneto-Trentino-Istrianza*, Vol. X, pp. 57-94, Fig. Padua, 1917.

In the present fourth contribution to the mycological flora of the Philippines, the author lists 149 fungi collected and communicated as previously by Prof. C. F. BAKER.

Almost all the species enumerated come from Lucon Island and principally from the region of Los Bassos and Mount Maquiling (1098 metres high).

Four genera and 109 species, the latter belonging chiefly to the Deuteromycetes, are described as new to science.

OF PREVENTION  
AND CONTROL

709 - **Principal Diseases of Vegetables in Ontario, Canada.** — HOWITT, J. E. and JONES, D. H., in *Ontario Department of Agriculture, Ontario Agricultural College Bulletin* 258, pp. 48 + Figs. Toronto, Ont., 1918.

DISEASES  
OF VARIOUS  
CROPS

This bulletin aims at supplying growers with the information necessary for the identification of the most common bacterial and fungoid diseases. The most efficient remedies are also given.

A list is given of the diseases attacking asparagus, dwarf beans, beet, cabbages, cauliflower, carrot, celery, maize, cucumber, lettuce, melon, onion, pea, potato, pumpkin, tomato and turnip.

710 - **Lettuce Drop, Caused by *Sclerotium Liberiana*, in Florida U. S. A.** — See this *Review*, May 1918, No. 583.

(1) See *R. Oct.*, 1917, No. 965 (*Ed.*)

(2) See *B.*, Sept. 1915, No. 976 and *R.*, May 1918, No. 587. (*Ed.*)

- 711 — **Observations on the Parasitism of the Ascomycete, *Ustilina vulgaris*, in France.** — PATOUILLARD, in the *Bulletin de la Société de Pathologie végétale de France*, Vol. IV, Pt. 2, p. 100 Paris, 1917

This fungus, well known as a saprophyte, appears to have caused the death of two lime trees in Ain, by attacking them at the base at the ground-level. The two trunks were covered for a height of 8 or 12 in. with a continuous layer of fungus, save for a width of 4 in. which remained unattacked.

The wood was completely invaded by the mycelium and had become soft up to the centre of the trees, so that a simple gust of wind sufficed to blow them down. This *Ustilina* is very common on old stumps near by, both in its aecidial and conidial forms but always as a saprophyte. In the present case it is clearly a parasite.

### WEEDS AND PARASITIC FLOWERING PLANTS.

- 712 — **The Worst Weeds in Cereal Crops, in Indiana, U. S. A.** — See No. 639 of this Review.

- 713 — **The Destruction of Weeds by Sodium Bisulphate.** — *Feuille d'informations du Ministère de l'Agriculture*, Year XXIII, No. 8, p. 8 Paris, 1918.

Experiments have been undertaken in France with the object of destroying weeds among cereal crops by means of sodium bisulphate.

It was found that suitable proportions to use were: — about 80 gall. per acre of a 45 % sodium bisulphate solution (99 lb. of bisulphate dissolved in 22 gall. of water), or 360 lb. of bisulphate per acre to be treated.

Sodium bisulphate is much easier to use and requires fewer precautions than sulphuric acid, which is so often used for the same purpose.

The bisulphate is produced in large quantities by powder-works which supply farmers with 5 or 10 ton truck loads at 1½ d. per 220 lb. free on rail, put up in wooden tubs provided by the buyer.

The following powder-works can supply the bisulphate: Angoulême, Bergerac, Toulouse, Saint-Chamas, Saint-Fons, Moulin-Blanc, Vonges.

### INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

#### GENERAL

- 714 — **Hymenoptera Parasitic on Injurious Insects, in Southern Brazil.** — BRÊTHES, J., in the *Anales de la Sociedad Rural Argentina*, Year LIII, Vol. LII, No. I, pp. 7-11 + 2 Fig. Buenos Ayres, 1916.

Dr. A. Ronna has sent from Pelotas (Rio Grande do Sul) to the Biological Institute of the "Sociedad Rural Argentina" 6 hymenoptera parasitic on insects and representing 1 genus and 5 species new to science, which are described by the author. These hymenoptera are given below.

- 1) *Lytopilus melanocephalus* n. sp., parasitic on an undetermined lepidopterous larva injurious to lucerne (possibly *Colias lesbia*).
- 2) *Aphidius brasiliensis* n. sp., parasitic on aphids.
- 3) *Heptasmicra brasiliensis* n. sp., possibly parasitic on *Oiceticus*.
- 4) *Heteroscapus ronmai* n. gen. and n. sp., parasitic on the larva of an unidentified lepidopteron.
- 5) *Perissocentrus argentinac* Crawford. var. *caridei* Brêthes (1).
- 6) *Tetrastichus isis* n. sp., possibly parasitic on *Oiceticus*.

(1) See R., October 1917, No. 981. (Ed.)

715 — *Dictyothrips aegyptiacus*, a Thysanopteron Injurious to the "Black Morocco" Variety of Vine, in Cyrenaica. — ZANON, V., in *L'Agricoltura coloniale*, Year XI, 2nd Half-Year, No. 6, pp. 394-397 + 2 Plates. Florence, 1917.

At Fuehat and in other vineyards in the neighbourhood of Bengasi, the author found, during 1916 and 1917, that *Dictyothrips aegyptiacum* (Marchal) Del Guercio was present 'almost exclusively on the "Black Morocco" variety of vine ("ribier" in French, "uva damascena" in Italian) somewhat suffering from drought and grown on a trellis and kept low.

This tiny thysanopteron not only soils the foliage with its excreta which appear as scattered groups of small black points, but also pierces the leaf blade, causing the formation of discoloured areas of varying size, and eventually the drying-up of the leaves themselves.

The morphological description of the various stages of development of the insect is followed by notes on its biology.

716 — *Lonchaea aristella*, a Dipteron Injurious to the Fig Tree and the Wild Fig Tree in Italy 1. — I. SAVASTANO, L., in *Annali della R. Stazione di Agricoltura e Frutticoltura, Acireale*, Vol. IV, pp. 113-146 + 2 Pl. Acireale, 1917. — II. SILVESTRI, F., in *Bollettino del Laboratorio di Zoologia generale e applicata della R. Scuola superiore d'Agricoltura in Portici*, Vol. XII, pp. 123-146 + 19 Figs. Portici, 1917.

SAVASTANO, who was the first (in 1915) to report the presence of *Lonchaea aristella* Beck ("mosca nera del fico", black fig fly) in Italy, has continued his studies on this dipteron, injurious to the fig tree in the Sorrento peninsula, and especially in Vico Equense.

SILVESTRI made observations in the neighbourhood of Portici, near Naples, and in Cilento, and examined specimens of the insect from various Italian localities and other districts bordering on the Mediterranean (province of Porto Maurizio, Perugia, Caserta, Benevento, Bari, Lecce, Cosenza, Catania, Trapani, Palermo, Sassari, and Portugal, Spain, Corfu, Tripoli, Algeria). He recognised that the fly is a parasite which does much damage to the wild and the ordinary fig trees.

Both authors give much information on the biology and habits of the insect of which SILVESTRI gives a detailed morphological description.

The only varieties of fig tree attacked are those the fruit of which have large scales arranged almost horizontally, not short and converging towards the interior of the eye. Among the cultivated varieties those attacked are, in the province of Naples, "troiano" and "natalino"; in Cilento, "pas-carolo" and "fico a tre produzioni"; in Sicily, "biancolillo" and other white and black varieties.

Of the wild fig-trees, which, according to SILVESTRI is the fly's favourite plant host, the varieties with an elongated, oval receptacle, well-developed cavity and horizontal scales, are the best suited to the development of the insect.

The enemies of the insect mentioned by SAVASTANO include ants, the coleopteron *Sinoxylon sexdentatum* Oliv., the becacico and the finch. From pupae of *Lonchaea*, collected at Portici and Resina, SILVESTRI ob-

(1) See B. July, 1915, No. 777. (Ed.)

tained specimens of a chalcid hymenopteron, *Pachyneuron vindemmiae* (Rond.), which however, is of little or no importance in controlling the insect.

As regards artificial means of control, besides collecting and destroying the ripe and unripe receptacles which have fallen, the cultivation of the varieties most attacked should be given up, or at least limited. The wild-fig, unless absolutely necessary to ripen the receptacles of varieties of real economic importance, should not be cultivated. Where caprification is necessary only those varieties of wild fig should be used the receptacle of which has short scales converging towards the interior of the eye.

According to SAVASTANO, too great cultural care should be avoided, especially excessive fertilising with farm-yard manure, because this causes a greater separation of the scales, thus facilitating attack by the insect.

The practice of "touching", adopted in the province of Naples, by which a drop of olive oil is placed in the eye in August to hasten ripening, is an indirect means of defence against the fly; the eye contracts, the scales do not open, and the oil penetrates the interstices, so that the insect cannot deposit its eggs in the fruit.

717 - *Corythuca spinulosa* Gibson, a New Lace-bug on Wild Cherry in New Jersey.

— DICKERSON E. L. and WEISS, H. B., in *Entomological News*, Vol. XXIX, No. 4, pp. 121-125 + 1 Plate. Philadelphia, April, 1918.

This paper gives a morphological and biological description of *Corythuca spinulosa* Gibson, first observed towards the end of the summer of 1916 feeding on leaves of wild cherry (*Prunus serotina*) at Jamesburg, New Jersey. So far this species has only been found in that locality.

718 - *Insects Injurious to Forest Trees in Sweden in 1916.* — TRAGARDH, IVAR, in *Skogen*, Year V, Pt. 1, pp. 10-20 + 5 Figs.; Pt. 2, pp. 45-62 + 8 Figs. Stockholm, 1918.

The paper contains a list of the insects injurious to forest trees reported in Sweden in 1916, together with notes on their distribution throughout the kingdom, especially from the point of view of local climatic conditions.

*Ips typographus* L. ("Granbark borren") and *Pityogenes chalcographus* L. ("Sextandade Barkborren"). The province of Härnösand was the chief centre of attack; here the insects were reported from nearly all the forests (70 %). Then came, Mellersta Norrland, Gävle, Dala, and Östra, with 50 %. No damage, however, was reported from Övre Norrbotten or the province of Skellefteå, but in Nedre Norrbotten, Umeå, and the province of Bergslag, 25 to 28.5 % of the forests were attacked. In the southern districts of Västra, Småland and Södra, the figures vary between 10 and 22 %.

The temperature has a great influence on the development, and, consequently, also on the multiplication and diffusion of *Ips typographus*. According to the observations of KOLMODIN and HENNING, in the Orsa forests in 1914, the life cycle of the first generation covers a period of 70 days (May 16 to July 24), whereas in Germany (Tharandt) it lasts 52 days (May 30 to July 21). This difference is accounted for by the temperature. At Tharandt, according to UHLIG, the total temperatures for the 52 days was

1145°C. with an average of  $+22.02^{\circ}$ ; at Falun (the nearest observatory to Orsa) the total for the 70 days was 1151°C., with an average of  $+16.4^{\circ}$ .

*Bupalus piniarius* L. ("Tallmätaren"). — The districts which suffered most in 1916 were Nyköping (Sörby), Jönköping, Västbo (Nennesmo), Tjust, Södra Møre, and all the Kalmar district. In studying the distribution of the insect from 1889-1916, it is seen that the chief centres of attack are found in the east of Sweden, to the east and north of the 550 mm. isohyet. The atmospheric precipitation decreases as one passes from the Atlantic to the Baltic districts, and, as the rainfall decreases the possibility of development of *Bupalus* increases. The attacks of this insect are most frequent and widespread in those districts and years in which the total rainfall is below 550 mm.; this is seen from the following table.

	Average precipitation in mm.	Precipitation at the time of an attack in mm.	Decrease — %
Orebro . . . . .	577.4	458.8	20.5
Nyköping . . . . .	563.3	409.8	27.2
Gävle . . . . .	487.5	377.7	22.4
Kalmar . . . . .	434.1	368.7	15.4

*Lophyrus sertifer* Geoff. and *L. pini* L. ("Tallsteklarna"). — In 1916, these insects were observed in a few districts only — Storlandet, Luleå, Garpenberg, Halmstad, Tjust, and Lunnerbo. An examination of the chart of the distribution of *Lophyrus* in Sweden during the period 1880-1915 confirms the general diffusion of the insects from the south to the far north and, at the same time, shows clearly the influence of temperature in their development. The chief centres of attack are to the south of the isotherm  $+5^{\circ}\text{C}$ .

The following were also reported:— *Myelophilus piniperda* and *M. minor* ("Märgborrarna"); *Ips sexdentatus* Boern. ("Tolvtandade Barkborren"), *I. acuminatus* Cyll. ("Skarptandade Barkborren"); *Hylobius abietis* L. ("Snytboggen"); *Melasoma aenea* L. ("Algullbäggan"); *Agelastica alni* L. ("Blå Allövbäggan"); *Liparis monacha* L. ("Nunnan"); *Eriogaster lanestris* L. ("Björkspinnaren"); *Panolis griseovariegata* Goeze ("Tallflyet"); *Hibernia defoliaria* Cl. ("Lindmätaren"); *Tortrix resinella* L. ("Martsgallvecklaren"); *Argyresthia illuminatella* Zell. ("Granknoppsmalen") and *Lyda hieroglyphica* Christ. ("Tallkultur-Säckespinnarestekeln").

719 — The Chemical Nature of the Vitamines. Isomerism in Natural Antineuritic Substances (1). — WILLIAMS, ROBERT, R. and SEIDELL, ATHERTON (Bureau of Chemistry, U. S. Dept. of Agriculture), in *The Journal of Biological Chemistry*, Vol. XXVI, No. 2, pp. 431-456, 5 Diagr. + 1 Plate. Baltimore, Md., September, 1916.

RURAL  
HYGIENE

Recent investigations by WILLIAMS (*Journal of Biological Chemistry*, Vol. XXV, p. 437, 1916) demonstrated a dynamic isomerism in the hydroxypyridines which has a most profound influence upon the antineuritic properties of these substances. This fact suggested that a similar isomerism may exist in the natural "vitamines" and be responsible for the instability which has so far prevented their isolation. With this conception in mind the authors directed attention to the natural antineuritic substances of yeast and obtained results which strengthen the conjecture that an isomerism plays a determinative part in the physiological action of the natural "vitamines" not less striking than in the hydroxypyridines.

A great obstacle confronting previous investigators of "vitamines" has been the difficulty of securing adequate amounts of sufficiently concentrated products for experimental study. Since SEIDELL (*U. S. Pub. Health Reports*, Vol. XXXI, p. 364, 1916) has shown that the antineuritic substances of autolyzed yeast are completely adsorbed and retained in a physiologically active condition by fuller's earth, the authors considered that this solid combination of relatively pure "vitamine" and an inert inorganic substance, would offer greater advantages for this study than any product previously available. There is practically no loss of active "vitamine"

(1) As regards vitamins and their importance in feeding, see: — *B.* 1912, No. 1139; 1914, No. 871; 1915, No. 1239; *R.* 1916, Nos. 612 and 1254; 1917, Nos. 163 and 260; 1918, Nos. 24, 62, 125, 182, 315, 316, 377, 501, 616, 657, 662; 782 and 784 of this *Review*. (Ed.)

in the process of "activating" the solid and the small amounts of other substances adsorbed simultaneously with the "vitamine" do not appear to be of noteworthy consequence.

The results of the experiments described in this paper were the following:—

The physiological properties of autolyzed yeast filtrate were not appreciably altered by treatment with relatively concentrated caustic alkali.

In the case of fuller's earth "activated" by contact with autolyzed yeast filtrate, aqueous alkali modified the physiological action in respect to its power to maintain the weight of pigeons on a deficient diet, but did not sensibly affect its antineuritic function.

By alkaline extraction of "activated" fuller's earth a crystalline antineuritic substance was obtained, the physiological action of which was apparently not due to adhering mother liquor. On attempting to purify this substance further by re-crystallization, its antineuritic properties were lost and the resulting product was found to be identical with adenine. By suitable treatment of the resulting adenine, it acquired antineuritic properties, and the power to give a blue color with the Folin-Macallum reagent. The explanation of the results obtained appears to be that an isomer of adenine is the chemical entity responsible for the characteristic physiological properties of the "vitamine" under investigation.

*Theoretical Considerations concerning the Chemical Nature of "Vitaminines".* — Numerous writers have held the view that the "vitaminines", by which term the writers mean certain constituents of untreated foodstuffs, are complex compounds.

Accordingly various investigators have submitted products to autolysis with mineral acids as a preliminary to chemical investigation, the object of such treatment being to reduce the complex natural compounds into simpler ones which possess at least the more essential physiological characteristics of the parent substances. That hydrolysis with mineral acids does effect some change in the "vitaminines" is definitely proved by the fact that extract of rice polishings, after hydrolysis, has a distinctly altered physiological action, being much more efficacious as a curative agent than the original extract. It is only reasonable to suppose that this change results from cleavage of the original molecules. The evidence which the authors have obtained regarding the effect of alkalis on "activated" fuller's earth suggests that the alteration of physiological properties observable in this case is possibly due to a different type of cleavage. (They recognize that this change in properties is equally well accounted for by other assumptions, such as that of the existence of two types of "vitaminines" only one of which is destroyed by alkali).

Further, they have given evidence that "vitaminines" can be reduced to still simpler compounds which are physiologically active. Although the antineuritic properties of foodstuffs and of crude extracts persist through long periods of storage, it has been the experience of investigators who have attempted to isolate the "vitaminines" that the final relatively purified fractions are apparently much less stable, since simple re-crystallization may

often serve to destroy the curative property. In this paper it is shown that certain fractions of yeast may automatically lose their curative property when they are allowed to stand a few days at ordinary temperature.

These facts suggest the following hypothesis which is in part a re-statement of old conceptions. The "vitamines" contain one or more groups of atoms constituting nuclei in which the physiological properties are resident. In a free state these nuclei possess the "vitamine" activity and under ordinary conditions are spontaneously transformed into isomers which do not possess antineuritic power. The complementary substances or substituent groups with which these nuclei are more or less firmly combined in nature exert a stabilizing and perhaps otherwise favourable influence on the curative nucleus but do not in themselves possess the "vitamine" type of physiological potency. Accordingly it is believed that while partial cleavage of "vitamines" may result only in a modification of their physiological properties, by certain means disruption may go so far as to effect a complete separation of "nucleus" and "stabilizer", and if it does so will be followed by loss of curative power due to isomerization. The basis for the assumption that an isomerization constitutes the final and physiologically most significant step in the inactivation of a "vitamine" is found in studies of synthetic antineuritic products. This assumption is supported by evidence, presented in this paper, of the existence of such an isomerism in the crystalline substance.

If the above hypothesis concerning "vitamines" is fundamentally sound there are two possible successful issues of a study of the alkaline extract of activated fuller's earth; first to crystallize a free or combined curative nucleus before it has opportunity to isomerize into a non-curative substance; or, second, to isolate this nucleus in an inactive form and convert it into the active isomer, thus proving that it is related to the original antineuritic substance. Experiments described in the paper analysed show a measure of success has been attained in both of these directions.

720 - **Experimental Studies on the Food Value of Bran, in France** (1). — LAPICQUE, L. and CHAUSSIN, J., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXI, No. 7, pp. 319-323. Paris, April 13, 1918.

The present percentage of flour extraction in France is between 82 and 83 %; if 85 % extraction were again adopted would the 2 or 3 % of extra flour obtained be only an inert mass, or, given that this addition increases the amount of food substance, would the benefit in food material be lost by the increased work of the intestines?

The authors previously studied experimentally on man the food value of wheat flour containing slightly more husk than white flour and found no difference in their food values (2). They again studied this question in the following form which seemed to them more conclusive:— the subject was placed on a strict maintenance diet, the greater part of which was composed of flour containing the debatable product, which was removed

(1) See R. 1918, January, No. 3; February, No. 216; March, No. 344; April, No. 379. —

(2) See R. April 1918, No. 379. (Ed.)

later on; if the product is really useless maintenance will still continue.

The subject chosen was a dog, and it was found that when the bran was withdrawn from the ration gradual starvation occurred. Consequently bran (including the products of commercial milling which are discarded in an 80 % extraction but included in a 90 % flour) is decidedly nutritious for a carnivorous animal like the dog and obviously much more so for man.

- 721 - **Determination of the Indigestible Residue *in vitro* by the Action of Pancreatin on Wheat or its Milling or Baking Products.** — DEVILLERS, I., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 17, pp. 700-702. Paris, April 29, 1918.

Investigations into the utilisation of wheat as a food have shown the inaccuracy of the proportion of wheat believed to escape assimilation in man.

As chemical methods attack wheat by too diverse actions, by forces having an action different to that of the digestive juices, and physiological methods were impracticable because of their slowness, artificial digestion was resorted to. The author describes his method of digestion by Defresne's pancreatin in the presence of sodium borate, crystallised calcium chloride, hydrochloric acid and distilled water.

The residue undigested by the pancreatin reduced to 100 parts of product dried at 105-110° was 8.26 to 12.86 for the wheats tested, 35.22 for the bran (sharps), 4.87 to 8.17 for the flours analysed, and 7.53 to 8.24 for the bread.

- 722 - ***Phymata noualhieri*, a Hemipterous Enemy of *Musca domestica* in Mexico.** — DE LA BARREDA, L., in *La Revista agrícola, Órgano oficial de la Dirección de Agricultura, Secretaría de Fomento, México*, Vol. 1, No. 7, pp. 282-284 + 1 Fig. Mexico, December 1, 1917.

At the Agricultural Station of Oaxaca (Mexico) the author observed that a branch of "lila" (*Melia sempervirens*) infested with larvae of *Phymata noualhieri* was soon covered with numerous dead flies. He bred the hemipteron, which hunted flies energetically. It is also possible that it kills them by some poisonous secretion.

AGRICULTURAL  
EDUCATION

- 723 - **A First Year Course in Home Economics for Southern Agricultural Schools in the United States.** — STANLEY, I., in *U. S. Department of Agriculture Bulletin* No. 540 pp. 1-58, Washington, D. C., July 27, 1917.

This bulletin outlines a course of study in home economics for southern high schools of the United State.

It emphasizes the connection between such instruction and actual home experience and the danger arising from formal methods of presentation. It calls attention to underlying general principles and applies them in a typical course of study, which, while based on southern conditions is applicable in other communities.

The principles involved in the 160 lessons set forth in this publication are fundamental; however, to secure the best results with this work, teachers should make a special effort to adapt the lessons to the conditions found in the homes of the pupils.

A complete course in home economics, as outlined by the American

Home Economics Association of Baltimore would include the following subjects :—

1) *Food*: (a) Selection (home-grown and purchased food). (b) Preparation. (c) Planning and serving of meals. 2) *Shelter*: (a) House sanitation. (b) Planning of house. (c) Decoration and furnishing of the house. (d) Care of the house. 3) *Clothing*: (a) Selection. (b) Making. (c) Keeping in repair. (d) Laundry work. 4) *Care and training of children*. (a) Care of a baby. (b) Problems of a young child. (c) Amusements for children. 5) *Hygiene and sanitation*: (a) Definition of health. (b) Definition and classification of diseases. (c) Means of preserving health. 6) *Home care of the sick*. 7) *Household management, including systemization of housework, expenses, accounts*. 8) *Training for the enjoyment of leisure time*.

*Outline of lessons*. — The following order has been used for each of the 160 lessons outlined in this bulletin: 1) The subject, stated as a "Problem". 2) The chief ideas, listed as Points to be brought out. 3) The references, which have been confined to material available in bulletins of the U. S. Department of Agriculture and of the various State colleges and experiment stations. 4) Under "Correlation" are suggested ways in which other courses may make use of home-economics subject matter.

724 - **Experimental Projects of the Division of Pomology of the University of California**. — HOWARD, W. L., in the *Monthly Bulletin of the California State Commission of Horticulture* (Proceedings of the 30th State Fruit Growers' Convention), Vol. VII, Nos. 1 and 2, pp. 62-64. Sacramento, California, January-February, 1918.

EXPERIMENTAL  
AND  
ANALYTICAL  
WORK

The total number of official experimental projects, in the Division of Pomology of the University of California, amounted in the autumn of 1917 to 24. Not all are located at Davis; 4 are at Berkeley, and parts of others are out in the state, namely near Gilroy, Rucker, San Jose, Vacaville, Watsonville and Hayward.

There are now on the experimental farm 55 acres of fruits used for experimentation and instruction. Experimental investigations cover pruning studies with young and old apricot trees, different methods of pruning bearing prune trees, pruning young and bearing peach trees, pruning of old and young apple and pear trees, training and shaping young apricot, cherry, plum, prune, peach and pear trees. Experiments in the summer pruning of both young and old trees are also in course.

Pollination studies include cherries, almonds, prunes, plums and pears.

The almond project consists of experiments at Davis and systematic observations over the whole state. A series of orchard soils investigations is also in progress. One part of this investigation consists of a tillage and cultivation experiment. Another part has to do with the improvement of orchard soils by means of mulching with straw and manure instead of cultivation, the tillage experiments being carried on at Davis while the mulching work is located both at Davis and in several orchards near Rucker and Gilroy.

An experiment in orchard irrigation is being carried on at Davis in cooperation with the irrigation division of the University. Peaches are being studied first; later other fruits will be added. One of the larger long-

time experiments is being carried on at Davis to determine the best or most profitable distance apart for planting apricots, cherries, peaches, pears, plums and prunes. The yield record of the orchard covering a period of 15 or 20 years or longer will determine the best or most profitable planting distances.

The cold storage studies with deciduous fruits are being carried on at Berkeley. These include the keeping qualities of grapes held at different cold storage temperatures, keeping qualities of pears in cold storage, and the keeping qualities of apples in cold storage as affected by the health and vigour of the trees and also by the stage of ripeness at harvesting time. The new Agriculture Building, Hilgard Hall, at Berkeley, has the best experimental cold storage plant in the United State.

Six new projects deal with fruit drying problems. These include a survey of the fruit drying industry of the state; variety tests of fruits for drying purposes; standardization of fruit drying methods, equipment for drying, effects of finishing in the shade by stacking the trays, and effects of sulphuring on fruit tissue and its possible relation to palatability of product. Extensive data along these lines were collected during the last season.

At Davis extensive studies of fruit bud development are in course.

Special studies are being made with walnuts, pecans, chestnuts, filberts and pistachio nuts.

Variety tests of all kind of fruits are being made. The best collections of varieties are: peach 85, apricot 40; cherry 40; almond 30; pear 30.

Under miscellaneous experiments might be mentioned work in spraying; various tests with small fruits, including both bush fruits and strawberries; individual trees performance records; a collection of phenological data with all fruits; trials with tree washes against borers and rabbits, washes for protecting pruning wounds, etc.

The division keeps an individual record in map form and card index form for every fruit tree that is growing in the University Farm orchards. The orchards are being conducted both for experimental and instruction purposes.

## CROPS AND CULTIVATION.

### AGRICULTURAL METEOROLOGY

725 — **Agricultural Meteorology in New Castile, Spain.**—QUINTANILLA, G., in the *Boletín de Agricultura Técnica y Económica*, Year X, No. 110, pp. 115-132. Madrid, February, 1918.

The average yield per acre of cereals in New Castile is:—wheat, 5.80 cwt., barley, 10.74 cwt., oats, 6.29 cwt., and rye, 6.03 cwt. The figures for the province of Cuenca alone are:—wheat, 4.93 cwt., barley 9.66 cwt., oats and rye, 4.38 cwt.

The ignorance of the farmers, the absence of modern machinery and chemical fertilisers are not sufficient to explain these remarkably poor crops. The primary cause is to be found in the unfavourable climatic conditions. Spanish emigrants, especially Castilians, in a more favourable climate, with the same labour, tools, and methods produce at least double the quantity of wheat as in their own country. Agricultural meteorology,

the importance of which is recognised throughout the world, assumes an especially urgent character in Spain.

The following data are available on the weather conditions of New Castile :—

**TEMPERATURE.** — Fundamental characteristics :— short growing season and considerable annual variations in temperature. The author calls “ persistent ” frosts those which occur regularly each year, “ rare ” those which occur less frequently, *i. e.*, one in every two, three, or four years on the average.

In the province of Guadalajara “ persistent ” frosts occur from November to April, “ rare ” frosts occur in October and May. In the province of Cuenca “ persistent ” frosts continue from November to May and “ rare ” ones occur in October and June. Only the months of July, August and September are consistently free from frost. In the province of Madrid “ persistent ” frosts occur from November to April, and, more rarely, occur also in October and May. At Toledo the duration of frosts is from November to March, and the season consistently frost-free includes the months of May, June, July, August and September.

The short frost-free season (the conditions in the province of Cuenca are very similar to those of northern Sweden) suffers seriously from drought, marked annual variations, and frequent very high temperatures. The maximum and minimum temperatures for the last 5 years are :— Madrid  $+40.5^{\circ}$  and  $-14^{\circ}$  C. ; Cuenca  $+38.5^{\circ}$  and  $-12.5^{\circ}$  C. ; Toledo  $+40.4^{\circ}$  and  $-6.5^{\circ}$  ; Guadalajara  $+39.6^{\circ}$  and  $-13^{\circ}$ .

**RAINFALL.** — Madrid, 417 mm. ; Cuenca, 477 mm. ; Toledo, 361 mm. ; Guadalajara, 410 mm. This would be a sufficient amount of rain if it were evenly distributed, and would ensure a good cereal harvest. The distribution of the rain does not, however, always correspond to the requirements of the crops, and frequently the lack of water at the critical period (earring for cereals) contributes not a little to a low yield. The weather conditions most unfavourable to crops in Spain are, therefore, frost and drought. In order to control these factors it is above all necessary to know exactly their distribution and frequency so as to choose the most suitable varieties, determine the periods for ploughing, etc. The attention of the Minister of Agriculture, of the Society of Spanish Agriculturists and of all agricultural societies, is drawn to the interest presented by this subject and the formation of a service with a technical staff and equipment, fitted to deal with the problems so closely touching Spanish agriculture is demanded. Methods of dealing with the climatic and agro-geological conditions of the Peninsula are also suggested.

**CHOICE OF RESISTANT TYPES.** — By selection and hybridization there have been obtained in Sweden, Canada, the United States, etc., types of wheat, barley and oats particularly resistant to low temperatures. Acclimatization experiments in Spain with Russian and American varieties have given almost entirely negative results. In Spain, as elsewhere, it would probably be wiser to use local varieties, apply pure strain selection first and eventually improve them by hybridization and selection. Among the nat-

ive varieties are some six-rowed barleys which have given results superior to those obtained with foreign varieties in all comparative cultural tests.

PERIOD FOR SOWING. — Taking as a basis observations made at Alcala Henares the author, though on the whole in favour of early sowing, finds it impossible to give a fixed date on account of the unsettled weather conditions. In some years the maximum temperature ( $40^{\circ}$  C. in the shade) occurs during the second fortnight in June; in this case sowing should be done as soon as possible so that the wheat may ripen before the great heat. In other years wheat, if sown early, regularly suffers from frost, which attacks the young plants even at a very advanced stage of growth.

CHOICE OF SOIL AND CULTURAL METHODS. — Thorough weeding, surface cultivation, the use of chemical fertilisers which increase the concentration of the soil solution, are all efficient methods of controlling drought, but in any case it is essential that the arable layer should have a certain depth below which a good harvest cannot be obtained even if the best methods are adopted.

The author lays stress on the necessity of such examinations of the soil which will immediately give the data by which it is possible to calculate approximately the probability of growing successfully any crop in a country with so unfavourable a climate.

726 - **Orchard Heating Against Frost in Utah, U. S. A.** — WEST, F. L., and EDLEFSEN, N. R., in *Utah Agricultural College Experiment Station, Bulletin* No. 161, pp. 1-47 + 2 Figs. Logan, Utah, October, 1917.

In the States of Florida, Ohio, Washington, Colorado, and California and Oregon in particular, the protection of orchard trees against frost by heating with heavy oil has been adopted on a large scale with distinctly positive results. In Utah, every three years out often the fruit crop is reduced by spring frosts, so that the question of protection by heating should not be neglected, but it must first be shown whether it would prove economically practical. To decide this it is necessary to determine for each species of fruit tree:—1) the average number of times the fires must be lit and the expense entailed; 2) the amount and price of the fruit thus saved. The study made on this subject by the author from data supplied by five of the most important fruit centres (Utah, Box Elder, Salt Lake City, Weber, and Cache) leads to a negative conclusion as is shown by the results given below.

NUMBER OF TIMES THE FIRES SHOULD BE LIT. — The critical period for fruit trees with respect to frost coincides with the interval between the beginning of flowering and setting. Table I gives the figures concerning apple, apricot, cherry and peach trees collected by the Agricultural Stations of Provo (Utah), Corinne (Box Elder), Salt Lake City, Ogden (Weber), and Logan (Cache). Table II shows the number of times which, according to the author, it would have been necessary to light the fires. In the case of the peach trees they should be lit an average of three times a year.

EXPENDITURE AND PROFIT. — For the peach tree, taking as a basis the calculations drawn up with the greatest care, the total annual expenditure is \$ 50.50 per acre. The average yield is 400 bushels per acre, and the loss

due to frost about 80 bushels (20 %) to a net value of \$ 28 (the average price of peaches on the Utah market is about \$ 0.55 a bushel).

The figures would be slightly better for apple but it must be remembered that in this case too, the number of heatings proposed by the author represents a minimum which would always be much exceeded in reality as a precaution, as is proved in all orchards fitted up with the necessary apparatus.

This study shows that the advisability of heating and fumigating Utah orchards at the present price of fruit and fuel is doubtful, for the benefit obtained would hardly cover or justify the expense, even under the most favourable conditions of good weather forecasting and capable staff.

TABLE I. — *Duration of the interval between the beginning of flowering and setting (average 1920-1916).*

Station	Apicot.	Peach	Cherry	Apple.
Provo, Utah . . . . .	—	Apr. 1-Apr. 30	—	Apr. 14-May 15

727 — *Soil Acidity and the Hydrolytic Ratio in Soils.* — SPURWAY, C. H. (Assistant Professor of Soil Physics, Michigan Agricultural College), in the *Journal of Agricultural Research*, Vol. XI, No. 12, pp. 659-672 + Bibliography of 9 Publications. Washington, December 17, 1917.

SOIL PHYSICS,  
CHEMISTRY  
AND  
MICROBIOLOGY

Recent studies (1) have shown a certain relationship between the acidity of a soil, as shown by a litmus or phenolphthalein indicator, and its content in aluminium and iron compounds. The author's investigations into glacial soils showed a connection between the aluminium and iron salt content of the soils and their reaction to the above-mentioned indicators. In determining for 29 soils the percentage of calcium, iron, aluminium and silica soluble in N/5 hydrochloric acid a definite relationship was found between the ratio of calcium to iron or aluminium soluble in N/5 hydrochloric

(1) See B., 1914, No 980; R. 1916, Nos 727 and 1163. (Ed.)

acid and the soil reaction. All soils with a ratio  $\frac{\text{lime}}{\text{ferric oxide} + \text{aluminium}}$  exceeding  $\frac{1}{1.3}$  are acid and those in which this ratio is lower are alkaline. There is, therefore, reason to believe that the reaction of the soils studied depends chiefly on the hydrolytic ratio between the hydrolysing compounds of alkali soils and those of iron and aluminium.

It is thus possible to determine the amount of lime required to neutralize acid soils by estimating the amount required to bring the soluble calcium content to the ratio  $\frac{\text{lime}}{\text{ferric oxide} + \text{aluminium}} = \frac{1}{1.3}$ . Amounts calculated by this process are very near to those determined by an indirect titration method proposed by the author, so that the two methods corroborate each other. The new process consists in treating increasing quantities of soil with an invariable quantity of titrated lime water and determining the reaction of the solutions with phenolphthalein and their electrical resistance. The amount of lime required to neutralize an acid soil is independent of its concentration, thus proving neutralization to result from a chemical reaction. Nevertheless soil still absorbs lime after neutralization, but by physical means. It is, however, possible that a mass action may cause chemical reactions in the presence of an excess of lime.

**728 - Salts Injurious to Vegetation and their Relationship to the Irrigation of Arid and Semi-arid Regions.** — PERKINS, A. J. (Director of Agriculture), in *Department of Agriculture of South Australia, Bulletin* No. 103, pp. 24. Adelaide, 1916.

Present Australian irrigation areas, and in particular those situated on the banks of the Murray, are under the influence of arid conditions of climate. Land so situated will become exceedingly productive when brought under cultivation and irrigated. Experience throughout the world, however, teaches that all such land, when brought under the influence of irrigation, is liable to become salt-impregnated to the extent of barrenness. At times, when first handled, such land shows no apparent signs of the presence of salt; salt, however, is present, but distributed evenly and invisibly through the depth of several feet of soil. A few seasons subsequent to the application of irrigation, salt may become apparent either uniformly throughout a block, or in scattered patches which gradually increase in area. This salt has risen to the surface through surface evaporation; and, knowing this, it is the business of irrigators to do everything in their power to hinder the action of surface evaporation and hold in check the rise of salt.

Towards this end the tillage of irrigated areas, when given in the way of initial preparation of the soil, must be deep and thorough, infinitely more so than is the case in the average routine of farming. In addition to this it is essential to keep the surface soil well screened from the direct rays of the sun during the summer months and where circumstances do not permit of this the moister layers of the subsoil must be kept well-protected by a deep layer of soil mulch. Nor should this be forgotten in autumn, when irrigation areas are bare, in the interval that lies between the removal of the summer crop and the seeding of the winter crop.

Over-irrigation, leaky water channels, shallow drainage channels, and the slow removal of salt-impregnated drainage waters must be avoided.

Irrigation waters that are unduly charged with soluble salts must be avoided. Irrigation water showing 20 grains of soluble salts to the gallon, and used on the 3 acre feet basis, will add to the soil annually more than one ton of soluble salts to the acre; 40 grains to the gallon nearly  $2\frac{1}{2}$  tons to the acre and so on. A portion of these salts will no doubt be taken up by the plants; another portion, however, will go towards swelling the existing stocks of injurious salts originally present in the soil.

If, in spite of these precautions, it is impossible to prevent the ultimate rise of salt, or again, if from the outset the land is evidently over-charged with surface salts, special steps towards the removal of the salts must be taken. Whatever steps may eventually be decided upon, none are likely to prove effective unless adequate provision is made for the systematic removal of drainage waters. Naturally, pipe drainage should be avoided if possible. Ultimately, however, in many cases it will be necessary to determine whether the cost of establishing an adequate system of pipe drains is not amply set off by the extremely high productivity of land so treated and irrigated under arid conditions of climate.

If the land shows 0.1 per cent of sodium carbonate it should be treated with gypsum prior to leaching operations. This, however, is a contingency rare in local experience; under Australian conditions the flood waters pass through the soil, dissolve the soluble salts, and convey them without hindrance through the drain pipes into the country drainage.

The profits resulting from properly conducted irrigation operations under Australian conditions of climate are enormous; the indirect advantages to the State as a whole are equally great. If, however, Australian irrigators are not prepared to take into account this important salt question, and to guard themselves adequately against it, all the expenditure of time and capital will in the end prove vain, and the irrigation areas will revert to the condition of those of Mesopotamia.

#### 729 - The Effect of Certain Factors on the Carbon Dioxide Content of Soil Air. —

BIZZELL, J. A. and LYON, T. L. (Contribution from the Laboratory of Soil Technology, College of Agriculture, Cornell University, Ithaca, N. Y.), in the *Journal of the American Society of Agronomy*, Vol. X, No. 3, pp. 97-112 + 9 Figs. Washington, March, 1918.

Some higher plants are said to influence certain bacterial processes in the soil, such as stimulating nitrate formation during the most active period of their growth. Later, however, they have a depressing effect, and, since the conditions which favour the formation of carbon dioxide in soils are similar to those favouring nitrification, these two processes may be supposed to be parallel to each other. This is the opinion of many workers (1).

All determinations hitherto made, however, lack uniformity on account of the different conditions under which they were carried out and the various methods employed. The author, therefore, undertook a series of experiments in large lysimeter tanks, which received no other moisture

(1) See R. 1917, No. 795. (Ed.)

that from rain. The samples of air were removed from their drainage tubes. Some of the tanks were filled with clay loam, others with silt loam.

In clay loam oat crops produced great fluctuations in the carbon dioxide content of the soil air. The greatest apparent production was at the flowering period. This was followed by a marked decrease of  $\text{CO}_2$  which appeared to be due to the depressing effect of the crop on the production of  $\text{CO}_2$  by bacterial action.

In silt loam the crop apparently produced little effect on the formation of carbon dioxide, whereas the addition of lime caused a increase in the  $\text{CO}_2$  content of the air of both cropped and uncropped tanks, through in clay loam liming produced no such effect.

In silt loam burnt lime caused a larger production of  $\text{CO}_2$  than the chemically equivalent quantity of ground lime.

The results do not make clear whether the increased  $\text{CO}_2$  production caused by burnt lime is due to a stimulation of bacterial activity or stimulation of the crop:

730 - **The Relation of Weed Growth to Nitric Nitrogen Accumulation in the Soil.** — CALL, L. E., and SEWELL, M. C., in the *Journal of the American Society of Agronomy*, Vol. X, No. 1, pp. 35-44 + 7 Tables + Bibliography of 19 Publications. Washington, January, 1918.

The favourable effect of tillage upon nitrification is generally attributed to the incorporation of organic matter, the distribution of bacterial flora, aeration, and moisture. The authors attempt to prove that too much importance has been attached to these factors and that the good effects of tillage are due above all to the destruction of weeds which might absorb the nitrates.

After reviewing the publications on this subject (which show that nitrification is not essentially increased by greater aeration and a higher water content, though these factors are necessary) the authors give the results of various experiments made at the Kansas Agricultural Station during several years on plots of wheat cultivated by eleven different methods. A comparison of the yields, moisture contents and nitrate contents shows that marked differences in yield cannot be attributed to the water content which is nearly always constant, but that there is a close relation between yield and nitrate content. Experiments conducted by the authors themselves showed that the accumulation of nitrates is much larger in soils free from weeds even when such soils are not farmed. They conclude that, in a sufficiently light soil, much labour may be saved by adopting only the essential cultivation processes and destroying the weeds by other methods such as rotation and grazing by livestock, especially sheep.

731 - **Protozoa and the Phenomena of Reduction in Soil (1).** — VON WOLZOGEN KÜHR, JR., C. A. H. (Bacterioloog aan de Cultuuraafdeeling te Pasoeroean), in *Archief voor de Suikerindustrie in Nederlandsch Indië*, No. 27, pp. 1125-1182 + 11 Figs. + Bibliography. Soerabaja, 1917.

The principal biochemical reduction phenomena occurring in the soil and the analytical methods for recognizing them are rapidly reviewed.

(1) See B., 1915, No. 786. (Ed).

When they have reached a certain intensity these reduction phenomena result in changing ferric into ferrous compounds; the best reagent for recognizing these phenomena is potassium ferricyanide. Quantitative determinations include: — 1) the “*reduction index*” (“*reductiegetal*”), expressed in cc. of a decinormal solution of  $\text{KMnO}_4$  required to oxidise the quantity of “ferrous” iron liberated by 100 gm. of soil (dried at  $105^\circ\text{C}.$ ) in a sulphurous solution; 2) the “*ferro-index*” (“*ferro-cyfer*”), expressed in cc. of a decinormal solution of  $\text{KMnO}_4$  required to oxidise the “ferrous” iron extracted from 100 gm. of soil (dried at  $105^\circ\text{C}.$ ) in an acetic solution.

The recent publications on soil protozoology (CUNNINGHAM and LÖHNIS, RUSSELL and HUTCHINSON) (1) (FRANCÉ) are reviewed. These studies show that a high water content favours the appearance of protozoa; in the same way as an excessive water content also favours the phenomena of reduction in the soil the presence of more numerous protozoa (amoebae, flagellates, ciliates) may serve as an index to show reduction processes. It is relatively easy to determine the number of protozoa present in 1 gm. of soil, since sterilisation precautions as rigorous as those required when the bacteria are counted are no longer necessary, and many methods have been described (CUNNINGHAM and LÖHNIS, KOCH (2), Kopeloff (3)). The examination of numerous soil samples has shown that, from a point of view of the number of protozoa present and the degree of reduction, soils may be divided into three classes:—

- 1) *Good soils*, showing little or no reduction, containing few or no protozoa (from 0 to 50 protozoa per 1 gm. of soil);
- 2) *Bad soils*, with a high “reduction index” and many protozoa (50 to 100 or more per gram);
- 3) *Very bad soils* with a very high “reduction index” and few or no protozoa (0 to 50 per gram).

It is seen that, as the reduction process continues, the number of protozoa increases, reaches a maximum, then decreases. This phenomenon may be represented graphically by curves called “*curves of protozoa reduction*” (“*protozoënreductiekrommen*”) specially designed for each of the reduction processes: — cellulose fermentation, reduction of the sulphates and butyric fermentation.

As the protozoa are aerobic, their number increases during the first stages of the reduction phenomena, then they feed on anaerobes and the aeration of the soil is sufficient. As the reduction process continues, the anaerobes increase and the air decreases, till the development of the protozoa is checked and the maximum reached. Finally, during the continuation of reduction, the activity of the anaerobes increases to such an extent that the protozoa decrease more and more and die, being also attacked by the toxic substances formed during reduction, such as volatile fatty acids, sulphuretted hydrogen, etc. The number of protozoa present in 1 gm. of soil can show the reduction process to which the soil is subjected. Butyric

(1) See B., 1915, Nos. 460 and 1250. (Ed.) — (2) See, R., 1916, No. 269; — (3) See B., 1915, No. 1122. (Ed.)

ferments especially are fatal to protozoa as butyric acid kills them. The reduction curve is also very low (limited number of protozoa). During the reduction of sulphates, however, a large proportion of the sulphuretted hydrogen combines with the iron, the protozoa suffer less and are very numerous.

Protozoa form, therefore, a biological indicator of the reduction phenomena in the soil which the author applied to a large number of soils from sugar-cane plantations in Java. These investigations have shown that there is a relation between the water content, "reduction index", "ferro-index", and the number of protozoa per gram of soil.

**732—The Influence of Nitrifying Bacteria on Phosphates.**—HOPKINS, C. G. and WHITING, ALBERT L., in *University of Illinois Agricultural Experiment Station, Bulletin No. 190*, pp. 395-406. Urbana, Illinois, June, 1916.

The purpose of the experiment herein reported was to determine whether the farmer supplying nitrogen to his soil in the form of organic matter could depend upon its decomposition to render soluble the finely ground rock phosphate, and so maintain the necessary supply of available phosphorus. Two experiments were carried on; the first for the purpose of testing the ability of nitrite bacteria to dissolve pure rock phosphate; the second in order to test the effect of nitrate bacteria on pure tricalcium phosphate. The methods of determination consisted in measuring by chemical analysis, in the first instance, the amount of nitrogen which they had changed from ammonia to nitrite, in the second one the amount of sodium nitrite which they had changed to nitrate, and in both cases the amount of phosphorus and calcium which had at the same time made soluble.

The results are summarized as follows:—

Nitrite bacteria make phosphorus and calcium soluble from insoluble phosphates when they oxidize ammonia into nitrite. About one pound of phosphorus and about two pounds of calcium are made soluble for each pound of nitrogen oxidized, aside from the action of the acid radicles associated with the ammonia. The ratio of solubility found on the basis of nitrogen to phosphorus and calcium conforms to the following reaction:

According to this equation, 56 pounds of nitrogen liberate in soluble form 62 pounds of phosphorus and 120 pounds of calcium.

Plants are important factors in the liberation of phosphorus, owing to the production of carbon dioxide and the removal of the soluble phosphorus produced by the bacteria.

Neither ammonia-producing bacteria nor nitrate bacteria liberate appreciable amounts of soluble phosphorus from insoluble phosphates. Other acid-producing bacteria make phosphorus soluble from insoluble phosphates according to the nature and amount of the acid produced.

A comparison of the amounts of nitrogen, phosphorus, and calcium required by farm crops with those possible of solution by biochemical action (see the appended table) shows possibilities far beyond the plant requirements; which leads to the conclusion that plenty of rock phosphate

in contact with decaying organic matter must give the plants an excellent opportunity to obtain both phosphorus and calcium as well as nitrogen.

733 - Changes in the Nitrogen Content of Stored Soils. — ALDRECHT, W. A. (Contribution from the Department of Soils, University, of Missouri) in the *Journal of the American Society of Agronomy*, Vol. X, No. 2, pp. 83-88 + Bibliography of 7 Publications. Washington, February, 1918.

Determinations showed that wet or dry samples of soil stored in or near a laboratory in containers not hermetically closed risk contamination from ammonia. Moreover, when wet soils are allowed to dry slowly bacterial action seems to affect the nitrogen content very little. The ammoniacal nitrogen contained in the soil is held by a purely physical adsorption phenomenon, not by moisture.

734 - Report on Irrigation Surveys and Inspections in Canada for 1916-17. — I. DRAKE, E. F. (Superintendent of Irrigation), Report of the Superintendent. — II. PETERS, F. H. (Commissioner of Irrigation and Chief Engineer), Report on Irrigation and Canadian Irrigation Surveys, in *Department of the Interior of Canada*, pp. 79 + 8 Diagrams + 1 Plan + Bibliography of 14 Publications. Ottawa, 1917.

The report of the Irrigation Branch of Canada for the year ending March 31, 1917, includes 2 reports.

The first is by Mr. E. F. DRAKE, who deals briefly with the state of irrigation development, with hydrometric surveys (the territory covered by this work is divided into 13 districts, each in charge of an engineer, who, with one helper and the necessary gauge observers, performs all the field work; during the open water season, 177 gauging stations were maintained. records being taken at 138 gauges on irrigation canals and ditches; during

PERMANENT  
IMPROVEMENT,  
DRAINAGE  
AND  
IRRIGATION

the winter, 84 stations were maintained) and drainage (projects, subsidies and legal agreements).

The second report, by Mr. F. H. PETERS, deals with the organization of the staff, office work, hydrometric work and the study of irrigation projects 1) for land lying east of Macleod (using the Oldman river), of an area of 25 000 acres and at an estimated cost of \$ 228 000 ; 2) for the Taber district, Alberta (17 000 acres) ; 3) for the Lethbridge Northern District (area of 97 531 acres ; estimated cost \$ 2 274 316) ; 4) for land situated in the basins of the Milk and St Mary rivers (a project requiring a Treaty between the United States and Canada ; area of over 500 000 acres, for which 7 different irrigation schemes are described).

The inspection of the irrigable lands in the Eastern Section of the Canadian Pacific Railway Company's Irrigation Block, begun in 1913, was completed in 1916. About 130 240 acres were inspected. Experiment plot work was carried out at Strathmore and Ronalane (Alberta) on the amount of water required to obtain the highest yields of alfalfa, clover, wheat, oats, barley, peas, potatoes, maize, turnips, timothy, etc. Further information on the same subject was obtained at Coaldale, near Lethbridge, and crop reports were obtained for the Cypress Hills District, Saskatchewan, and for Calgary, Alberta.

The results of the experiments are given in numerous tables.

735 - **The Colorado River and its Utilisation.** — I. LA RUE, E. C., in *U. S. Department of the Interior, Geological Survey, Water-Supply Paper*, No. 395, pp. 231 + 5 Figs. + 25 Plates. Washington, 1916. — II. GRUNSKI, C. E., in *U. S. Senate, 65th Congress, 1st Session, Document No. 108*, pp. 38. Washington, 1917.

I. — The U. S. Geological Survey was the first to study the hydrography of the Colorado basin by establishing gauging stations on the Gila River, at Buttes, Arizona, in 1889. Since then all the services (5) of the various federal government departments interested in the subject have collaborated in a study of the water-system of the Colorado or have studied it separately from different points of view. Mr. LA RUE has collected the many observations made so as to present a more complete consideration for the best methods of utilising the Colorado river, the course of which is 2200 miles

After describing the physical conditions of the Colorado basin the author gives historical notes on the various explorations of the river from 1531 to 1911, and a hydrographical and geological bibliography of the basin. In his study on the system of the river and its tributaries the author gives in a series of tables the output of each of them according to observations made from the beginning. The present state of irrigation of the Colorado basin is described and a detailed examination made of the river and its tributaries, the possibility of increasing the area irrigated by building numerous weir reservoirs, the regulation of the water courses and construction of canals.

In 1913 the area irrigated by the river and its tributaries was 1 581 000 acres in the United States and 50 000 in Mexico, or 1 631 000 acres in all,

According to the author it would be possible to irrigate 4 002 000 acres in the United States and 897 000 acres in Mexico, or 4 899 000 acres in all.

The unused motive power is estimated at 2 666 910 H.P. At the present time 25 hydro-electric works develop 77 525 H.P. in the Colorado basin.

The author also studies the regulation of the river and its tributaries so as to avoid floods. He values at \$ 30 000 000 to \$ 50 000 000 the value of land subject to damage from floods in the Imperial Valley, and at \$ 10 000 000 to \$ 15 000 000 the land requiring protection between Bulls Head Rock and the frontier. The extent and frequency of the floods are also examined.

II. — Mr. C. E. GRUNSKY, whose study was presented to and published by the U. S. Senate, re-examines the possibility of developing irrigation in the Colorado basin. He studies not only the old projects and the present concessions granted to irrigation companies, but thoroughly examines the international point of view and the collaboration between the United States and Mexico to solve the difficulties concerning the regulation of the Colorado river and the quantity of water to be delivered to Mexico by any diversion canal below Pilot Knob. All the questions touching on an agreement between the United States and Mexico on this subject are enumerated.

736 — **Schemes for Barrage-Reservoirs in Tunis.** — COIGNET, J., in *L'Hydraulique en Tunisie*, pp. 143, 2 Tables, 3 Diagrams, 2 Plans + 3 Maps. Tunis, 1917.

After considering the need for utilising the surface water in Tunis by making great barrage-reservoirs, the author quotes objections to the construction of works holding up the water of rivers that do not flow all the year round or of beds that are in flood a few times only each year. Besides the benefit to agriculture barrages would, with the systematization of the watercourses, furnish motive power for various industries as well as drinking water for towns and centres of colonization.

The author describes the chief dams he has studied, amongst which he mentions :—

1) The barrage-reservoir of Hamman Zriba destined to complete the drinking water supply of Tunis and neighbourhood as well as to provide drinking and irrigation water for the centres of colonisation situated down stream from the barrage. This reservoir to be constructed on the Oued El-Hammam at the entry of the Zriba gorges will cover an area of 95 hectares and store 11 430 000 cu. metres of water. The reservoir will annually receive about 20 000 000 cu. metres. The height of the barrage will be about 100 ft.

2) The barrage-reservoir on the Oued Gerond which can hold 40 000 000 cu. metres, giving a delivery of 12 500 litres per second. The height of the dam is about 143 ft.

The area that could be irrigated with 4000 cu. m. per hectare (cereals) would be about 100 000 hectares situated chiefly between Kairouan and Sousse. This dam would admit of developing a force of 5 000 HF. Its construction would, however, encounter certain technical difficulties, chiefly

in the displacement of the railway. In fact, the project necessitates the submersion of the Rahrmate tunnel.

3) The systematization of the Medjerdah with the construction of 2 large barrage-reservoirs at Oued Tessa and Testour and the utilisation of the barrage-bridge of El-Bathan, which would allow of irrigating all the outskirts of Tunis and of 50 000 hectares between Testour and Grombalia. The statistics of the areas to be irrigated and the quantities of water required indicate only 27 000 hectares for the Medjerdah for the first few years, but as the Testour reservoir will provide 430 000 000 cu. m., the irrigation area can be afterwards increased by about 30 per cent.

The author gives interesting information regarding other projects of barrage-reservoirs to be constructed on the rivers Kasseb, Mellegue, Boul Kebir, Koceine, Masri (O. Melah) and Chiba, and Sedjanne, the execution of which would allow of irrigating a large area.

In conclusion, the author insists upon the urgent need for immediately constructing barrage-reservoirs in Tunis so that the country can replace or procure at least a part of the indispensable products that are generally lacking.

737 - **Irrigated Farms in Utah, U. S. A.** — Sec No. 811 of this *Review*.

739 - **The Decomposition of Green and Stable Manures in Soil.** — POTTER, R. S. and SNYDER, R. S. (Assistant Chief and Assistant in Soil Chemistry, Iowa State College Experiment Station), in the *Journal of Agricultural Research*, Vol. XI, No. 13, pp. 677-698 + 9 Figs + Bibliography of 8 Publications. Washington, December 24, 1917.

This paper is a continuation of previous studies (1) the principal aim of which was to determine the rate of decomposition of original or added organic matter in soil by estimating the amount of carbon dioxide evolved from manured soils. The last experiments were made in two series — one with applications of calcium carbonate, the other with liming.

The principal results show that the organic matter in soil decomposes more rapidly in soil treated with calcium carbonate or lime than in untreated soil. The decomposition of the total organic matter of a soil treated with stable manure or green manure (clover or oats) is hastened by the addition of calcium carbonate or lime.

Stable manure seems to hasten slightly the decomposition of green manures accompanying it, and these two forms of manure help to preserve the lime in the soil. No appreciable difference was noted in the rapidity of decomposition of green manures when applied dry and as a fine powder or fresh and in large pieces.

740 - **Sulphuric Acid and Fertiliser Industries in the United Kingdom.** — I. *The Board of Trade Journal*, Vol. C, No. 1110, pp. 268-271. London, March 7, 1918. — II. *The Chemical Trade Journal and Chemical Engineer*, Vol. LXII, No. 1607, pp. 203-207. London, March 9, 1918. — III. *Mark Lane Express Agricultural Journal*, Vol. CXIX, No. 4511, p. 258. London, March 11, 1918.

A Committee was appointed by the British Minister of Munitions in

(1) See R., 1917, No. 9. (Ed).

February 1917, to consider and report on the position of the sulphuric acid and fertiliser trades as affected by the new acid plants which have been erected during the war by the Ministry of Munitions.

From the report just issued it appears that the production of sulphate of ammonia and of phosphatic manures before the war provided the principal outlets for sulphuric acid, these two industries absorbing about 60 % of the pre-war production.

In consequence of the progressive introduction of by-product coking the output of ammonia was steadily increasing, and at the outbreak of the war amounted to 400 000 tons per annum expressed as sulphate. About 15 % of this production was not marketed in the form of sulphate, but was converted into other ammonia products. The home consumption of sulphate of ammonia for agricultural purposes was only 60 000 tons per annum, and the remainder was mainly exported.

For some years before the war the manufacture of superphosphate in the United Kingdom was in a very unsettled condition owing to the rapidly increasing importations of foreign manufacture and the gradual decline in the export trade. The export of superphosphates had reached a maximum of 160 000 tons in 1911, but had afterwards declined to 63 000 tons in 1913. The cause of this decline is to be sought partly in the erection of superphosphate plant in countries which previously imported this fertiliser, and partly in the competition of continental countries which, with the aid of cheap by-product acid from zinc manufacture, and in some cases with specially favourable freight conditions, succeeded in displacing their less favourably situated British competitors.

The United Kingdom possesses no natural advantages for the manufacture of superphosphates, since both pyrites and phosphates have to be imported as raw materials. It is, therefore, natural that when the consumption of superphosphate in countries such as Spain and Portugal reaches a certain point, local manufacture is undertaken, and, with the advantage of proximity to the raw material, soon succeeds in overcoming the competition of imported superphosphate from less favourably situated countries.

The expansion in the production of ammonia during the war has been somewhat accelerated owing to its association with the by-product coking industry. The production of sulphate of ammonia has, however, suffered a temporary decline, owing to the diversion of large quantities of ammonia to the production of nitrate of ammonia. In view of the requirements of sulphuric acid for explosives manufacture, plants have been erected on a considerable scale for the conversion of crude ammonia into concentrated ammoniacal liquor. A substantial proportion of the requirements of ammonia for munitions purposes have thus been purchased in a form which requires no sulphuric acid for its manufacture. The total production of sulphate has thus been temporarily reduced from 350 000 tons to a little over 250 000 tons.

At the same time, there has been a large increase in the home consumption for agricultural purposes, owing to the substitution of this fertili-

ser for nitrate of soda, the entire supply of which has been required for explosives manufacture. The export trade has nearly disappeared, the only exports now allowed being relatively small quantities to Allied countries and British Possessions.

The production of superphosphate has been greatly reduced during the war owing to the lack of sulphuric acid. The production of superphosphate in 1916 fell to about 500 000 tons, as compared with about 800 000 tons in 1913. During the last few months, however, the paramount necessity of increasing the home-grown food supply has been realised, and steps have been taken to secure a large and immediate production of superphosphate. Renewal and extension of superphosphate plant is accordingly proceeding at the present time with a view to recovering the lost ground as speedily as possible.

After hearing the evidence and considering the figures which have been laid before them, the Committee concluded that by far the most important prospect of utilising the increased quantities of acid is in the manufacture of artificial fertilisers.

With regard to sulphate of ammonia, which before the war was largely an export trade, it is probable that the impetus which has been given to home consumption will continue to be felt. It must be remembered, however, that the probable increased home consumption, will to a very large extent be provided by a reduction of the export of this fertiliser below the pre-war figures. The limiting factor is at present the amount of coal carbonised in connection with recovery plant, and the acid consumption for sulphate manufacture bears a direct relation to this quantity, and not to the home consumption. During the war, although every effort has been made to extend by-product coking plants, the increased production of ammonia has only been about 7 per cent. The coke-oven industry may be expected to absorb larger quantities of acid during the years following the war, but the increase can hardly be considered of much importance to the acid situation.

The manufacture of ammonia from atmospheric nitrogen by the cyanamide process and by the Haber process may ultimately assume importance in the United Kingdom, but as the success of these processes is conditional upon the provision of cheap power, and as the processes are as yet undeveloped they cannot be so important a factor as to influence to any marked extent the conditions immediately following upon the cessation of hostilities. On the other hand, the introduction of synthetic methods for the production of nitric acid, which are now in early stages of operation, tends to diminish the consumption of sulphuric acid for the manufacture of nitric acid.

The Committee have found that the immediate increase in the consumption of acid after the war is almost wholly a question of the development of the superphosphate industry. They have accordingly considered evidence both from agricultural experts and from fertiliser manufacturers as to the probable post-war position. It is evident from the opinion of these witnesses, quite apart from any question of manufacturing facilities, that the greatly extended use of phosphatic manures is both economically profitable

and essential for the efficient cultivation of the land. The extent to which such extended use will in fact take place depends mainly upon the agricultural policy of the Government. Prof. T. H. MIDDLETON, Deputy Director General of the Food Production Department, submitted to the Committee an estimate of the post-war increase of fertilisers based on the assumption that 3 600 000 acres of arable land would be added to the existing area in the United Kingdom and that a larger proportion of the grass land would be manured. This estimate further indicated that an additional quantity of 620 000 tons of superphosphate and 629 000 tons of basic slag could with advantage be used. This increased quantity of superphosphate would correspond to the absorption of 200 000 tons of sulphuric acid.

The available supply of basic slag is not likely to approach the figure mentioned above, but as this phosphatic manure can to a considerable extent be replaced by superphosphate, it is evident that a much larger quantity of superphosphate could be employed if it were available.

It has been difficult to obtain any exact data regarding the question of the future export market for superphosphate. The export trade has declined, and fertiliser manufacturers themselves do not appear to anticipate any considerable revival. It would, therefore, be unwise to count upon the export trade as a means of permanently reducing the surplus of sulphuric acid to any extent, although in the years immediately succeeding the war Belgium may be a large buyer.

In view of the proved agricultural need for greater quantities of fertilisers, the Committee are of opinion that the large surplus of sulphuric acid plant which will become available at the end of the war provides an opportunity of an altogether exceptional nature for the development of a vigorous agricultural policy in relation to the efficient cultivation of the soil. Having regard, therefore, for the guarantees which are given to the farmer under the Corn Production Act, the Committee recommend that the powers provided by Section 9 of the Act should be widely used to enforce the adequate use of fertilisers.

In conclusion, the following recommendations are made for providing an outlet for the surplus sulphuric acid which may be expected over the pre-war production as regards the production of fertilisers:—

a) That in the exercise of any compulsory powers given by the Corn Production Act every possible step should be taken to extend the use of fertilisers.

b) That in every way — by lectures, by practical demonstrations, and by experiments carried out at Government expense on plots easily accessible in various parts of the country — farmers should be encouraged and educated in the increased use of fertilisers.

c) That arrangements should be made with shipping, railway, and canal companies for cheap and adequate transport of raw materials, acid, and fertilisers, and that cheap freights should be arranged for the carriage of fertilisers to any part of the Empire or any Allied or neutral country where an opening for a market may offer.

741 - Some Availability Studies with Ammonium Phosphate and its Chemical and Biological Effects upon the Soil (1). — ALLISON, F. E., in *Soil Science*, Vol. V, No. 1, pp. 1-79 + 10 Figs. + Bibliography of 36 publications. Baltimore, January, 1918.

The investigations were carried out with "Ammono-Phos", an ammonium phosphate fertiliser prepared by the American Cyanamide Company. It consists of ground mineral phosphate mixed with sufficient sulphuric acid to free all the phosphoric acid, which is removed by filtration and washing. Gaseous ammonia is produced by steaming crude calcium cyanamide in an autoclave under a pressure of several atmospheres; the ammonia is bubbled into the phosphoric acid until it is converted chiefly into di-ammonium phosphate, though at the same time some citrate-insoluble iron and aluminium ammonium phosphates are formed. Phosphoric acid is then added, using methyl orange as an indicator, till the proportion of mono-ammonium phosphate is attained which will make the insoluble phosphates assimilable. When evaporated to dryness the solution gives a commercial product, "Ammono-Phos", a light grey material resembling superphosphate.

Up to the present nearly all the investigations on the use of ammonium salts as fertilisers have been made with ammonium sulphate or other salts, but never with ammonium phosphate on account of its high price. Now that a satisfactory method has been found for producing it commercially it is important to determine the conditions under which this fertiliser gives the best results and the quantities in which it may be applied safely and economically to various crops.

According to the author's tests commercial ammonium phosphate fertiliser contains about 13.5 % ammonia and 43 % phosphoric acid, 96.5 % of which is soluble in water and citrate. The nitrification of ammonium phosphate is similar to that of ammonium sulphate, but the ammonification differs. Soil fungi utilise the various nitrogenous compounds tested in the following decreasing order: — ammonium phosphate, ammonium carbonate, ammonium sulphate, urea, ammonium nitrate, sodium nitrate.

On an average the nitrogen recovered from a sandy soil after six harvests (one of barley, four of buckwheat and one of maize) was: 65.88 % for ammonium phosphate, 61.10 % for ammonium sulphate, 43.74 % for dried blood, and 41.19 % for cottonseed meal. In a loam soil the recovery was respectively: — 48.46 %, 50.42 %, 42.51 %, and 36.49 %. Liming increased the nitrogen recovery and the crop yield was in relation to this ratio except under very acid conditions, when ammonium sulphate gave a higher nitrogen recovery than phosphate, but a much smaller crop. The author believes the relatively low nitrogen recovery is due to the loss of free nitrogen or ammonia through the soil as well as through the plants. The increased lime requirement per acre resulting from the respective applications was: — for ammonium sulphate 794 lb., ammonium phosphate 525 lb., dried blood 263 lb., and cottonseed meal 113 lb.

Pot experiments showed an almost equal utilisation of nitrogen for commercial ammonium phosphate, its aqueous extract and sodium nitrate.

(1) See *R.*, 1916, No. 272. (Ed.)

Only the water insoluble ammonium phosphate gave a slightly lower yield than the other forms of nitrogen. Greenhouse experiments did not, on an average, show great differences in the availability of the phosphorus of the ammonium phosphate, superphosphate or basic slag. In very acid soils superphosphate was sometimes superior to ammonium phosphate as a source of phosphorus because it does not appreciably increase the acidity which ammonium phosphate does increase.

Germination experiments showed that, with equal quantities of nitrogen, ammonium phosphate has a toxicity equal to that of ammonium sulphate, but inferior to that of sodium nitrate and ammonium chloride, when applied in high concentrations. In very sandy soils toxicity is obtained with  $\frac{1}{10}$  the amount of fertiliser required in clay or silt soils. The toxic action of commercial ammonium phosphate does not exceed that of pure mono-ammonium phosphate. As regards the action of the various nitrogenous and phosphoric fertilisers on germination, lining decreased the growth of maize when the fertiliser was applied in small quantities, and increased the growth when large quantities of fertiliser were used. As a rule mixing fertilisers did not lessen the toxic effect. Maize, buckwheat, barley, wheat and oats resist heavy applications of fertiliser, but vetch, rape, and cowpea are relatively susceptible.

Under laboratory conditions the effect of fertilisers applied to 200 gm. of soil in glasses, was the same whether they were uniformly mixed with the soil or placed in direct contact with the seed. Under field conditions applications of 100 lb. of ammonium phosphate per acre in rows did not harm maize, but applications of 150 lb. proved slightly injurious.

In conclusion it may be said that ammonium phosphate has as a rule the same nitrogen value as ammonium sulphate and the same phosphorus value as superphosphate, and might be used to replace these two fertilisers. The few exceptions, under abnormal conditions, do not alter this conclusion, all the more so because ammonium phosphate is rapidly nitrified and utilised by micro-organisms and plants. The fertiliser resembles ammonium sulphate in its toxic effects when applied in high concentrations, and is slightly less toxic than sodium nitrate. As with other soluble fertilisers care must be exercised in the amount used when it is applied in drills.

742 - **The Identification of Grasses by their Vegetative Characters.** — CARRIER, LYMAN, (Agronomist in Pasture Investigations), in *U. S. Department of Agriculture, Bulletin No. 461*, pp. 30 + 60 Figs. Washington, January 19, 1917.

An attempt is made to identify grasses by the vegetative characters of their structure and of some special organs of the root, stem, and leaf, so that the inflorescence is not required for this purpose. Many attempts have been made previously to do this, especially by McALPINE, WARD, STEBLER and SCHRÖTER, and PERCIVAL. The author follows in part Percival's method, and gives a dichotomous table of 56 species which are classified and illustrated in the bulletin.

OF PLANTS

743 - **Composition of Citrus Leaves at Various Stages of Mottling** (1). — JENSEN, C. A. (Assistant in Plant Malnutrition, Office of Biophysical Investigations, Bureau of Plant Industry, U. S. Dept. of Agric.), in the *Journal of Agricultural Research*, Vol. IX, No. 6, pp. 157-166 Bibliography of 11 Publications. Washington, D. C., May 7, 1917.

Previous studies of the soil factors influencing the mottling of Citrus leaves in southern California have shown that the percentage of mottling of the Citrus leaves varies inversely with the humus content of soils in Citrus groves; that decomposing organic matter increases the amounts of soluble salts in the soil; and that a system of basin mulching in Citrus groves, especially on certain soil types, has produced an improvement in tree growth and fruit setting in comparison with the furrow system of irrigation and surface cultivation.

The purpose of the study here reported was to see if mottled Citrus leaves showed a deficiency of the mineral elements directly affecting chlorophyll formation.

It was found that very badly mottled orange and lemon leaves contained higher percentages of iron, calcium, magnesium, and phosphoric acid than healthy leaves, the average percentage of the entire leaf being considered. The leaves in the medium stages of mottling sometimes contained more and sometimes less of these elements than healthy leaves.

In nearly all cases the midribs of the healthy leaves contained less of the above mentioned elements than the mesophyll tissue. In badly mottled leaves the midribs contained a higher percentage of calcium than the mesophyll tissue, usually as much magnesium, and usually more phosphoric acid.

With very few minor exceptions, the leaf stems contained less iron, calcium, and magnesium than either the midrib or mesophyll area in both healthy and mottled leaves. The percentages of calcium, magnesium, and phosphoric acid, however, increased in the leaf stems of badly mottled Citrus leaves, but usually not in the medium mottled leaves.

Old leaves contained higher percentages of calcium and magnesium than new leaves not fully grown.

In all the Citrus leaves analyzed, the phosphoric acid was quite uniformly distributed in the midribs, the mesophyll tissue and the leaf stems (regardless of age or stage of mottling), indicating that phosphoric acid is early and freely transferred through the conducting tissue to the mesophyll areas. Sharply outlined yellow spots in the mesophyll areas of orange leaves contained less calcium, magnesium, and phosphoric acid than the green parts (mostly veins) of the leaves.

Judged by a comparison of the average percentages of the inorganic elements determined in healthy Citrus leaves and in leaves in the medium stages of mottling, the data obtained did not show that the initial mottling could be accounted for by deficiency in the transfer of the iron, calcium, magnesium, and phosphoric acid from the conducting system of the leaf stem and midrib to the mesophyll tissue. On the other hand, sharply localized yellow areas in old orange leaves contained less of these elements than the

(1) See also R. February 1918, No. 173. (Ed.)

adjoining green areas (mostly veins), but whether that relation obtained in the initial stage of mottling was not determined. In very badly mottled Citrus leaves there was in general an increase in the percentage of these elements in the conducting tissues, including the leaf stems, indicating difficulty in their transfer to the mesophyll tissues in very advanced stages of mottling, probably because the leaf had become functionless.

Green leaves and the green parts of spotted leaves of the golden privet (*Ligustrum aurea*) contained about twice as much calcium and appreciably more magnesium than the yellow leaves. Yellow leaves and the yellow parts of spotted leaves contained more iron than and about 2.5 times as much phosphoric acid as the green leaves or green parts of spotted leaves. Leaf stems of green privet leaves contained lower percentages of iron, calcium, magnesium, and phosphoric acid than the leaves. Leaf stems of yellow privet leaves contained about one-half as much phosphoric acid as the leaves; the percentages of iron and magnesium were about the same, while the leaf stems contained more calcium than the leaves. The leaf stems of yellow privet leaves contained higher percentages of calcium and magnesium than the leaf stems of green privet leaves.

- 744 - **The Fats and Fatty Acids of the Grain Sorghums.** — FRANCIS, C. K. and FRIEDMANN, W. G., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station, Stillwater, Oklahoma, Bulletin No. 117*, 11 pp., 1 fig., 5 Tables. Stillwater, Okl., October, 1917.

Six fatty acids have been shown to be present in kafir, feterita and milo fat, namely: oleic and linoleic, stearic and palmitic, butyric and formic, predominating in the order given. Traces of saturated acids higher than stearic acid are present in kafir and milo fat. The tables given by the authors show that the physical and chemical constants of the fats and fatty acids of kafir, feterita and milo are similar. The percentages of fat obtained by the extraction method were as follows: feterita 2.72-2.80; milo 2.53-2.61; kafir 0.89.

- 745 - **The Chymase of *Solanum elaeagnifolium*.** — BODANSKY, A. (Department of Physiology and Biochemistry, Cornell University, Ithaca), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 1, pp. 103-105. Baltimore, Md., 1916.

In New Mexico and Arizona the berries of *Solanum elaeagnifolium* are used as a substitute for rennet in the coagulation of milk. By means of maceration and precipitation with acetone the writer has extracted from the mature berries a chymase which possess the following properties:— It coagulates boiled natural milk without addition of calcium chloride. It proved more resistant to heat than animal rennin. In tests conducted between 37 and 55° C. the time of coagulation was inversely proportional to the quantity of the enzyme, other conditions being constant. Increase of temperature had the effect of increasing the rapidity of coagulation, but it also inactivated the enzyme. The optimum temperature was 84° C., in a dilution of one part of the solid enzyme preparation to 20 000 parts of milk, coagulation taking place in about 1 minute. In a dilution of 1:100 000 coagulation occurred in 10 minutes the enzyme being obviously inactivated.

germination advanced. It fluctuated in the cotyledon somewhat parallel to amide nitrogen, but in the shoot it decreased while amide nitrogen increased.

Amides accumulated in the shoot throughout all the different stages of germination, but not in such large proportions as previous investigators have reported. This may be due to the faulty methods of analysis formerly employed. In the cotyledon the amide nitrogen fluctuated somewhat at early stages, but later increased remarkably, while  $\alpha$ -amino-acids were disappearing rapidly.

Amides accumulated while carbohydrates and ammonia decreased. It may be inferred that they were produced synthetically from the latter compounds. The evidence for such a view from this study, however, is insufficient to be conclusive.

$\alpha$  amino-acids accumulated rapidly, especially in the cotyledon during the earlier stages of growth. In the later stages of growth they decreased considerably in the shoot and disappeared rapidly and completely from the cotyledon.

The accumulation of amides simultaneously with the decrease of  $\alpha$ -amino-acids and ammonia in the shoot indicates that  $\alpha$ -amino-acids serve for amide production in the nitrogen metabolism of the etiolated pea plant.

**748 - The Effect of One Plant on Another.** — PICKERING, SPENCER, in *Annals of Botany*, Vol. XXXI No 122, pp. 181-187 + 3 Figs. London, April, 1917.

As a result of numerous investigations started in 1895 the author noted the injurious effect which one plant may have on another. In a series of pot experiments he found the following species to be subject to such influence: — apple, pear, cherry, plum, six kinds of forest trees, mustard, tobacco, tomatoes, barley, clover and two varieties of grasses. The plants exercising the injurious effect were apple seedlings, mustard, tobacco, tomato, two varieties of clover and sixteen varieties of grasses.

Some plants can exercise this action on other individuals of their own species; this is the case with tobacco, tomato, mustard and apple. This may be compared with the well-known phenomenon of the bad development of a young plant near an older one. The author believes that the roots of the plant exercising the injurious influence secrete a toxic substance. Recent experiments confirmed this theory. He made three pot experiments with mustard. On the surface of the first pot was placed a tray containing soil, and so perforated that the water percolated through to the pot below. In this case growth was normal and there was no injurious effect. In the second test a crop of mustard was grown in the tray, but the holes were stopped and the water for the plants in the pot below was given to them direct. Growth was also normal in this case. The conditions in the third test were similar to those of the second, except that the holes were left open and the water for the plants below only reached them after having passed through the tray. In this test the growth of the mustard in the large pot was reduced to  $\frac{1}{100}$  of the normal growth.

The extent of this action varies greatly ; in pot experiments reduction in growth varies from 6 to 97 % ; in field experiments with trees it may be very small or sufficient to kill the plant.

Attempts have been made to explain this phenomenon by many hypotheses, such as rapid exhaustion of the soil, etc., but they have all been rejected. The toxic substance which appears to cause the action oxidises rapidly ; water containing it loses its toxic properties when exposed to the air for 24 hours.

749 - **Selection of Wheat in Ontario, Canada.** — ZAVITZ, C. A., in the *Ontario Department of Agriculture, Agricultural College, Bulletin 261*, pp. 30 + 4 Figs. Toronto (Ontario), February, 1918.

PLANT  
BREEDING

WINTER WHEAT — 1) The mass selection method is still followed by the Canadian Seed Growers' Association and by some experiment stations. Seed obtained in the third year after three successive selections is sold as a guaranteed selected product.

2) An excellent example of the results of individual selection is shown by the winter wheat Dawson's Golden Chaff derived from a plant isolated in 1881 near Paris, Ontario. This plant, remarkable in the midst of lodged wheat on account of the strength and elasticity of its straw, which prevented its lodging, transmitted its character to its descendants, which now form one of the favourite wheat varieties. By individual selection of the variety Imperial Amber a pure line was obtained with a yield exceeding that of the parent variety by 3.9 bushels per acre.

3) The hybrids Dawson's × Tasmania Red, Dawson's × Bulgarian and Dawson's × Turkey Red gave in all cases an average grain yield superior to that of the parent plants.

The cross Dawson's × Bulgarian gave a new variety, O. A. C. No. 104, which, during 6 years, gave an average of 45.0 bushels per acre, *i. e.*, 4.2 bushels more than Dawson's and 7.5 bushels more than Bulgarian. Not only did O. A. C. exceed the yield of both its parent plants, but it also exceeded the other varieties more widely grown in Ontario — Imperial Amber, Kharkov and Yaroslaf. The new variety is beardless, like Dawson's and has white glumes, like Bulgarian.

In addition to these selection experiments numerous tests were made on yield, resistance to rust and lodging, with the following results : —

The average grain yields for 5 years were : — Imperial Amber, 45.8 bushels per acre ; Kharkov, 45.7 bushels ; Gillespie Red, 45.2 bushels ; McBean's Golden Chaff, 45.1 bushels ; Tuscan Island, 44.9 bushels ; Grand Prize, 44.7 bushels ; American Banner, 44.6 bushels. These are the varieties best suited to the district. Theiss, Kharkov, Tuscan Island, Yaroslaf and Banatka were freest from rust ; Tystofte Smaa and McBean's Golden Chaff were both badly attacked. Dawson's Golden Chaff, American Banner, Imperial Amber, Michigan Amber, McPherson and Scott were the earliest varieties. The varieties with the weakest straw and, consequently, most subject to lodging, were Banatka, Theiss, Crimean Red, Geneva and Kharkov.

SPRING WHEAT. — 1) A new hybrid obtained by crossing the Red Fife

and Herison Bearded varieties gave, on a five year average, a yield (40.7 bushels per acre) superior to any of the spring varieties tested in Ontario.

The results are given of numerous selection experiments with spring and winter wheat and rye, all of which confirm the influence of selection of the largest and heaviest seed on the crop.

**750 - Increased Self-Fertilisation of Petkuser Rye by Pure Line Selection, in the Netherlands.** — MEYER, GMELIN H., in *Cultura*, Year XXX, No. 353, pp. 14-19. Wageningen, 1918.

In 1915 the author sorted out 56 ears of Petkuser rye in order to determine whether distinct and improved types could be isolated by pure line selection. The results are of special interest with regard to the self-fertilisation of rye (1).

In 1916 the plants of each strain were divided into three groups:— 1) plants freely exposed to cross-pollinisation; 2) plants the inflorescences of which were partially isolated with muslin, the web being coarse enough to let pass a certain amount of pollen carried by the wind; 3) plants the inflorescences of which were completely isolated with parchment.

In 1917 the ears of a certain number of descendants of each of these three groups were completely isolated before flowering by bags of parchment. The plants thus subjected to forced self-fertilisation showed marked differences in the percentage of setting. Some, as those of line 3, had as much as 57 seeds per ear, whereas others did not produce as much as a single seed. Line 3 was remarkable for its high degree of self-fertilisation, with an average of about 20 seeds per ear. It is, therefore, possible by pure line selection to isolate types of rye with a degree of self-fertility much above the normal.

The author intends to continue this selection work taking into consideration the shape and colour of the ear. The original number of strains has been gradually reduced to three — Nos. 28, 37 and 3 — by successive elimination of the worthless ones. Line 28 has an ear with square section of the real Petkuser type. Line 37 is characterised by a special colour of the unripe ear and by a tendency to produce three seeds per spikelet, which makes it very broad and compact. As has been already said, line 3 ranks first in self-fertilisation.

**751 - Selection Experiments with Two Cultivated Oats According to the Position of the Seed in the Spikelet, in France.** — DANTEL, L. and MIRGE, E., in *Annales des sciences naturelles*, Vol. XX, Nos. 1-6, pp. 289-308 + 11 Tables + 6 Figs. Paris, 1917.

The spikelets of oats are composed of a variable number of alternate flowers which may be arranged as follows:—

1) Two fertile flowers, internal and external, and a much larger and more membranous sterile flower;

2) Three fertile flowers, one of which, known as "intermediary", is between the external and internal flowers;

(1) The degree of self-fertilisation of rye is very low; the percentage of setting in self-fertilised plants rarely exceeds 5 %. See R. Feb., 1918, No. 146. (Ed.).

3) A single fertile flower called "single" flower, and one rudimentary sterile flower; the former represents the external flower of the preceding cases.

Four very different kinds of seed correspond to the various flowers:—*a*) external; *b*) single; *c*) intermediary; *d*) internal. The size, morphological peculiarities and proportion of these seeds serve to differentiate the principal varieties of cultivated oats. It is generally admitted that the external seeds are heavier than the internal ones, but the kernel is not so plump. As regards weight and construction single seeds closely resemble external seeds, intermediary seeds internal ones.

This has been shown by the work of various authors (chiefly DENAÏFFE & SIRODOT, DUFOUR), but up to the present no investigation appears to have been made into the agricultural value of these different seeds and the possibility of a selection based on their separation, and the advantages to be derived therefrom. Nevertheless, the very position of these different seeds on the inflorescence and their respective development seems to show that there exists between them, in addition to their morphological differences, physiological differences capable of being transmitted to their descendants.

In order to solve this question the authors undertook from 1910 to 1913 a set of experiments the results of which they now give.

In the first place, from a commercial lot of the two varieties, Canadian white oats and Brie black oats, 1 000 seeds were chosen at random, and divided into the four above mentioned groups to determine the proportion. A predominance of intermediary seeds was found in the white oats, and of external ones in the black oats.

An equal number (300) of the seeds of each group and the original mixture was sown in separate plots in order to determine the yield and characters of the descendants. The yields of the four groups (I-IV) and the original mixture (V) were:—

*White oats.* — I) 245 gm.; II) 195 gm.; III) 175 gm.; IV) 215 gm.; V) 210 gm.

*Black oats.* — I) 135 gm.; II) 250 gm.; III) 160 gm.; IV) 130 gm.; V) 180 gm.

In white oats, therefore, the external seed gave the highest yields, in black oats the single seeds. This shows that the position of the seed on the spikelet does not influence the yield.

It was of interest to know whether the descendants of the external seeds of white oats and the single seeds of black oats were respectively richer in external seeds and single seeds, and, consequently more productive than the parent variety. To test this the descendants of each of the above groups of seed were sorted in 1911 with the following results:— in white oats the *single* seed predominated in the descendants of each group, being most numerous in those of the *internal* seeds. In black oats, on the contrary, the *external* seeds predominated, reaching their maximum in the descendants of the *intermediary* seeds. Thus, in spite of selection, the same type of seed (single in white oats, external in black oats) was

predominant in all the groups. Moreover, selection did not accentuate or even preserve, the character which it should have perpetuated, for the number of seeds in each category was about the same from whatever kind of seed it was derived.

The inefficiency of the selection was also clear when the composition of the descendants of the sorted and mixed seeds was compared. The differences were very small, practically negligible, and all the seed, whether sorted or not, may be said to have given the same result.

Determinations were also made for each group of the weight of 100 seeds and the relative proportion, in weights, of the coat and kernel. It was found that these factors depend neither on heredity nor selection, but vary according to the varieties and environmental conditions (climate, etc.).

CONCLUSIONS. — 1) The proportion of the different seeds, as characterised by their position on the spikelet, is not hereditary but subject to environmental conditions the influence of which is manifest in a different way according to the variety under consideration.

2) The weight of the different seeds is very variable.

3) Selection based on the separation of these different seeds is of slight value as regards their distribution among the descendants, their weight, or the relative proportion of coat and kernel.

4) The different seeds are of unequal value as regards yield and the quality of the product, but these values are not characteristic of the seed and vary with the variety and climatic conditions.

5) The 1913 experiments gave results differing slightly from those of the preceding years; they showed the actual and general predominance of two-seeded spikelets, but this predominance, present in all the groups whatever their origin, cannot be attributed to selection.

6) Finally, if the position of oat seeds on the spikelet gives them certain morphological peculiarities (known for a long time and enabling them to be easily distinguished), it gives them no physiological property or special hereditary quality so that it does not make efficient selection possible.

752 — **The Inheritance of Characters in Rice, in India.** — PARNELL, F. R., RANGASWAMI AYYANGAR, G. N., and RAMIAH, K., in *Memoirs of the Department of Agriculture in India, Botanical Series*, Vol. IX, No. 2, pp. 75-105 + 21 Tables + 5 Coloured Plates. Calcutta, November, 1917.

The experiments described were started at the Government Farm of Coimbatore in 1913 with about 100 varieties of rice.

SIZE OF OUTER GLUMES. — The rice spikelet is single-flowered, with two outer sterile glumes, 1 inner fertile glume, and a palea; these two last are joined and referred to together as inner glumes. The outer glumes are small, rarely more than  $\frac{1}{4}$  to  $\frac{1}{5}$  the length of the inner glumes, except in the Rakki Pakshi Bhatta variety in which both kinds of glume are about the same length.

In a plot of rice with short outer glumes which had been exposed to cross-fertilisation, were found several varieties with long outer glumes. Eight of these were selected and all their descendants were long glumed. On the other hand some of the short-glumed varieties transmitted this

character without change, whereas others had mixed descendants including short-glumed and long-glumed plants in the Mendelian ratio of 3 : 1, thus showing the short-glumed character to be dominant to the long-glumed.

**GOLDEN COLOUR OF INNER GLUMES AND INTERNODES.** — The colour is usually light green, but in many cases it is gold, and when such this character is recessive to green, the ratio of green-glumed to gold-glumed plants in  $F_2$  being 3 : 1. In other cases transmission of colour is so complicated as to suggest the presence either of another determinant for the gold which is incompletely dominant to green, or of an inhibitory factor acting only on the glumes, the internodes remaining golden.

**FACTOR CONCERNED IN THE DISTRIBUTION OF COLOUR IN THE GLUMES.** — The inner glumes are often of a characteristic blackish-brown colour which affects the furrows more particularly. As the golden colour, the blackish-brown may be subjected to a factor which localises it in the centre of the glume, the top and base of which remain entirely green. This factor is dominant; in  $F_2$  the respective numbers of plants with piebald glumes and those with glumes of uniform gold or with blackish-brown furrows down their whole length, are in the Mendelian ratio of 3 : 1.

**PURPLE PIGMENTATION.** — This is due to the presence of anthocyanin in the cell sap. The character "pigmented" is dominant to the character "unpigmented". Between the pigmented and unpigmented individuals there are the two ratios 3 : 1 and 9 : 7, which suggests the presence of two distinct factors of pigmentation. This hypothesis was confirmed by the results of an experiment in which purple pigmented plants were obtained from a cross between the unpigmented Garudan Samba variety with an  $F_3$  hybrid, also unpigmented. The two purple factors were evidently distributed in a heterozygous state in the two parents.

**DARK PURPLE COLOURING OF THE PULVINUS AND AURICLE.** — In the absence of the factor causing this colour the *pulvinus* (swollen zone at the base of the leaf-sheath immediately above the node) and the auricle remain green or greenish-white. In this case the pigmented character is also dominant.

Similar conditions also govern the purple pigmentation of the leaf-sheath; this pigmentation often extends to the ligule.

**PURPLE LINING OF INTERNODE (L), PURPLE GLUMES (G), PURPLE STIGMA (S), PURPLE AXIL (A).** — To study these characters, the determinants of which are expressed by the letters in parenthesis, a cross was made between two plants of the Basangi variety, one of which had purple lining of the internode, purple glumes and no pigmentation of the stigma or axil (LLGGssaa), the other purple stigma and axil but no pigment in the other organs (llggSSAA).  $F_1$  gave a hybrid with the formula LlGgSsAa.

In  $F_2$  it was found that each character, considered separately, is dominant to the character "unpigmented". Considered together, however, these characters showed that:— 1) purple lining is associated with purple glumes (L and G in conjunction); 2) purple stigma is associated with purple axil (S and A in conjunction); 3) green internodes and glumes are associated with purple stigma and axil. In  $F_2$  there are, then, only three

distinct types:— **LGsa**, **LGSA**, **lgSA**, present in the ratio 1 : 2 : 1; thus **L** is coupled with **G**, **S** with **A** and **LG** repels **SA**.

The  $F_1$  hybrid with the formula **LlgGssAa** thus only forms two types of gamete: **LGsa** and **lgSA** which combine in  $F_2$  to form 1 **LLGGssaa**, 2 **LlgGssAa**, 1 **llggSSAA**, i. e., two pure types resembling the parents and 1 type resembling the  $F_1$  hybrid.

The two factors **S** and **A** are constantly coupled and the authors never found any exception to this rule. **L** and **G**, however, sometimes show aberrant types thus proving the connection between them to be less strong than that between **S** and **A**. Cases of repulsion were observed not only between the two groups **LG** and **SA**, but also between **LG** and **S**, **G** and **S**, **L** and **S**.

**RIPENING BLACK CHARACTER OF INNER GLUMES.** — In certain varieties of rice, when the grain begins to ripen the glumes turn almost entirely black, becoming paler later so that, when ripe, they are of a dull smoky colour. The black character is dominant to the straw-coloured character and evidently depends on two factors. This was shown by an examination of  $F_2$ , in which the number of plants with black glumes and yellow glumes respectively were in the ratio of 3 : 1 or 9 : 7, according to whether the parent is heterozygous for one or both of these factors.

**COLOUR OF THE GRAIN.** — The colour of husked rice varies, from white through a series of intermediate shades, to red.

By crossing the Sadai Samba (white) and Boru Muruthagna Bhatta (red) varieties, were obtained, in  $F_2$ , red-grained and white-grained individuals in the ratio of 3 : 1. Red therefore is dominant to white.

In certain cases, however, the segregation of these characters is more complicated.

Two natural red varieties gave, in  $F_2$ , three definite groups, — a) full-red grain, b) grey-brown grain and c) white grain, in the ratio 9 (red) : 7 (grey-brown × white) as if the red were due to the simultaneous presence of two factors one of which by itself produces the grey-brown type. On the other hand, further investigation including  $F_3$  and  $F_4$  tends to show that full red is due to one single determinant, which produces red in the presence of the purple pigmentation factor, and grey-brown in its absence.

**Improving Alfalfa by Selection and Hybridisation in Manitoba, Canada.** — Southworth, W., in *The Agricultural Gazette of Canada*, Vol. V, No. 2, pp. 158-162 + 2 Figs. Ottawa, February, 1918.

The experiments described have been carried out since 1915 at the Manitoba Agricultural College with the aim of producing types of alfalfa suitable for forage and seed, and, at the same time, resistant to the low temperatures of the Canadian winter.

**PURE STRAIN SELECTION.** — At present the plants being tested number 4,000 and belong to 8 different strains, one of which seems to unite in good proportions a high forage yield and high seed yield.

**HYBRIDISATION.** By crossing common alfalfa (*Medicago sativa*) with the yellow-flowered type (*Medicago falcata*) known for its resistance to

low temperatures, 31 plants were obtained in the  $F_1$  which are remarkable for their strength and vigour.

It is hoped to isolate types valuable both for their yield in forage and resistance to cold.

754 - Sugar Beet Seed Production and Stock of the United States. — I. Beet Seed Crop of 1917 Larger; Acreage Smaller, in *Facts About Sugars*, Vol. VI, No. 2, pp. 27. New York, 1918. — II. Beet Seed Report Issued. *Ibid.*, No. 13, pp. 253. — III. Country Has Ample Beet Seed Supply for Season; *Ibid.*, No. 15, pp. 287. (1).

AGRICULTURAL  
SEEDS

The sugar beet seed production of the United States during the year 1917 is reported by the Department of Agriculture at 5 546 000 lb., an increase of 335 000 lb. or rather more than 6 per cent over the crop of 1916. While the seed production was larger, the acreage devoted to cultivation of seed beets was 13 per cent less than in 1916, the crop of 1917 being grown on 4 579 acres, as compared with 5 268 acres devoted to seed beets in the preceding year.

The far western States of California, Idaho and Utah were responsible for the increase in production in 1917, the other seed producing areas showing a decrease. In these three states the crop last year was 2 458 000 as against 1 628 000 lb. in 1916, a gain of 51 per cent. The acreage devoted to seed production in these States was 2 523, as compared with 2 178 in the year before, an increase of 15 per cent.

In the other great seed producing area, embracing the states of Colorado, Kansas, Nebraska and Montana, the seed crop of 1917 was 12  $\frac{1}{2}$  per cent. smaller in 1917 than in 1916, the figures being 3 030 000 lb. for last year and 3 445 000 lb. for the year before. In 1916 this territory produced 66 per cent. of the country's total seed crop while last year its production was only 54.5 per cent. of the total. The acreage devoted to seed beets decreased in this territory from 2 725 acres in 1916 to 1 978 acres in 1917, a decrease of nearly 28 per cent.

AND BULL  
CROPS

Beet seed production in Michigan and Ohio in 1917 was only 58 000 lb., as compared with 128 000 lb. in 1916, a falling off of more than half. The area in seed beets in these states decreased from 365 acres in 1916 to only 78 acres last year.

In point of production per acre the Colorado-Kansas-Nebraska-Montana territory made the best showing, obtaining an average of 1 532 lb. of seed to the acre, as against an average of 974 lb. to the acre for California, Idaho and Utah and an average of 744 lb. to the acre for Michigan and Ohio. The Great Western Sugar Company, the Utah-Idaho Sugar Company and the United States Beet Seed Company were the country's largest producers.

According to the final figures on sugar beet seed stocks in the United States on January 31, 1918, as collected by the War Emergency Seed Survey, there were on hand 19,249,371 lb. of imported beet seed, and 7,947,614 lb. of home grown seed, a total of 27,196,985 lb. (1)

As compared with the corresponding date of 1917, the report shows an increase of 3,740,918 lb. in the stock of imported and 2,495,443 lb. in the

(1) See R. 1917, No. 139, (E4).

stock of domestic seed, making a combined increase of 6 236 361 lb. or nearly 30 per cent., during the year. Importation of sugar beet seed into the United States during the twelve months' intervals, as reported by the Department of Commerce, amounted to 15 437 797 lb.

Checking up these figures for stocks on hand at the two dates and of receipts in the interim, it appears that the domestic sugar beet crop of 1917 required in the planting a total of 14 747 436 lb. of seed. The beet acreage for 1917 is estimated by the Department of Agriculture, at 675 400 acres, which works out at an allowance of 21.8 lb. of seed to the acre. This, however, takes no account of replantings nor of acreage planted which yielded no crop.

As regards seed supplies for the coming season and for that to follow it is apparent that there is sufficient seed on hand to plant a normal beet acreage for 1918, including the necessary replantings, and that after the planting season is over there should be a surplus of from 20 to 25 per cent. of the sugar beet seed requirements for 1919. Very little sugar beet seed has been imported since January 31, 1918, and it is not probable that any large quantity will be imported before the close of the 1918 planting season.

In view of the small surplus that will remain after the 1918 planting has been finished, it is evident that a considerable increase in domestic seed production, together with a large importation of seed, will be necessary in order to make possible a normal sugar beet acreage in 1919. Reports indicate that the beet sugar companies are awake to the situation and are preparing to increase their seed production this year.

**755 — The Best Varieties of Italian Rice.** — NOVELLI, N., in the *Giornale di Agricoltura della Domenica*, Year XXVIII, No. 17, p. 89 + 4 Figs. Piacenza, April 28, 1918.

The great number of varieties of Italian rice is a disadvantage which the "R. Stazione sperimentale agraria di risicoltura" of Vercelli is trying to overcome by selection, organisation of the production of selected seed, and the supply of such seed to growers. This would allow the cultivation of a limited number of the best varieties of rice.

The most productive varieties are known as "common", whereas the "semi-fine" or "fine" ones are earlier and more appreciated for the quality of their produce. At the present time, when a large production is essential, the author advises that the following varieties be sown: — "Chinese originario" or "Abbondanza"; "Onsen", now acclimatised and grown in North Italy on account of its very high yield and relative earliness; some of the good early types derived from "Chinese originario" (1) more suited to cold, shady soils and late sowing; these rices do not suffer from lack of nitrogenous fertilisers because they have little herbaceous growth and much seed — 60 % or more of paddy and 40 % or less of straw; "Lencino", which in suitable soils gives very high yields and does not drop its grain, even when ripe; "Ranghino" (2); "black" and "yellow Vialone". As varieties for transplanting "Chinese originario" and "Onsen" are especially recommended because they tiller rapidly and give a maximum crop. Where

(1) See R. 1917, No. 330. — (2) See R. 1916, No. 34. (Ed.)

it is necessary to increase the acreage under cereals at the expense of fields already fertilised and prepared for forage, it is advisable to make the first and most important cut of hay, then to transplant the rice, which in the meantime, has been grown in seed-beds.

To encourage the transplanting of rice the Ministry of Agriculture offers rewards of 30 to 50 lire per hectare (about 10s. to 16s. pr acre), to be divided between the most skilled growers and labourers.

**756 - "Early Dellarole" Rice.** — MARCARELLI, B., in *Il Giornale di Riscoltura*, Year VIII, No. 3, pp. 35-38 + 1 Fig. Vercelli, March 31, 1918.

This variety was isolated in 1911 from a rice from China by Signor NICOLAS DELLAROLE of Vinzaglio (province of Novara) who tested it under the most varied conditions. Having convinced himself of the constancy and uniformity of the descendants, he distributed it for cultivation on a large scale. It is now used not only in the districts bordering on that from which it originated, but also wherever it has been tested.

The principal characters of this new rice are :— easy adaptation to the most-varied soils, perfect grain from a commercial point of view, marked earliness. As it ripens in 120 to 130 days from the date of sowing, it is much to be recommended for old rice fields with cold damp soil so long as the irrigation water is warm. It also does well in new fields, converted from meadows, so long as nitrogenous fertilisers are not used excessively, as in this case it lodges. The author describes it as follows :— erect, little inferior in vigour to "Chinese originario"; culm relatively thin, not very resistant to lodging, arched at the cyme with white nodes, leaves removed from the culm, short and light green till earing, panicles rather close and arched, of average length and breadth, with long spikelets at their base; caryopses few, longer than those of "Chinese originario", of a fine straw colour when ripe; glumes not very thick, almost or entirely glabrous, with slightly defined sides and rudimentary awn; glumelles well developed, white, standing out well at the base of the glumes. The interior of the caryopsis contains a very thin, light perisperm (coat) and a compact, vitreous endosperm (albumen), giving a very transparent, pearly, commercial product which is much appreciated.

Tillering is limited, but hardly inferior to that of most early rices, and the ratio between the weight of grain and that of straw is about equal to that of "Chinese originario".

Ripening occurs during the first days of September, whatever the date of sowing (from March to the first week of May) and is rarely as late as the middle of the month. The yield is from 1.79 to 1.83 tons of paddy per acre; under the best conditions this yield may reach and even exceed 2 tons per acre.

Examination of the culms, panicles, caryopses, etc., gave the following result :—

Average height of plant . . . . .	90-100	cm.
Length of panicles . . . . .	17-20	
Number of spikelets per panicle . . . . .	7-9	

In view of its great earliness the new variety does not attain the maximum yield of "Chinese originario". It is advisable to sow it rather closely, not less than 1.11 to 1.19 cwt. of paddy per acre and 1.36 to 1.43 cwt. per acre when it is sown very late in old fields with cold soil.

— *Bulletin de la Direction générale de l'Agriculture, du Commerce et de la Colonisation de la Régence de Tunis*, Year XXI, No. 92, pp. 158-184. Tunis, July, August, September, 1917.

A general outline of the economic and environmental conditions, parasites and diseases is given, followed by a description of the principal crops, containing information useful to all those interested in Tunis.

There are some Leguminosae among those described which are of particular interest. The cultivation of beans, horse beans and chick peas, already adopted over wide areas of the Régency, should be yet more widely extended. Lentils, one of the Leguminosae hitherto little cultivated, should do well and give a high yield per acre. Peas could also be grown with good results and fetch high prices; in normal times France imports nearly 900 000 cwt of peas annually.

The dwarf bean is less strong and needs favourable positions. For this reason its cultivation must be tested for some time before its extension can be recommended.

758 - *Canna edulis* in Trinidad.—FREEMAN, W. G., in the *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XVI, Pt. 4, p. 174. Trinidad, 1917.

As in many other tropical countries *Canna edulis* is abundant in Trinidad and Tobago, where it is known as "tous les mois". It is cultivated in gardens, and, in cases where it has escaped cultivation, grows wild. The boiled roots may be eaten by human beings, and, in some countries such as Queensland, they are used for the extraction of starch. A sample analysed at Hawaii showed the following composition for the small and big roots respectively, the composition being similar to that of the potato:— Water

81.58, 65.86; nitrogen-free extract 15.57, 31.34; protein 1.37, 1.20, fat 0.13, 0.15, fibre 0.54, 0.64; ash 0.81, 0.81.

The plant is easily grown by planting pieces of the root at distances of 1 foot in rows 3 or 4 feet apart. It takes from 6 to 8 months to ripen, and, at Trinidad produces about 15 tons per acre. The roots keep well, and when stored in sacks do not decay for three months.

Recently (*Report of the Hawaii Agricultural Experiment, 1916*) the cultivation of this plant as a food for pigs was recommended.

**759 - *Canavalia ensiformis*, and *C. gladiata* in Trinidad and Tobago.** — SHERWESBURY, HERBERT S., in the *Bulletin of the Department of Agriculture, Trinidad and Tobago*, Vol. XVI, Pt. 2, pp. 65-67; Pt. 4, pp. 224-225. Trinidad, 1917.

FORAGE CROPS,  
MEADOWS  
AND PASTURES

Since 1915 *Canavalia ensiformis* has made considerable progress in Trinidad as a cover crop in coconut and cacao plantations. The fact that the dry beans (white) are edible makes it preferable to other cover crops. It is also a good quality forage. *C. gladiata*, is similar to the preceding plant, but of stronger growth with brownish-yellow or red seeds. It may be put to the same uses.

Analyses of the seeds, the results of which are given below, showed that the two species contain no hydrocyanic acid:— *C. ensiformis*. — Water 15.5, carbohydrates 45.2, protein 27.6, fibre 5.4, ash 3.1, fat 3.2, food units 122; weight of whole bean 1.97 gm., percentage of skin 14.4. *C. gladiata*. — Water 12.7, carbohydrates 53.6, protein 25.1, fibre 2.4, ash 2.9, fat 3.3, food units 125; weight of whole bean 2.73 gm., percentage of skin 15.5.

The nutritive value of these beans is equal, or even superior, to that of French kidney beans.

**760 - Growing Sorghum in Kansas.** — CUNNINGHAM, C. C. and KENNEY, RALPH, in *Agricultural Experiment Station, Kansas State Agricultural College Bulletin No. 218*, 54 pp., 15 tables, 24 Figures. Manhattan, Kansas, 1918.

The authors base their statements on experimental data and the experience of practical farmers in all parts of Kansas. The summary of their work is given below.

The sorghums are more resistant to heat and drought than maize. They are, therefore, more profitable in those sections where, because of drought, hot winds, and shallow soils, maize is not a reliable crop. Sorghum will outyield maize as a forage or silage crop in any part of the state.

Sorghum leaves the ground in poor condition for the following crop, and is therefore commonly considered hard on the ground. Pound for pound of material produced, sorghum does not remove more fertility than other crops.

Crops that make their growth during the latter part of the growing season should follow sorghum rather than autumn or early spring seeded crops like wheat or oats.

The varieties of grain sorghum most extensively grown in Kansas are Blackhull kafir, Pink kafir, Dwarf Blackhull kafir, Dwarf milo, and Feterita. Blackhull kafir gives best results with favourable conditions. Pink

kafir yields better than the Blackhull variety on poor soils or in unfavourable seasons, or where the growing season is too short for the latter. Dwarf milo and feterita and other early varieties are grown where the season is too short, or the rainfall too deficient, for Pink kafir. The varieties of the sorghos or sweet sorghums most extensively grown in Kansas are :— Black Amber, Red Amber, Orange and Sumac. The Red Amber is the best variety for western Kansas. Kansas Orange and an early strain of Sumac are best for eastern Kansas.

Three methods of planting the sorghums are employed in Kansas :— surface planting, open furrow planting, and listing. Surface planting is best on heavy, poorly drained soils in eastern Kansas. The open furrow method, which consists of seeding in rather shallow furrows made by two discs set on either side of the planter shoe, usually gives the best results in eastern Kansas, where drainage is good and rainfall abundant. Listing is practical, and generally the best method in western and central Kansas.

Usually the sorghums should be planted about ten days later than maize.

Rowed sorghum for grain should be seeded at the rate of 4 to 8 pounds per acre, depending on the soil and rainfall. If grown for forage or silage this amount should be doubled. Sorghum broadcasted or drilled for hay should be seeded at the rate of 1 to 2 bushels per acre. It should be sown later than sorghum for grain. Rowed sorghum should receive as thorough cultivation as maize.

The proper stage to harvest rowed sorghum depends on the purpose for which it is intended. Sorghum for feed should be cut when the grain is in the dough stage. For silage it should be cut when in the hard dough stage, or nearly ripe. For grain, it should be cut when fully mature. For syrup it should be harvested in the dough stage. Sorghum drilled or broadcasted for hay should be cut in the milk or soft dough stage. It makes the best quality of feed when it reaches the proper stage for cutting just before frost.

Sorghum cross-fertilises readily, which almost always results in deterioration. Continual roguing to remove hybrid and foreign heads is necessary to maintain a pure variety. Sorghum seed for home use should be field selected and kept in the head until planting time.

Sweet sorghum is utilized to a limited extent in Kansas for syrup production. This industry is increasing.

The grain sorghums, kafir, milo and feterita, when properly fed, are but slightly inferior to maize for feeding livestock. They are similar to maize in composition, but are not as palatable, and a smaller percent of the nutrients is digestible. Feeding tests carried out at the Kansas Agricultural Experiment Station indicate that they have from 85 to 90 per cent of the feeding value of maize for fattening hogs and cattle and from 90 to 95 per cent for fattening sheep. Sweet sorghum and kafir make excellent forage. Sorghum silage is about equal to maize silage.

The sorghums are comparatively free from diseases and insect enemies. Kernel smuts is the only serious sorghum disease in Kansas. This

can be readily controlled by treating the seed with formaldehyde (40 per cent solution). Chinch bugs, grasshoppers and the kafir ants are the only insect enemies that seriously damage sorghum in Kansas.

761 — Experiments on the Cultivation of *Paspalum dilatatum* in the Colonial Garden of Palermo. — *Bollettino di Studi ed Informazioni del R. Giardino coloniale di Palermo*, Vol. IV, Pt. 2, pp. 54-57. Palermo, 1917.

*Paspalum dilatatum*, grown in the Colonial Garden of Palermo, did very well without irrigation. It reached an average height of from 3.38 to 4.92 feet. Sown in autumn it was already well developed in April. It was cut during the first days of June and yielded 14 tons of hay per acre.

762 — Oil Yielding Plants of Indo-China. — CREVOST, CH., in *Bulletin économique de l'Indochine*, Year XX, New Series, No. 127, pp. 563-619 + 18 Plates. Hanoi-Haiphong, November-December, 1917.

PLANTS  
YIELDING  
OILS, DYES  
AND TANNINS

The author (Agricultural and Commercial Inspector, and Curator of the Agricultural Museum), after having described the present situation in Indo-China with regard to the production of oil-yielding plants and oils, and its possible development, gives a detailed list of the oil-yielding species capable of being used industrially or commercially. The plants are studied, classified in families, with their scientific names, synonyms, common and native names, geographical distribution, description, extraction, and the quality and value of their oil.

Myristicaceae. — *Knema*, *Myristica glaucescens* Hook f. and Th. = *Knema corticosa* Lour = *M. corticosa* Hook f. and Thoms.

Bixaceae. — 1) Lucraban, *Hydnocarpus anthelminticus* Pierre. 2) Chaumoogra (1), *Taraktogenos Blumei* Hassk. — 3) False chaulmoogra, *Gynocardia odorata* R. Br.

Guttiferae — 1) *Calophyllum inophyllum* Lin. — 2) *C. Thorelii* Pierre — 3) *C. Balansa* Pitard. — 4) *Garcinia tonkinensis* In. Vesque, Cày-doc (2).

Ternstroemiaceae. — Tea-oil plant, *Thea sasangua* Nois = *T. oleosa* Lour = *Camellia drupifera* Lour.

Malvaceae. — Cotton plant: 1) *Gossypium herbaceum* Lin. and 2) *G. hirsutum*.

Bombacaceae. — Kapok of Indo-China: 1) Silk cotton tree, *Eriodendron anfractuosum* D. C. — *Bombax pentandrum* Lin. = *Eriophorpos Javana* Rumph = *Gossampinus alba* Ham. = *Eriodendron Rheedii* Planch. — 2) Silk Cotton Tree, *Bombax malabaricum* D. C. = *B. Ceiba* Lin. = *B. heptaphylla*.

Sterculiaceae. — 1) *Sterculia cochinchinensis* Pierre — 2) *St. foetida* Lin. — 3) *St. Pexa* Pierre. — 4) *St. Lævis* Wall. — 5) *St. alata* Roxb.

Meliaceae. — *Amoora* sp.?

Simarubeae. — 1) *Irvingia malayana* Pierre — 2) *I. Oliveri* Pierre.

Sapindaceae. — 1) Soapnut tree, *Sapindus Mukorossi* Gaertn.

= *Paviesia annamensis* Pierre. — 3) *Schleichera trijuga* Wild. = *Melicoca trijuga* Juss. = *Sch. pubescens oleosum* Pierre. — *Stadmannia Sideroxylon* — *Cussambium oleosum*.

Anacardiaceae. — *Buchanania latifolia* Roxb.

Moringaceae. — Horse radish tree, *Moringa pterigosperma* Gaertn. = *M. oleifera* Lamk = *M. zeylanica* Pers. = *M. polygona* D. C.

Leguminosae. — 1) Pea nut, *Arachis hypogea* Lin. — 2) Soja = *Glycine Soja* Sieb. and Zucc. = *G. hispida* Miq. = *Dolichos Soja* Lin. = *Soja hispida* Moench.

Rosaceae. — *Parinarium Annamense* Hance,

Combretaceae. — Malabar almond tree, *Terminalia Catappa* Lin.

Cucurbitaceae. — 1) *Hodgsonia heteroclita* Hof. and T. — 2) *Momordica cochinchinensis* Spreng = *Muricia cochinchinensis* Lour = *Momordica mixta* = *M. dioica* Wall.

Pedaliaceae. — Sesame, *Sesamum indicum* Lin. = *S. italicum* Retz. = *S. orientale*.

Labiatae. — Perilla, *Perilla ocymoides*,

Sapotaceae. — Tonkin Bassia, *Dasilippa Pasquieri* M. Dub.

Lauraceae. — 1) Litsea, *Litsea citrata* Bl. — 2) *Teranthera sebifera* Pers.

Rutaceae. — 1) Shaddock tree, *Citrus decumana* Murr. = *C. costata* Rafn.

Euphorbiaceae. — 1) *Aleurites montana* Wils., 2) Candle nut tree, *Aleurites moluccana* Forst., 3) *Stillingia sebifera* Michx., this is the Cáy-soi (=tallow tree); this is followed by an extract of the report of M. GROSJEAN of the Lyons Mission in China, pp. 385-389; 4) *Rottlera sebifera*; 5) Croton, *Croton tigtium* Lin.; 6) Physic Nut tree, *Jatropha curcas* Lin., (1); 7) Makken; 8) Castor Oil, *Ricinus communis* Lin.; 9) *Hevea brasiliensis*

Urticaceae. — Hemp; 1) *Cannabis sativa* Lin. and 2) *C. gigantea*.

Coniferae. — Pine.

Palms. — 1) Coconut, *Cocos nucifera* Lin. — 2) Oil Palm, *Elaeis guineensis* Jacq.

STIMULANT,  
AROMATIC,  
NARCOTIC  
AND  
MEDICINAL  
PLANTS

763 — Coffee in Abyssinia. — SPALLETTA, A., in *L'Agricoltura Coloniale*, Year XI, 1st. Half-Year, No. 1, pp. 70-88; No. 2, pp. 111-132 + 2 Plates; No. 3, pp. 196-222 + 1 Map; No. 4, pp. 284-297; Bibliography of 138 Publications. Florence, February 28, April 30, June 30, August 31, 1917.

WILD AND CULTIVATED SPECIES AND VARIETIES. — Coffee is not a native of Arabia, as many wrongly believe, but of the high mountains in the south-west of Abyssinia, where it grows wild and where the purest, most aromatic and most appreciated varieties are found. The wild or cultivated Abyssinian varieties are: "Ennaria" or "Naria", "Arrari" or "Arrarino", "Zeghié", "Gentel".

The "Ennaria" coffee plant is the stock from which all the other existing varieties are derived. "Ennaria" coffee closely resembles "Mocha"

(1) See R. Sept., 1917, No. 853. (Ed.)

coffee, with which it is sometimes mixed, and which it frequently surpasses in quality. It has two sub-varieties: — "Caffa" (the district where it originated) and "Ennaria" properly speaking, derived from the other Galla districts. The seed of the first variety is smaller, rounder, and of a darker green than that of the second, which is elongated.

The "Arrari" coffee plant takes its name from the place where it originated. This coffee is sometimes mixed with Mocha. There are two sub-varieties: — "Arraro", from near the town of Arrar, with elongated seed (hence its English name of "longberry"); "Ittou", in the district of the Ittou-Gallas and Arussis, with small, yellow seed; the colour is due to the fact that it is only put on the market 2 or 3 years after being harvested, so that it is thoroughly dry.

The "Zaghié" variety comes from the Lake Tzana district, near Zaghié and Quorata. It is the least appreciated quality on account of its lack of aroma.

The "Gentel" variety differs from the preceding one by the manner in which the seed is treated; it is produced and consumed almost exclusively in the Ouollo-Gallas district; it has a very agreeable, rather strong flavour.

CENTRES OF COFFEE PRODUCTION IN ABYSSINIA. — There are three principal centres: 1) the basin of the Omo and Didessa; 2) Arrar and neighbourhood; 3) Tzana Lake district in Godjam.

The first, by far the most important, is the original centre of the coffee plant which grows there wild on the hillsides and in the valleys at a height from 4 920 to 6 560 feet, forming almost exclusively the vegetation of the undergrowth, and sometimes of the clearings, in the forests. It is also cultivated. In the Lake Tzana district the coffee plant was introduced at a very remote date and has become semi-wild.

CLIMATE AND VEGETATION. — Abyssinia includes three large climatic zones: — 1) the lower or "quolla" called by the Gallas "worebo"; 2) medium or "voine dega" called by the Gallas "worebo angescho"; 3) upper or "dega", called by the Gallas "angescho". The first is a district of great depressions or valleys below 4 920 feet, hot, damp (as the result of water-courses, lakes, and periodical rains), with a luxurious vegetation. This zone is not cultivated because it is unhealthy; the natives go down there from the table-lands only to collect the ripe fruit of the wild coffee plants. The second zone is widely cultivated, with a perpetual spring, where all the European fruit plants flourish and give as much as three harvests a year. Its altitude is from 3 950 to 9 840 feet. The third, above 9 840 feet, is the zone of wide pasture lands, and above it are the eternal snows.

SOIL. — That of the Tzana Lake district is alluvial, cool and very fertile. In Arrar the coffee plant flourishes in granitic soils and ceases growing in the clay soils. In the Galla district the soil is volcanic and very fertile.

CULTURAL METHODS. — The woody or herbaceous vegetation of virgin soils is destroyed by fire. The soil is ploughed and sometimes, manured, and sown before the rainy season. The irrigation, even when

primitive, is practically sufficient. The sole cultural care is the removal of weeds.

Nurseries are rare in the Galla district. As a rule, at the rainy season, the natives go to the forest and choose young plants for sowing. These they place obliquely in the soil, with the earth attached to them, at a depth of from 12 to 14 inches, covering them with soil so that only about 4 inches of the plant is above ground. If an adult plant is used it is topped to about 7 inches.

When nurseries are formed the seeds are sown as soon as they are extracted from the ripe fruit. The young plants are only transplanted when they are at least 28 inches high, *i. e.*, at the end of one or even two years. Permanent plantations contain 800 plants. The first flowering occurs one year after transplantation and before the rains, *i. e.*, in April. The first harvest is made two years after the first flowering. The plant reaches a height of 10 to 16 feet (sometimes 20), and lives and bears fruit for 20 years, in rare cases 30.

In Arrar the cultivation of the coffee plant is rational and intense. In the Tzana district the plant is semi-wild and is not cultivated, the coffee alone being harvested.

Finally the author studies the commercial routes through which Abyssinian coffee passes and considers the future of the cultivation of the plant in that country.

**764 - Tobacco in Honduras.** — MAKINSON, G. A., in *Commerce Reports*, No. 288, pp. 950-952. Washington, 1917.

Honduran tobacco has always enjoyed a preeminent position in the estimation of Central American tobacco smokers, so much so that native tobaccos of the neighbouring Republics are often put on the market under the name of "Tabaco de Honduras" in order to obtain higher prices. It is commercially known as "Copan tobacco", because the best quality and largest quantities are produced in the Department of Copan, which borders on both the Guatemalan and Salvadoran frontiers. It is also produced in commercial quantities in the Departments of Ocotepeque, Gracias, Santa Barbara, and El Paraiso, the capitals of the respective Departments being the marketing centres. The estimated average annual production of each district is as follows: Paraiso, 7 500 lb; Santa Barbara, 250 000 lb; Gracias, 50 000 lb.; Ocotepeque, 410 000 lb.; and Copan, 1 000 000 lb.

*Planting, Harvesting and Curing.* — Tobacco is planted during October — that is, from 2 to 4 weeks before the close of the rainy season — so that the young plants have sufficient time to take root before the long dry season sets in. The seeds are planted in nurseries during July and the young sets transplanted about 4 months later. One pound of seed should produce approximately 20 000 plants, and growers place about 2 250 plants to the acre.

The leaves are ready for gathering between February and April and the custom is to start harvesting as soon as the plant has fully developed ;

this is sometimes determined by the appearance of yellow tints in the leaves or when the leaves show signs of brittleness on being doubled or bent. The stock is cut whole a little above the roots and the seed is obtained later from the suckers that sprout from the remaining lower part of the stem. The stocks are then hung out, head down, in the open air and exposed to the sun. If any are harvested in the rainy season (which is rare) they are dried in the shade. After being dried in the sun for 15 or 20 days the stocks are pressed for 3 days, and the leaves are then separated from the stems and sorted into 3 grades, according to size. They are then tied in bundles of 1 lb. each — the stems being utilized for fastening — and are alternately pressed and sunned until the veins are thoroughly dried. Owing to negligence and the varying judgements of different farmers the resulting product is not always uniform, which sometimes results in obtaining lower prices. Dried leaves average from 9 to 20 in. in length, and a well-cultivated acre should yield from 400 to 650 lb.

Both strong, mild, dark and light tobaccos are produced, these properties depending largely upon the nature of the soil and, to a somewhat lesser extent, upon the amount of rainfall and the time and method chosen for cutting and curing. If the plants are permitted to ripen thoroughly the leaves will be rather dark in colour, whereas if cut earlier a lighter shade will be obtained. A poor, sandy soil is said to produce a mild tobacco and a rich clay soil a somewhat stronger plant. In seasons of copious rainfall it is noticed that the leaves are invariably of a dark hue.

*Cost of Production.* — It costs from 8 to 12 cents United States currency to raise a pound of tobacco in Honduras, and the market price ranges from 15 to 25 cents, depending on the class and quality. It is supposed that most of the tobacco cultivated in Honduras was originally derived from Cuban seed, and the more progressive growers still continue to import Cuban, Jamaican, Porto Rican, and American seed. When ready for market Honduran tobacco closely resembles that grown in North Carolina and Virginia. It burns well and has a pleasant aroma, and connoisseurs state that its failure to achieve just recognition of its worth is due solely to the primitive and unscientific methods employed in its harvesting and curing.

*Methods of Packing — Export Trade in Tobacco.* — Tobacco is packed for shipment in bales of 100 lb. each, which are well wrapped in several layers of banana leaves and tightly tied with strong banana fibre. Although apparently crude, this method of packing is considered the most practical, combining as it does the qualities of lightness and cheapness.

As the tobacco fields of Honduras are in closer proximity to the railroads and seaports of Salvador and Guatemala than to those of Honduras, nearly all the crop is strapped on the backs of native Indian runners or mules and carried over the frontier trails to the neighbouring Republics. These caravans pass the border at remote hamlets, where no custom uses are established, so that statistics showing the volume of this trade are not available. However, it is well known that practically all of the high-grade cigars and cigarettes manufactured in Central America are either of pure

Honduran tobacco or contain a large admixture of it. The amount and value of tobacco exports through the seaports of Honduras for the years 1915 and 1916, respectively, were 56 800 lb., worth \$6 810, and 89 025 lb., worth \$19 610.

Honduras tobacco, after being manufactured into cigars and cigarettes in Guatemala and Salvador, is exported in considerable quantities to South America, particularly Peru, the Caribbean countries, and Europe. The volume of this business amounts to many thousands of dollars annually.

*Efforts made to expand industry and markets.* — Of recent years the Honduras Gouvernement has taken measures to foster the industry, and aside from maintaining several schools where young natives are taught to cultivate and cure the crop scientifically, steps are being taken to improve the quality of the plants and to find new outlets for the constantly increasing production. The Government recently sent several youths to the tobacco districts of Cuba, where they were able to study the up-to-date methods employed there in the various branches of the industry.

Tobacco is principally used in Central America for cigars and cigarettes; pipe smoking and chewing have not been introduced among the natives, although nearly all of them, including minors and women, smoke. Among the labouring classes the women of nearly every household prepare the cigars and cigarettes for the family needs. During the fiscal year 1914-15 \$7 480 worth of cigarette paper was imported, the greater part of this supply coming from Spain and small shipments from the United States and Germany.

Up to the present no attempts have been made to manufacture high-grade cigars or cigarettes on a large scale, although with an abundance of raw material and cheap labour it would seem to warrant a careful investigation. Nearly every man and woman of the labouring class understands the rudiments of cigar making, although none of them are particularly expert at it. However, they could soon be trained to turn out as good cigars as are manufactured in Cuba. An almost unlimited supply of this labour could be obtained at from 25 to 50 cents per day. Cigar factories in Guatemala utilize native labour and their products (Honduras tobacco with Sumatra wrappers) are said to compare favourably with those of many factories in Cuba, Porto Rico, and the Philippines.

In addition to supplying the demand for good cigars in Honduras itself, a profitable market could be worked up among the other Central American Republics.

#### VARIOUS PLANTS

##### 765 — *Marvel of Peru (Mirabilis Jalapa)*, a Plant which should be Utilised —

MANCADA-GUIGNONNE FRANCISCA in *la Revista Agrícola*, Year XVI, Pt 372, pp 112-113, Rome, May 1 1928.

The author has made a long study of this plant and concludes that its cultivation for various industrial uses is advisable.

When grown in gardens the plant flowers excessively to the detriment of the seed which is small. In arid soil, however, especially if fertilised with ash, it flowers less and the seeds are much larger and richer in starch.

The stamens, pistils, and perianth (which dries up without separating from the seed) give a fast purplish colour which dyes silk.

The starch contained in the seed is of very good quality. When freed from the husk and germ the seeds give a very fine flour, which may be used for making bread, paste, biscuits, etc.; they may also be subjected to alcoholic fermentation as they contain a sugar.

The cultivation of this plant in malarial districts would be very advantageous; the flowers open in the evening and during the night give off a very strong, small which keeps away mosquitoes, or stupefies them, thus making them inoffensive.

766 — “Chamiso” (*Atriplex canescens*) and “Quelite Salado” (*Atriplex acanthocarpa*), Plants of the Arid Districts of North Mexico Suitable for growing in Saline Desert Soils. — PARON, CARLOS, in *La Revista Agrícola, Órgano oficial de la Dirección de Agricultura, Secretaría de Fomento, México*, Vol. 1, No. 2, pp. 18-49 México, September 15, 1917

“Chamiso”, or “costilla de vaca”, or “costilla” (*Atriplex canescens*) is found in northern Mexico, New Mexico and Texas. The variety most common in Mexico is *angustifolia*, which prefers rich, strong land, and, though not of necessity halophytic, also does well in medium soil, and can stand perfectly well sodium salts such as chloride or carbonate. It grows to a height of from 3.28 to 4.92 feet and its foliage is about 6.56 feet in diameter. Its leaves are tender and good as forage. The wood is used as fuel.

The “quelite salado”, or “saladillo” (*Atriplex acanthocarpa*, which must not be confused with another plant also called “saladillo”, the Chenopodiaceae *Suaeda Torreyana* or *S. Moquini*) is found in the same districts as the preceding species, but is smaller and of more rapid growth because almost entirely herbaceous. It is always halophytic. Its leaves are more tender and appetising, and sodium is extracted from its ash.

The author recommends that these plants be sown or transplanted to cover the dried-up soil of the old bed of the Lake of Texcoco.

767 — The “Miaray” (*Citrus miaray* n. sp.), a New Citrus Fruit of the Philippines. — WESTER, P. J. (Agricultural Adviser, Department of Mindanao and Sulu), in *The Philippine Agricultural Review*, Vol. X, No. 4, pp. 450-457 Manila, 1917

The Philippines already hold first rank in the number of indigenous forms of the genus *Citrus*, and this very fact is a promise of discovery of still unrecorded species in the less explored regions of the Archipelago. Apart from a purely botanical point of view, new forms are at present also of great interest, as opening up new possibilities in hybridization, especially in connection with the problem of breeding new types resistant or immune to the citrus canker *Pseudomonas citri* Hassk.

The “miaray” (*Citrus miaray* n. sp.), described and named by the author, was found by him in August, 1917, in Impolunao in the interior of the Province of Bukidnon, Mindanao, at an elevation of 750 metres.

With its willowy, slender, drooping branches and dense crown of dark green foliage, the miaray is an exceedingly handsome ornamental tree

FRUIT  
GROWING

about 6 metres in height. The fruit is about the size of a lime. It is pleasantly acid and may be used like the lime. The clean, vigorous growth of the tree indicates that it is likely to prove a desirable stock for other cultivated varieties of the citrus.

768 — **Soil Management Investigations in a Young Apple Orchard.**— WOODBURY, C. G., NOYES, H. A. and OSKAMP, JOSEPH, in *Purdue University, Agricultural Experiment Station, Bulletin* No 205, Vol. XX, 52 pp., XXIII Tables 12 Figs. Lafayette, Ind., September, 1917

The object of this investigation (carried on at Laurel, Indiana) has been to study the effects, and particularly the factors responsible for the effects of tillage with cover crop, mulch and sod on apple trees. The present report covers the formative period of the life of the trees. The land comprising the experimental plots had been used as a permanent pasture for nearly 40 years previous to planting the orchard. The investigation has to do mainly with the upland area, the hillside plot being included for any additional light it might throw on the behaviour of the upland plots. The systems of soil management include four major treatments, viz., clean cultivation with a winter cover crop; a heavy mulch of straw applied to the trees and the grass cut and let lie; the grass cut and allowed to lie where it falls, no mulch given the trees; the grass cut and raked up to form a mulch collar about the trees.

The Laurel soil contains a high percentage of silt and clay, and varies but little in its physical composition, specific gravity and water-holding capacity. The soil (to a depth of 9 in.) is not notably deficient in any essential element, however it is not very productive. The low organic matter content and the high proportions of silt and clay, make the soil one through which water percolates slowly and one which is easily puddled; coupled with these conditions is a slight acidity. The subsoil is not greatly different from the surface soil.

The average annual precipitation during the five-year period 1912-1916 has been 38.71 in. The spring months are usually much better supplied with moisture than the autumn months. Periods of dry weather frequently prevail in June and July, which are commonly broken by heavy precipitations in August.

While there have been no wide variations in phenological behaviour of trees under different systems of soil management, yet there does occur a marked slackening up of growth on grass plots during dry periods in summer.

Trees grown under a clean culture cover crop system or under a heavy mulch made 44.5 per cent greater average yearly gains in trunk girth than trees grown in grass with a light mulch or no mulch at all. There was no significant difference between the three varieties, Grimes, Jonathan and Stayman, in their response to soil management treatments. The Stayman variety made slightly greater gain in girth of trunk on all plots than did Grimes or Jonathan.

It is largely in dry periods that the value of certain systems of management in conserving soil moisture are made manifest. During two such

periods, occurring in June two out of the five years, where an adequate mulch was maintained on the surface of the ground either through the agency of cultivation or a heavy supplemental covering, the percentage of soil moisture was more than twice that in grass land. These soil moisture conditions are closely correlated with the girth increase made by the trees. The great importance of water in tree growth is further emphasized by a study of the precipitation data which show that the variation in growth due to seasonal moisture conditions, appears to have been quite as large as that due to cultural practices.

The soil temperature studies were carried out under field conditions (at a uniform depth of 9 in. on all plots) by means of soil thermographs. As the soil temperature is largely a reflection of the air temperature, the extent to which soil temperature can be controlled by cultural practices is quite limited. The data do not support the opinion that rain is of importance in warming the soil. There is no indication that the single factor of soil moisture had an influential bearing upon the temperature existing under the different systems of soil management. The temperature range varies inversely with the amount of mulch covering the soil. The role of soil temperature within the limits of ordinary cultural practice appears to be a neutral factor in tree growth in Indiana.

From a study of the chemical changes induced in the Laurel soil by cultural practices during the period 1910 to 1915, it appears that clean cultivation tends to deplete the soil of its organic matter, despite the fact that a cover crop is being turned under each year. The straw mulch plot has increased slightly in organic matter while the sod plots, as a whole, have come nearer to holding their own in volatile matter, humus and nitrogen than the clean culture cover crop plots. There is no apparent correlation between the previously mentioned chemical factors and tree growth.

A study of the average bacterial population shows that there are, in most cases, more bacteria present in the sod ground at Laurel than in the clean culture cover crop plots; that the variations in mulch on the sod plots have some influence on bacterial numbers; that tree growth and soil moisture cannot be correlated with bacterial numbers (1).

Tests show that ammonification varies with the season. Differences between plots are not consistent with seasonal climatic variations and it is impossible to say that cultural practice has affected the ammonifying power of this soil. Tests show that nitrification varies with the season, but that a growing crop of grass or rye lowers the nitrate content of the soil; that the most nitrates are found under the clean culture cover crop system, the straw mulch ranking second in amount of nitrates; that the girth gains of the trees are roughly proportional to the nitrate content of the soil; that there is no relation between the nitrifying power of the soil and either cultural practice or tree growth; however, the ratio between the nitrates present in the field and the nitrifying power of the soil does bear a relation to tree growth.

## VINE GROWING

770 — **The Present Position of Hybrid Bearers.** — PEE-LABY, E., in *La Vie Agricole et rurale*, Year VIII, No. 13, pp. 219-221., Paris, March 30, 1918.

The author summarises the principal results of the annual report of the Commission of Investigation of the Central Agricultural Society of Haute-Garonne. This forms an interesting supplement to his study published in the same journal\* (1).

The cultivation of hybrids increases each year. It is taking foot in the fine wine-producing districts, such as Burgundy, Bordelais, etc., not to oust the established wines, but to supply the workers of the district with a very cheap, good ordinary wine, owing to the little care these vines require.

The Commission carried out its investigations chiefly in the department of Haute Garonne, and the departments bordering on it. The south-west of France is, moreover, the district in which hybrids are most extensively grown.

1. — **OLD HYBRIDS (BLACK).** — *Seibel* No. 1. — Does well direct in loam; irregular and small yielder in calcareous soils; very subject to anthracnosis under certain conditions.

*Seibel* Nos. 2\* and 63. — Larger producers and less sensitive than No. 1, especially 63; wine poor in alcohol; easily protected against mildew.

*Seibel* 128 \*. — Was the most remarkable in 1917 on account of its fine, heavy yield, but it is very uncertain; very slightly subject to anthracnosis.

*Seibel* 138 \*. — More regular and stronger than 128; its wine does not derive its colour from the pulp; largely grown because it can be planted direct.

*Seibel* 156 \*. — Low resistance in certain environments, especially lime; must be fairly well protected against disease.

*Seibel* 1000 \*. — To be preferred because of its greater resistance to disease and better quality wine; anthracnosis sometimes causes it to non-set in damp districts.

*Seibel* 2007. — Much in demand on account of its large fruit and its regularity in spite of its incomplete ripening.

*Seibel* 2003. — Does very well in loam; affected by lime.

*Coudere* 7103 \* and 4401 \*. — The first is preferred because it gives a larger yield, though the quality is inferior; subject to oidium.

*Coudere* 7120. — More popular than the two preceding ones because almost immune to oidium when planted in a relatively warm district or in an exposure which allows it to ripen its grapes which are of the third period.

*Coudere* 503. — Does not appear to propagate except at the beginning of hybrid planting; resistant to blackrot.

1. **NEWER HYBRIDS.** — *A. Black.* — *Seibel* 4121 \*. — Much in demand on account of its good resistance to disease and regular yield.

*Seibel* 4643 \*. — Much appreciated for its delicate and large grapes; needs sulphur spraying although not very subject to mildew.

*Coudere* 106-46. — Regular yield and high resistance to mildew.

*Maléque* 829-6 \*. — Notable for the size of its bunch and grapes and its good quality wine; easily protected against mildew.

(1) See R. March, 1918, No. 303. To avoid repetition and to facilitate reference the hybrids already mentioned in article 303 are marked with an asterisk (\*). (*Ed.*)

*Malègue* 1551-2 \*. — Heavier producer than 829-6; is better adapted to the eastern Pyrenees than the south-west because it requires more heat.

As a general rule *Malègue* vines should not be grown in soils favourable to anthracosis.

*Gaillard* 194 \*. — Appreciated for its regular yield, which is average and does not need protecting when there is an invasion of mildew; in the Centre and East this vine is in demand on account of the quality of its wine; in the South and South-West where Aramon products are usual, those of 194 are considered too weak; its yield has been appreciably increased by long pruning.

*Jurie* 580 \*. — Gives a high yield and is very resistant to diseases.

*Baco* 1. — Little grown in the South-West on account of its small fruit and excessive earliness which necessitates picking a fortnight before the normal harvest.

*B. Pink*. — *Seibel* 2859 \*. — Is being more and more widely grown; strong foliage which does not require sulphate spraying when in a good exposure; suffers from excessive moisture which may be seen by the beginning of rot on the bunches.

*C. White*. — *Seibel* 793 \*. — Almost immune; turns grey-pink when ripe; regular and fairly vigorous when planted ungrafted in good soils; its wine, though not very fine, is not of a bad flavour and fairly alcoholic.

*Seibel* 850 \*. — Stronger; larger fruit; regular; foliage easily protected.

*Seibel* 880 \*. — Grown a little everywhere; wine better than that of 850, used in the South-West for making sparkling wine.

*Seibel* 2653 \*. — Known as *Flot d'or*.

*Seibel* 3021 \*. — Is without doubt a hybrid of the future; was much in demand in 1917.

*Seibel* 4681. — More resistant than 3021.

*Gaillard* or *Girard* 157. — Much spoken of; found by some to have too low a resistance; must be treated with sulphate 2 or 3 times, and with sulphur, 1 or 2 times; others consider it a large regular yielder of good grapes and worth the necessary treatments; the Commission found it in all the vineyards visited.

*Couderc* 235-120 \*. — Good yield and resistance, but rots regularly before ripening.

*Malègue* 1647-8. — Known as *Vert doré*; grapes of excellent flavour; foliage of good practical resistance.

*Malègue* 1157-1 \*. — Slightly less resistant but larger yielder.

*Malègue* 1897-12 \*. — Rather pretty bunches with a slight musk flavour.

*Bertille-Seynes* 450. — Fine bunches with average fruit, slightly foxy and ripening in the second period.

*Maurice Baco*. — Fine foliage, heavy yield; maturity somewhat too late for certain districts of the South-West, slightly subject to mildew and especially grey rot.

III. — NEW HYBRIDS. — *A. Black* (1).

*B. White*. — *Seibel* 4657 \*. — The author corrects his previous remarks (2); this vine did so badly after the turning point that he has removed it from the list of plants to be recommended; as soon as ripe the grapes become loose and drop one after the other without the slightest shake; at vintage time only the bare stalks of the bunches remain.

*Seibel* 4603 \*. — Another correction; at harvest time it is almost completely rotted; the author discards it too.

*Seibel* 4762. — Good resistance to mildew; neither bunches nor grapes are very large; but are excellent and very sweet, ripening in the second period.

*Seibel* 5451. — Higher yield than 4762, with much larger bunches and fruit, round, ripening at the end of the first period; not very subject to rot; foliage less strong requiring some sulphate; grapes very sweet and of good flavour.

(1) There is nothing to add to that contained in No. 303 of March, 1918, p. 362. —

(2) See No. 303, p. 361. (*Ed.*)

*Seibel* 4905. — Good yield; fine, well-flavoured grapes, less sweet than the two last; very regular; strong foliage resistant to mildew; ripening in the second period.

*Seibel* 5770. — Fine yield of good bunches with fruit above the average, ripening in the first late period; though very close the grapes do not rot; they are very good and very sweet.

FORESTRY

771 — **The Larch.** — SCHOTTE, J. (Meddelanden från Statens Skogsförsöksanstalt), in *Skogs-vårdsföreningens Tidskrift*, Year XV, No. 4-6, pp. 445-706 + 107 Figs. + 11 Tables. Stockholm, 1917.

This paper is a study on the genus *Larix* and its different species spread through the various countries of the globe made in view of their importance to silviculture in Sweden. At the same time it is an important contribution to silviculture in all countries. The author and his collaborators study above all the identification and geographical distribution of the different species of larch known throughout the world, their varieties, forest characteristics, susceptibility to disease and insect attack, production of wood, the quality and utilisation of this wood and the division of the different species of larch into pure and mixed stands. To distinguish the species are given two tables of identification, which enable the forester to distinguish 11 species of the 16 already known.

*Classification table of larch, based on the cones.*

I. — CONES VERY DEVELOPED (exceeding 2 to 2.5 cm. in length).

A) Bracts longer than the scales.

a) Straight bracts.

1) Scales with even edges . . . . . *Larix occidentalis* (1)

2) Scales with cut edges. . . . . *L. Lyallii* (2)

b) Curved bracts.

1) Cones 7 to 10 cm. high. . . . . *L. Griffithii* (4)

B) Bracts shorter than the scales.

a) Straight scales.

1) Bracts visible, ripe cones with neither hair nor down.

α) smooth twigs. . . . . *L. europaea* (7)

β) slightly downy twigs . . . . . *L. Potanini* (5)

γ) hairy twigs. . . . . *L. olgensis* (14)

2) Bracts usually invisible, ripe cones with down or hair. . . . . *L. sibirica* (10)

b) Scales with curved point . . . . . *L. leptolepis* (6)

II — SMALL CONES (Less than 2 to 2.5 cm in length)

a) very small cones (length 1.5 to

2 cm.) . . . . . *L. americana* (18)

b) cones rather larger (length up to 2.5 cm.)

1) Leaves about 3.5 cm. long. . . . . *L. dahurica* (12)

2) Leaves about 2 cm. long. . . . . *L. kurilensis* (15)

It should be noted that *L. chinensis* is not included in this table, though according to the descriptions available, its cones are very similar in character to those of *L. americana*, whereas the cones of *L. europaea* show considerable differences in measurements and form.

*Classification table of larch, based on the twigs and leaves.*

I. — HAIRY OR DOWNY TWIGS.

- A) TWIGS COVERED WITH A GREYBROWN DOWN . . . . . *L. Lyallii* (2)
- B) TWIGS SLIGHTLY DOWNY OR HAIRY
- a) Leaves blueish-green, twigs reddish
- 1) Leaves about 2 to 3.5 cm. long. *L. leptolepis* (6)
- 2) Leaves about 2 cm. long. . . . . *L. kurilensis* (15)
- b) Leaves green.
- 1) Twigs pendant, reddish when young, slightly hairy, leaves long (up to 4 cm.) . . . . . *L. Griffithii* (4)
- 2) Twigs non-pendant, upright, yellowish when young, downy, leaves long (up to 3 cm.) . . . . . *L. occidentalis* (1).

II. — TWIGS SMOOTH.

- A) LEAVES RELATIVELY LONG (3 to 5 cm.); twigs dry with a strong smell of jasmin . . . . . *L. sibirica* (10)
- B) LEAVES OF AVERAGE LENGTH (2.8 to 3.5 cm.); twigs fresh with a slight smell of balsam. . . . . *L. dahurica* (12)
- C) LEAVES RELATIVELY SHORT (rarely more than 3 cm.) . . . . .
- a) Twigs greyish-yellow, often with a slight smell of jasmin when dry . . . *L. europaea* (7)
- b) Twigs reddish with small cones . . . *L. americana* (18)

The appended map (see p. 830) shows the geographical distribution of the various larches (16 species and 3 hybrids).

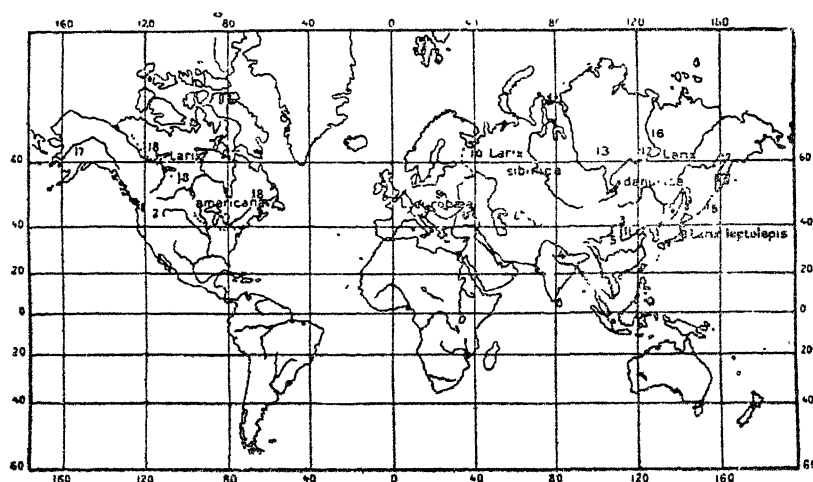

The following details are given on the use of larch in silviculture, especially with regard to Sweden, for the most suitable species.

The European larch is grown almost all over Sweden up to Haparanda; it was imported in 1750 and the first plantations made in 1780 with seed obtained chiefly from Scotland. The plantations are remarkable for the size and regularity of the trunk and not very thick top, which has led the author to believe that there is a Scotch variety of the European larch. Since the middle of the 19th. century a large part of the larch seed used in Sweden was imported from the Tyrol, giving plantations with a high proportion of twisted trunks and of bad shape with an insufficient growth in height and a thick top. These characters make the Tyrolese larch unsuitable for mixed stands and of little value for the production of wood.

Scotch larch, on the contrary, may be profitably cultivated in the best forest soils, and soon produces timber ready for sale in about  $\frac{1}{8}$  of the time the Scotch pine requires to do so. Since the larch is fairly often subject to canker (produced by an ascomycete, *Dasyscypha Willkommii*), it is advisable to form plantations mixed with other trees wherever possible. For this

purpose plantations of Scotch larch mixed with Scotch pine or birch are to be specially recommended; spruce should be avoided, and, in any case, treated as a dominated tree. It is also advisable to use only seed of Scotch and Silesian larch, even though produced locally. The thinning of European larch should be early and intense, so that the first frees the tops and liberates the plants dominated. Intense low thinning should then be practised to eliminate the dominated trunks with bushy tops, especially if there is a dominated class in the plantation. These methods make the plantation more resistant to canker; to avoid attack by this disease trees of 20 to 30 years should be cut. European larch wood is appreciated for use as timber, for scaffolding, telegraph and telephone posts, and supports of all kinds. It keeps much better when in contact with soil than does Scotch pine.

*Map of the approximate geographical distribution of larches.*

1) *Larix occidentalis*. — 2) *L. Lyallii*. — 3) *L. chinensis*. — 4) *L. Griffithii*. — 5) *L. Potanini*. — 6) *L. leptolepis*. — 7) *L. europaea*. — 8) *L. europaea* × *leptolepis* (cultivated in England). — 9) *L. polonica*. — 10) *L. sibirica*. — 11) *L. Principii Rupprechtii*. — 12) *L. dahurica*. — 13) *L. dahurica* × *sibirica*. — 14) *L. olgensis*. — 15) *L. kurilensis*. — 16) *L. Canderi*. — 17) *L. alaskensis*. — 18) *L. americana*. — 19) *L. americana* × *europaea* (cultivated in England).

Siberian larch is to be recommended for plantations in central and northern Sweden. Like the Scotch larch its trunk is high and straight. As it is equally subject to canker, the same care is necessary. Its wood has qualities similar to those of Scotch larch.

*Larix leptolepis* is a species suited to plantations in south Sweden. It grows rapidly in height and diameter, though the rate of growth begins to decrease at an earlier age than that of the two previous species. Although also attacked by canker, it bears shade better than the other larches. On

account of its thick top it is not suited to mixed stands, but only to those on good soil where a heavy production of wood is required in a short time. Its wood is less appreciated than that of the other larches.

*L. occidentalis* is comparable to the European and Siberian larches. Like them it is subject to canker. As it produces the best resinous wood in America, experimental plantations of it are recommended.

772 - **Forest Trees of the Argentine.** — *Revista forestal*, 1st Year, No. 8, pp. 176, 179, 184; No. 10, pp. 243, 255, 260; No. 11, pp. 283, 292, 297; No. 12, pp. 335, 341, 345; 2nd Year, No. 15, pp. 449, 451; No. 17, pp. 499, 503, 507. Buenos-Aires, July, September, October, and November, 1917; January and February 1918.

Concise descriptions are given of the various uses to which the following trees may be put, with one or more plates of each.

"Espinillo aromita" (*Acacia Aromia* Gill. = *A. macracantha* Humb. and Bonpl.). Supplies fire wood and flowers from which a scent may be extracted.

"Iba-Jay" (*Eugenia edulis* Benth. Hook). Wood for cooperage, carpentry, joinery; tanning bark; flowers may be used for extracting scent; fruit may replace that of the tamarind.

"Iba Eé" (*Acanthosyris spinescens* Gr.). Wood for furniture making; fruit (nuts) gives a very alcoholic brandy; tree very ornamental and easily propagated.

"Espina de corona" (*Carugandra amorphoides*). Very compact and flexible wood for joinery. A Leguminosae all parts of which are rich in tannin. Bark, sap-wood and fruit rich in saponin, in which the fruit is especially rich, and used commercially to free hair, as well as woollen and silk materials, from fat.

"Aliso" (*Eupatorium* sp.). Compositae, very abundant on the banks of the Paraná and Paraguay, as well as on the islands and banks of the Bermejo. Wood white, light, used for field constructions and the manufacture of casks; suitable for paper-making.

"Guabiyú" (*Eugenia Guabiyú* and *E. pungens*). Very fine joinery wood; bark, leaves and branches have tanning qualities; edible fruit.

"Sauce blanco" (*Salix Martiana* Leyb. = *S. Humboldtiana* Willd.). Light wood used for making clogs and all light articles. Very abundant in moist soils. — "Sauce colorado" (*Salix Humboldtiana*). Reaches a maximum height of 50 feet; requires less than two years to attain complete growth. Excellent wood for furniture making. Like the preceding tree it does well on moist soils and is excellent for making fibre and paper pulp.

"Urunday-urá" or "Urunday blanco" (*Diplokeleba floribunda*). Wood for furniture making.

"Trementina", or "Molle", or "Molle guazú" (*Duvana praecox* Griseb. = *Schinus dependens* Ortega). Unlike the preceding trees which are all large, this Anacardiaceae is a bush; when incised it yields a resin; the leaves give an infusion used for the teeth; very fine pink wood.

"Toro-ratay", "Huiflag", or "Palo cruz" (*Tabebuia nodosa*). Santalaceae, 26 to 33 feet high; yellow wood of which the handles of tools are made; used in dying.

" Ivira pitá '(*Peltophorum Vogelianum* Benth). Leguminosae with tanning bark ; the pinkish-yellow wood, is used for cabinet-making, and more largely for making casks. " Ivira-pitá-guazú » (*Peltophorum rubium* = *P. Vogelianum*). A gigantic tree with hard, yellow wood ; medicinal fruit, leaves, and roots.

" Palo santo blanco " (*Bulnesia Gancedii*), known as " Guaiacum officinale " in Brazil, where it was imported from Jamaica. In the Argentine it is found with the preceding species ; fine, resistant wood of a dark green or blue ; used for buildings or as fire wood ; depurative infusions are made from it. The resin from the bark and sawings is used as a balsam.

" Inga " (*Inga affinis*). Large tree growing in moist soils ; edible fruit ; white wood not very resistant to inclement weather ; the bark contains a fine red colouring matter and is used in tanning ; by mixing an infusion of the bark with ferrous salts a blue-black ink is obtained.

Rendement financier, en 1916, de quelques forêts communales à gérance technique. *Ibid.*, No. 12, p. 227.

According to a publication of the Chief Federal Inspector of Forests (a report read at a conference of delegates from the various federal departments and of Swiss forest inspectors) the influence of the war on Swiss forestry and forest industry has been very great. Before the war the wood production of Switzerland was insufficient for the requirements of the country and had to be supplemented by about  $\frac{1}{4}$  of the native production. In 1913 the difference between the exports and imports of wood was over 85 million cubic feet. In 1914 the imports still exceeded the exports by 3 %, but in 1915 the position was reversed and the exports were equal to the 1914 imports, and about double those of the year 1915. In 1916 the exports exceeded the imports by three times in quantity and four times in value. Italy and France received most of the wood exported, Germany only occupying the third place.

The excess of exportation of wood, the setting aside of certain quantities for yards, and the decreased coal supply which has necessitated the use of wood for gas-making, has led to an abnormal rise in price, and a certain shortage of fire-wood. The Government has had to take various special

measures — the fixation of maximum prices, permission for extraordinary felling of fire wood, and to exceed the felling provided for in the management of public forests, and cooperation in the work of utilisation. Moreover the export of certain wood-products has been forbidden and that of others regulated by special permits. At the same time the felling of walnut trees has been prohibited, the cutting of wood belonging to private individuals controlled, and the penalties for cutting wood in the lands under forest control increased.

The felling of trees in the public forests has not been excessive, but not a few privately owned young plantations not under forest control have been sacrificed. Thoughtless felling will result in a marked depression in wood production for many years.

On the whole the normal amount of wood cut in Switzerland amounts to over 7 431 270 000 cubic feet, whereas, in 1916, it rose to over 14 154 800 000 cubic feet. To prevent ultimate loss the regulations previously applied to controlled forests have been applied to the other forests, and it is possible that this control may be continued even after the war. On the other hand it is proposed to improve the conditions of forestry and utilisation of wood by increasing the public forests.

An important event was the meeting of the Association of Swiss Foresters (autumn of 1917), the chief object of which was to discuss the report of a Committee of action, nominated in 1911 with a view to improve both the position of Swiss foresters and the technique of forestry. The war has helped the attainment of this object because it has proved to the public the importance and economic value of forests.

The value of the Swiss forests, calculated on a 3 % yield, is over £ 58 000 000, or about the total of the debt for the federal railways at the end of 1915, whereas there are only 200 officials to administer the public forests, which have a minimum value of over £ 26 000 000. More recognition of the work of the forest officials and greater freedom for them in the management of the public forests are, therefore, demanded. A more technical and intensive management even of the private forests is also demanded, as this would mean a marked increase in the quantity and value of the wood per acre.

In support of this M. BIOLLEY gives data concerning a communal forest of 283  $\frac{1}{2}$  acres at an altitude of from 2 424 to 3 608 feet which had been devastated by successive fellings, neglect and destructive utilisation by its contractors. For 50 years this forest has been controlled. As a result during the last 25 years the amount of wood has been increased, and age, volume per tree and growth have been improved. Whereas it yielded 39.5 cubic feet per acre in 1891, in 1916 it yielded 103.6 cubic feet. As a result of good management the cutting even exceeded the estimated amount, reaching 115.3 cubic feet in 1916.

The chief demand of the meeting was for a revision of the forest legislation in force in Switzerland in order to extend the principle of forest control, even from an economic standpoint. As has been done by the Swiss Society of Timber Merchants, the Society of Swiss Foresters proposes to

form a central forestry office which will supply information, give commercial technical help, and undertake propaganda. With this aim in view two publications are being prepared which will be largely distributed; the object of one is to show the extent to which the yield of public and private forests may be increased, that of the other to show the work forestry demands from experts.

For 1916 the financial yield of some of the technically managed communal forests showed a marked increase, although this was not due to excessive felling. Thus a minimum of £ 1.15.0 per acre for the Bernese communal forests, corresponding to a utilisation of 97.1 cubic feet, rises to a maximum of £ 6.0.0 for the communal forests of St. Gall, corresponding to a utilisation of 154.2 cubic feet per acre. The cost of exploitation is not included in these estimates.

774 — **Studies on Toxicity to Insects of Various Organic Compounds** — MOORE, WILLIAM: I. Toxicity of Various Benzene Derivatives to Insects; II. Volatility of Organic Compounds as an Index to the Toxicity of their Vapours to Insects, *Journal of Agricultural Research*, Vol. IX, No. 11, pp. 371-381 4 Figs Bibliography of 7 publications, and Vol. X, No. 7, pp. 365-371. Washington, June 11 and August 13, 1917.

I. — The author in a previous paper (1) pointed out the possibility of fumigating animals with nitrobenzene to destroy their external parasites. In that work and in later experiments with nitrobenzene as many as 500 animals (cattle, sheep, hogs, chickens, dogs, cats, rats, and guinea pigs) have been fumigated, with only two cases of possible poisoning. Nevertheless, in view of the extreme toxicity of nitrobenzene, it was felt that it might be too poisonous for general use. For this reason a study of 28 benzene derivatives was undertaken with a view to determining their toxicity to insects; and from the result of this study it was hoped that one or more compounds might be found which would be quite toxic to insects while non-toxic to higher animals or plants. A knowledge of the toxicity of the vapour of these compounds is valuable not alone for fumigation purposes but also as an index of their work as contact sprays, since SHAFER and, more recently, MCINDOO have shown that most contact sprays kill by the action of their vapour rather than by the plugging of the spiracles.

One-litre Florence flasks of pyrex glass, closed with rubber stoppers coated with lead foil, were used as fumigation chambers. Measured quantities of the compound to be tested were placed on a piece of filter paper cut as small as possible, the paper was suspended from the stopper inside the flask, and the compound was allowed to evaporate. After several different insects were used in preliminary tests, the house fly (*Musca domestica*) was selected. Five flies were put into each flask, the chemical introduced, and the flask tightly stoppered. When all the flies in the flask were apparently dead, they were removed to a vial and given 24 hours to revive. If none revived, the time during which the flies were exposed to the vapour was recorded. But, if the flies revived, the experiment was repeated. In each case 5 tests were made.

(1) See the *Journal of Economic Entomology*, Vol. IX, No. 1, pp. 71-80, 2 Figs., 1916. (Ed.)

Since similar weights of the different chemicals do not contain the same number of molecules, and their toxicity could not, therefore, be accurately compared, it was decided to determine the toxicity in minutes for similar fractions of a gram-molecule of each chemical. Different quantities of each chemical were tested and curves plotted. As the quantities increased, it was found that each chemical had a point beyond which an increase would not give a reduction in the time required to kill. This is the point at which the air is saturated with the vapour, and differs for each chemical. As the quantity is decreased, a point is reached where the vapour is not of sufficient strength to kill. The plotted curves lie between these two points.

After the curves were plotted, it was found to be impossible to compare similar fractions of a gram-molecule; hence, the different fractions of a gram-molecule necessary to kill in a fixed time of 400 minutes were determined. A long period of time was selected as a more nearly correct index of toxicity. The fraction of the gram-molecule was determined by dividing the amount of the chemical necessary to kill in 400 minutes, at a temperature of 70° F., by the molecular weight of the substance.

*Relation of the Volatility of Organic Compounds to their toxicity.*

All the benzene derivatives tested proved to be more toxic to insects, molecule for molecule, than carbon bisulphide.

Physical characters, such as boiling point and vapour pressure, have more influence on the toxicity than chemical composition.

Up to 250° C. the higher the boiling point the more toxic the compound to insects. Beyonds 250° C. the compound is usually so slightly volatile that not enough of the chemical will evaporate to be effective.

Lipoids are very soluble in compounds with low boiling points and but slightly soluble in compounds with high boiling points.

Compounds with low boiling points, although less toxic, owing to their great volatility, may give better results than compounds with high boiling points, particularly in the fumigation of grain.

The toxicity of the benzene derivatives was found to be similar for other insects. A comparison of the bluebottle fly (*Lucilia sericata*) with the house fly shows that house flies die more quickly from compounds with a low boiling point than bluebottle flies, while compounds with a high boiling point are more toxic to the bluebottle flies than to the house fly. Similarly, the cockroach (*Blatella germanica*) succumbs less readily than the potato beetle (*Leptinotarsa decemlineata*) to low boiling compounds and more readily to high boiling compounds. This relationship may be due to morphological differences in the insects, possibly the diameter of the spiracles or trachea.

For the fumigation of animals a compound with a high boiling point is needed in order that relatively little of the material shall be in the air to be taken in by the animal or to irritate the eyes or nose. In this respect salicylic aldehyde is probably the best. The cost of this chemical is prohibitive for general fumigation; but, inasmuch as higher animals readily oxidize it to salicylic acid, which is very slightly poisonous, this compound might be used for the internal fumigation of horses to destroy bots as carbon bisulphide is now used.

II. — Having pointed out the relationship between the toxicity of various benzene derivatives and their boiling points, the question arose whether a similar relationship of boiling point and toxicity existed among other-volatile organic compounds. Early in the work it was discovered that boiling point was merely a convenient general index of the volatility of the compound and that the real relationship was probably between toxicity and volatility. It was at first thought that this relationship existed only with compounds having an action on lower organisms similar to that of chloroform and ether, but it was soon found to have a wider range of application.

In general, the same methods were employed as in the previous work. The results are given in the table on p. 835 and summarised as follows:

In general, the toxicity of a volatile organic compound is correlated closely with its volatility. A decreasing volatility is accompanied by an increased toxicity. The boiling point of the chemical is a general index of its volatility. Compounds with boiling points of 225° to 250° C. are usually so slightly volatile that they do not produce death except after very long exposures. The structure of the respiratory system of the insect is probably

responsible for the remarkable influence of volatility on the toxicity of the vapour of volatile organic compounds.

**775 - Observations on the Immunity to Rinderpest of the Nellore (Indian) Cattle and of the Nellore-Native Grade Crosses, in the Philippines.**—YOUNGBERG, STANTON (Chief Veterinarian), in *The Philippine Agricultural Review*, Vol. X, No. 4, pp. 436-447, 6 Diagr., Bibliography of 6 Publications, Manila, 1917.

During the year 1909 the Philippine Bureau of Agriculture purchased 103 head of first-class Nellore cattle, with the purpose of ascertaining if these cattle could readily adapt themselves to local condition, and if they could be used to improve the native breeds of cattle. It was found that the Nellore cattle readily adapted themselves to the conditions in the lower altitudes of the Philippine Islands and that the crosses upon native and Chinese dams produced a very good type of animal.

Since 1909 further introductions of Nellore cattle have been made from time to time, and they are now being used to a great extent throughout the Islands for improving the native stock. The high resistance to rinderpest of the "plains" cattle of India has long been recognized (1). Coincident with the extended use of Nellore cattle for breeding purposes in the Philippines the idea became disseminated that the grades were very highly resistant to rinderpest and that by importing cattle of Indian breeds and crossing them upon the native stock the rinderpest problem would be solved. In view of this, the author decided to test the resistance of pure-bred Nellore cattle to the Philippine strain of rinderpest and also to make more careful tests and observations in regard to the resistance of the Nellore native grades. The results led to the following conclusions:—The pure Nellore cattle are very highly resistant to the Philippine strains of rinderpest, the mortality being insignificant. They are not, however, absolutely immune.

In the case of native cattle, the infectivity of the virus is not appreciably attenuated by being passed through Nellore cattle. This fact makes the latter very dangerous as conveyors of the disease, as they may react without showing clinical evidence.

The half-bred Nellore-native cattle do not inherit the high degree of resistance to rinderpest possessed by the Nellore stock. In infections of moderate virulence they apparently have somewhat greater resistance than the native animals, but in virulent infections this resistance does not afford them any protection.

(1) LINGARD, ALFRED (*Report on the Preparation of Rinderpest Protective Serum*, Calcutta, 1904, p. 8) states that "The cattle and buffaloes of the plains show varying degrees of immunity, so much so that especially in the United Provinces it would be impossible to utilize them for supplying virulent blood or for the purpose of testing the protective value of sera where a marked susceptibility is necessary in the animals utilized. Further it is well known that some plains animals in this country may pass through attacks of rinderpest of so slight a character, that it may even be overlooked by the initiated in this disease". He also ascertained that these plains cattle "require a dose (of serum) 15 to 18 times less than that required by the small hill animals per 600 pounds body weight". Similar statements have been made by HOLMES, J. D. E. (*Indian Civil Veterinary Department, Memoir No 3*, p. 127; *Memoirs of the Department of Agriculture in India, Veterinary Series*, Vol. II, No 2, p. 42). (Author)

From the inconclusive evidence at hand, the three-fourths Nellorenative grades appear to have a greater resistance than the native stock. The rinderpest problem of the Philippine Islands cannot be solved by the importation of Nellore or other Indian Cattle, unless possibly by carrying it out to the extent of practically eliminating the native stock.

776 - **Official Measures Adopted in the Argentine for the Control of the Tick Transmitting "Tristeza".** — *Anales de la Sociedad Rural Argentina*, Vol. LI, No 2, pp. 124-125. Buenos Aires, March-April, 1917.

The Argentine Government, acting upon the advice of the Ministry of Agriculture and upon information furnished by various agricultural societies, issued a decree in April, 1917, for the purposes of 1) calling attention to the losses caused by ticks, 2) pointing out the necessity for vigorous sanitary action, and 3) authorising the application of the measures suggested by a Commission appointed by the Ministry of Agriculture in October, 1916, if considered suitable by the Live Stock Department.

The decree defines the limits of certain areas as tick-free, intermediate or infested. Very strict rules are laid down regarding the movement of cattle from one area to another; these will be enforced two years after the date of the decree. Cattle may be moved from unclassified establishments only after preliminary dipping and then only within their own defined area. Official dipping tanks will be installed in the larger cattle markets and wherever considered necessary throughout the intermediate and infested areas. Corrals are to be set apart for the temporary housing of tick-free cattle journeying from the north. The best insecticides for tick eradication will be obtained and exact instructions issued for their application in varying proportions throughout the different seasons, as well as practical instructions for dipping. The biology of the tick (*Margaropus annulatus*) and methods for its destruction are to be studied under direction of the Ministry of Agriculture, and only competent inspectors will be chosen to superintend the dipping-tanks. All expenses in connection with tick treatment will be reduced to a minimum.

777 - **Pathogenic Action of Ixodids.** — PARODI, SILVIO E., in *Anales de la Sociedad Rural Argentina*, Vol. LI, No 2, pp. 111-124 + 4 Figs. Buenos Aires, March-April, 1917.

This paper is a review of the subject of tick-infestation, and gives an account of the various parasites transmitted by Ixodids and of their evolution in the tick and in the animal host. The method of transmission from tick to host is described. The ticks dealt with include *Margaropus annulatus*, which transmits *Piroplasma bigeminum* and *Anaplasma marginale* as well as *Theileria* and *Nuttallia* (these last two blood protozoa have not hitherto been observed in the Argentine). The author records his own experiences in the investigation of the evolution of the parasite in the tick.

In the tubes of the salivary glands and, more rarely, in the ovarian glands of the females of *M. annulatus* he found filiform forms of the parasite, which might be defined as sporozoites. In the stomach glands he found oval forms, besides other more or less spherical ones, which he identified as more

developed forms (sporoblasts) than the former, and, consequently, consecutive.

While studying the transmission of *Anaplasma* he came to the conclusion that *Stomoxys* and Tabanids do not transmit this disease. Healthy animals placed with those infected, but freed from ticks, remained uninfected although they were attacked by these flies.

In the case of natural or spontaneous anaplasmosis the disease is always preceded by piroplasmosis. Several authors, chiefly DESCAZEAU and PICCOLLO, maintain that the piroplasms, through the meganaplasms (spherical masses of chromatin 2 to 3  $\mu$  in diameter) phase change into anaplasms, and these in their turn may change into secondary piroplasms. The author inoculated a cow at the same time with *Piroplasma* and *Anaplasma*, and observed that the two parasites always preserve their characteristic morphological conformation.

778 — **Thyroid Hyperplasia and the Relation of Iodine to the Hairless Pig Malady** (1), — HART, E. B. and STEENBOCK, H., in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 2, pp. 313-323 + 2 Plates. Baltimore, Md., February, 1918.

The writers' experience with the hairless pig malady supports the view that it is occasioned by a low iodine assimilation by either intestine or thyroid, resulting in a goitrous condition in both mother and young. This condition interferes more severely with foetal development than with the normal maintenance of the mother. It appears to be produced by rations with high protein levels and low laxative effects, with the accompanying condition of lack of exercise and unclean surroundings. Young sows exposed to such conditions are more prone to develop thyroid enlargement than are mature sows. The authors recognize that there is the possibility that some rations from certain regions are naturally so low in iodine as to make the scarcity of iodine the direct cause. They have found it possible to grow sows to maturity on natural feeding materials grown in southern Wisconsin, but of relatively low protein content and good laxative properties, with the production of normal offspring. On the other hand, these same feeds combined in different proportions and fortified with protein concentrates lead to the production of hairless pigs.

The authors are of the opinion, for the present at least, that they have not reached the stage where it is wise to advocate the general use of iodine in the feed of all brood sows; that the conditions leading to the production of hairless pigs should first be analysed fully in order that we may acquire a complete understanding of the reasons for the successful rearing of sows intended for breeding purposes through the use of natural materials, unfortified with potassium iodide. However, in regions and on farms where hairless pig production is endemic or persistent in character the direct use of iodides should be made.

779 — **Poultry Parasites.** — HADLINGTON, J., in the *Agricultural Gazette of New South Wales*, Vol. XXVIII, No. 9, pp. 671-673. Sydney, September 3, 1917.

Vermin in poultry houses naturally fall into two groups: parasites that

(1) See also R. March 1918 No. 305. (Ed.)

live and hibernate in the poultry house on roofs, etc., such as *Dermanyssus gallinae* (red mite), and those which pass their whole existence on the fowl, such as *Goniocoles abdominalis* (large chicken louse). The latter may be combated with a dust bath, or by dusting the birds by hand with insecticides, or sulphur, or with equal parts of sulphur and fine ashes. The best method of keeping poultry houses free from vermin is to spray them with kerosene emulsion as often as necessary. The emulsion, which should be applied by a force pump so as to reach all the cracks and crevices, is composed of 8 oz. soft soap dissolved in 1 gal. boiling water, 1 gal. of kerosene being slowly added while stirring, and the whole thoroughly shaken to effect emulsification. For use, 10 gals. soft water must be added, and if the spray is to be also a disinfectant, one table spoonful of miscible carbolic acid to each gallon of emulsion should be stirred in. Where the infestation is severe, 2 or 3 applications may be necessary at intervals of 1 or 2 days.

**780 — Infections Caused by *Bacterium pullorum* in Adult Fowls (1).** — HADLEY, PHILIP, assisted by CALDWELL, D. W., ELKINS, M. W. and LAMBERT, D. J., in *Agricultural Experiment Station of the Rhode Island State College, Bulletin* 172, 40 pp., 11 Tables, Bibliography of 13 Publications. Kingston, R. I., November, 1917.

The present paper gives the results of a study in which it was established that *Bact. pullorum* Rettger was the causal agent in an epidemic in adult fowls indistinguishable in its clinical picture and pathological manifestations from fowl typhoid. The primary observations and the experimental features of the study lead to the conclusion that latent *Bact. pullorum* infection was stimulated into active manifestations of fatal generalised infection as a result of intestinal irritation, or other physiological changes, following the feeding of a ration containing a large proportion of roughage in the form of oat husks. The authors point out the need of regarding more seriously the *endogenous* as opposed to the *exogenous* origin of "epidemic" diseases among poultry. Among possible endogenous disease-stimuli the importance of a hygienic feeding diet is especially emphasized. The existence of intermediate bacterial forms, resembling *Bact. pullorum* but varying slightly toward *B. gallinarum* is suggested, and it is proposed to make use of the terms *Bact. pullorum* A. and *Bact. pullorum* B. in order to keep these types distinct pending their further study. It is further suggested that *Bact. pullorum* appears to stand as a border-line group in the colon-typhoid intermediates, separating the actual paratyphoids (*B. gallinarum*, etc.) from the actual paracolons (*B. suispestifer*, *B. paratyphosus* A and B, etc.).

ANATOMY  
AND  
PHYSIOLOGY :  
GENERALITIES

**781 — Studies in Calcium and Magnesium Metabolism.** — I. GIVENS, M. H. and MENDEL, LAFAYETTE B., The Effects of Base and Acid; II. GIVENS, M. H. The Effect of Diets Poor in Calcium; III. GIVENS, M. H., The Effect of Fat and Fatty Acid Derivatives. — *The Journal of Biological Chemistry*, Vol. XXXI, No 2, pp. 421-423, Bibliography of 19 Publications; pp. 435-439, Bibl. of 15 Public.; pp. 441-444, Bibl. of 6 Publ. Baltimore, Md., August 1917.

The work described was carried out at the Sheffield Laboratory of Physiological Chemistry, Yale University, New Haven.

(1) See also R., Febr. 1918, No 180. (Ed.)

I. — The present investigation is primarily the outcome of a consideration of a claim of DUBOIS and STOLTE (*Jahrbuch für Kinderheilkunde*, Vol. LXXII, p. 21, 1913) that storage of calcium is dependent upon a suitable supply of alkali to the organism. By the addition of alkali carbonates to the food of children these investigators found that they could change a negative calcium balance to a positive one. They believed this outcome to be due to the neutralization, by the alkali, of the phosphoric and sulphuric acids formed in metabolism; also to a prevention of the formation in the alimentary canal of insoluble calcium soaps which cannot be utilized. According to the first consideration, by supplying alkali the unnecessary withdrawal of calcium as a neutralising agent for acids formed in metabolism is averted; and in the second instance the loss of unabsorbed calcium by the bowel is prevented.

The general plan of the studies of the authors involves metabolism experiments carried out with dogs, in which the income and outgo and the corresponding balance of various elements were ascertained under diverse conditions of diet. The results arrived at were as follows:—

Administration of base or acid produced no significant effect upon the balance of nitrogen, calcium, magnesium, and phosphorus in the dog.

Administration of hydrochloric acid increased the urinary excretion of calcium and thereby altered the relation of calcium to magnesium in the urine.

The calcium contained in milk was more effective than soluble calcium lactate in producing calcium retention.

Administration of large doses of alkali bicarbonate to a human diabetic did not decrease the urinary output of calcium.

II. — From a summary, given by the author in tabulated form, of all the available literature on the urinary alkali-earth excretion of *adult* dogs it is evident that there exists no *definite* relation between the diets and urinary calcium and magnesium. The tendency is for the excretion of these elements to increase as the intake of them increase.

From the literature on the subject we are led to conclude that a diet poor in calcium is not conducive to a storage of either calcium or magnesium, despite an abundance of nitrogenous food. This is further established by the author's investigations.

III. — The present conception of the digestion and utilisation of fats and other comparable esters of fatty acid would lead one to expect that if they are hydrolysed in the normally functioning alimentary tract the resulting fatty acid will either be absorbed promptly or excreted as insoluble soap with faeces. The extent to which absorption occurs may therefore depend not only upon the digestion of the esters but also upon the degree to which alkali earths are simultaneously present in the intestine to render the fatty acids insoluble and unutilizable. Conversely the loss of alkali earths through the bowel may likewise be promoted by the presence of large quantities of fatty acids. A study of the data here presented shows, with respect to the deportment of the calcium, that when the utilization is poor the loss of calcium is proportionate larger.

Similarly the negative calcium balance was smaller in those cases where the utilization of the fat was more satisfactory.

Although the quantity of calcium fed as calcium lactate in one of the periods was undoubtedly sufficient to induce a storage of lime on the basal diet this could not be accomplished when the fat utilisation was poor.

It is evident from the data presented that poor utilization of fats or fatty acids may increase the excretion of lime in the faeces and prevent the storage of calcium even when the calcium intake is comparatively abundant.

**782 — The Nutritive Properties of Maize (1).** — HOGAN, ALBERT A. (Department of Chemistry, Kansas State Agricultural Experiment Station, Manhattan, Kansas), in *The Journal of Biological Chemistry*, Vol. XXVII, No. 1, pp. 193-208, Bibliography of 21 Publications. Baltimore, Md., 1916.

The nutritive deficiencies of maize have been ascribed by the different investigators to : its lack of certain inorganic constituents ; protein deficiencies ; too small quantities of vitamins.

Most of the data described in this report were obtained by using albino rats as experimental animals. Some of them were given maize alone, others maize plus a salt mixture, a third lot maize plus an "ash-free" protein and a fourth maize plus "ash free" protein plus a salt mixture. The results are summarised as follows : —

The evidence indicates that when maize is fed to rats as the sole dietary the mineral constituents are the first limiting factor, and then the protein. In the case of swine these findings are apparently reversed. Protein is here the first limiting factor, and then the mineral element. The data also indicate that the maize proteins are less efficient for growth than casein. The addition of lysine and tryptophane to maize did not increase its efficiency for growth. The addition of some of the adequate proteins (egg white) seemed of only slight benefit. In view of these facts it seems possible that one of the limiting factors in maize as a food for growing rats is one or more of the growth accessories.

Young rats on a maize diet grow more rapidly when the grain is supplemented with casein than when supplemented with egg white. This observation assumes added significance since food mixtures containing protein-free milk, butter, and egg white are more efficient for growth than mixtures of maize and egg white, even though the protein of the maize mixture furnishes a relatively higher per cent of calories than does the protein of the more efficient diet.

Autoclaved maize mixtures failed to maintain body weight and ultimate failure resulted.

Since swine grow rapidly on a mixture of maize and egg white, it is believed that maize contains sufficient of the growth accessories for normal growth in swine.

783 - **Sudan Grass Silage.** — FRANCIS, C. K. and FRIEDEMANN, W. S., in the *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station Bulletin*, No. 115. Stillwater, Oklahoma, April 1917.

The department of chemistry of the Oklahoma Agricultural Experiment Station is engaged in investigating silage as prepared from the grain sorghums and closely related crops. A part of this experiment involves considerable work with sudan grass, and, owing to the apparent excellent quality of the silage, some of the results of this experiment have been published by the investigators in this bulletin. A steel silo 25 feet high and 9 feet wide, approximate capacity 75 tons, was used for curing the crop. The sudan grass was cut early in August during a dry period so that the plants did not contain as much moisture as desired. The sudan grass was cut to a three-quarter-inch length and a small stream of water was kept flowing into the blower, thus distributing the added water throughout the material as it was placed in the silo. During the filling of the silo the material was packed by three men tramping it into place as solidly as possible. The sudan grass owing to its leafy nature and dry condition did not pack readily. The day after the silo had been filled, water was added at the top until it ran out at the two-foot level. Three days later the contents of the silo had settled several inches and this place was filled with additional wetted silage to serve as cover. This material did not cure well, and was discarded when a strong mouldy condition developed, but the silage just beneath it cured nicely and retained its flavour throughout the feeding period. The composition of sudan grass silage as compared with maize silage is shown in Table I. The length of time which the material remained in the silo is indicated in the first column as days.

TABLE I, — *Percentage Composition of Sudan Grass Silage and Maize Silage (water-free basis).*

	Ash	Protein	Carbohydrates		Fat	Dry matter
			Fibre	N free extract		
Sudan grass silage fresh . . . . .	7.21	9.38	30.55	50.53	2.33	40.47
Maize silage fresh . . . . .	6.58	8.39	23.39	59.48	2.16	30.49
Sudan grass silage near top, 122 days . .	5.60	8.20	33.53	50.50	2.17	27.74
Maize silage near top, 148 days . . . .	6.81	9.56	23.62	57.41	2.60	27.75
Sudan grass silage from middle, 140 days	6.51	10.36	33.57	46.79	2.77	27.24
Sudan grass silage from middle, 182 days .	6.20	8.85	22.84	59.15	2.96	27.44
Sudan grass silage 2 feet above bottom, 281 days . . . . .	5.15	8.33	34.69	49.11	2.72	24.29
Spoiled sudan grass silage 2 foot-level, 192 days . . . . .	8.95	10.94	29.05	48.82	2.24	24.28

There is on the whole but little difference in the analyses of the maize silage and the sudan grass silage at the several stages of curing, the principal difference being in the quantity of fibre. The temperature developed in

the silo was noted at regular intervals until a decided fall was observed. From the data presented it appears that the maximum temperature was reached in about 21 to 30 days, being respectively 120° F. for the top portion, 104° F. for the middle portion, 21 feet from top, and 98.5° F. for the portion 5 feet from bottom.

The total quantity spoiled in this silo was approximately four feet, being the covering material. The sudan grass silage was somewhat bulkier than maize silage, was a light brown colour and had a faint acid odour. No alcohols were detected by the usual laboratory methods. The silage was fed to the College sheep, and, while proving a good feed, it did not appear to be relished by the animals so well as the maize silage, but quite as well as that made from other grain sorghums, and was relished much more in this form than as cured hay.

**784 - Nutrition Investigations upon Cottonseed Meal and Cottonseed Flour.** — RICHARDSON, ANNA E. and GREEN, HELEN S. (Nutrition Research Laboratory, Department of Domestic Economy, The University of Texas, Austin), in *The Journal of Biological Chemistry*. Vol. XXV, No 2, pp. 307-318, 5 Diagr. Baltimore, Md., June, 1916; Vol. XXX, No. 2, pp. 243-258, 13 Diagr. June, 1917; Vol. XXXI, No 2, pp. 379-388, 4 Diagr. August, 1917.

I. — In this paper the authors present a preliminary report on the efficiency of cottonseed meal as a food for promoting the growth, development and reproduction of the albino rat.

The results indicate that cottonseed meal does not contain sufficient mineral for growth, is not actively toxic, contains efficient protein, and perhaps fat-soluble growth-promoting substance, similar to those of butterfat, but in less adequate quantities.

II. — Albino rats have lived for 400 to 565 days with 50 per cent cottonseed flour in the diet.

The protein in a diet containing 50 per cent cottonseed flour, protein-free milk, and butter fat is sufficient for the normal growth and development of the albino rat and for reproduction to the third generation. No better growth is induced, but more frequent reproduction with lower mortality and more general well-being of animals are obtained, by the addition of 5 per cent casein to a diet containing 50 per cent cottonseed flour, butter fat, and protein-free milk.

Normal growth and reproduction do not result from diets containing 50 per cent cottonseed flour in which there is a lack of butter fat, protein-free milk, or both. However, 50 per cent cottonseed flour with 5 per cent casein and butter fat, without additional mineral beside that furnished by the cottonseed flour, supports normal growth and reproduction although the second generation does not grow quite normally on this diet.

No toxic effect is apparent in feeding from 45 to 50 per cent cottonseed flour to albino rats through four successive generations or during 565 days of the life of an individual. Petroleum-ether extract of the entire cottonseed fed in a well balanced diet has a depressing influence on the weight of the albino rat. Ethyl ether extract from petroleum-ether-extracted cottonseed and ethyl ether extract of Allison cottonseed flour have no harmful effect upon the albino rat.

III. — This paper considers the content in cottonseed flour of growth-essential factor other than protein and mineral, and reports the results of studies of the protein minimum of cottonseed flour. The results are summarised as follows: —

1) 20 per cent of the water extract of cottonseed flour dried on starch, equivalent per gm. to 2.5 gm. of cottonseed flour, *i. e.*, 50 per cent cottonseed flour in the diet, contains sufficient water-soluble food accessory for normal growth.

2) 4.35 per cent of the ether extract of cottonseed flour equivalent per gm. to 11.5 gm. of cottonseed flour, *i. e.*, 50 per cent cottonseed flour in the diet, does not contain sufficient fat-soluble food accessory for normal growth, but 12 per cent of the ether extract appears quite as efficient in supplying enough of the fat soluble accessory for normal growth as does an equivalent amount of butter fat.

3) 18 per cent cottonseed protein when supplied with adequate amounts of all other necessary nutritive factors induces practically normal growth of the male rat, and better than average growth in the female, and fairly normal reproduction, with high mortality and under size among the second generation.

4) 12 per cent cottonseed protein does not induce perfect growth.

Very little growth has been obtained with 6 per cent protein, the average gain in weight during 108 days being 8 to 9 gm. With only 4 per cent cottonseed protein rats have fallen off in weight when first placed upon this diet but have almost successfully maintained their weight for 50 days after.

785 - **Food Value of the Pea Nut (*Arachis hypogaea*)** (1). — DANIELS, AMY L. and LOUGHLIN, ROSEMARY (University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 2, pp. 295-301 + 3 Diagrams. Baltimore, February, 1918.

Up to the present the pea nut has been used chiefly as a cattle feed with such excellent results that the authors undertook a study to determine more exactly its food value. Feeding experiments on young rats showed the pea nut to be lacking in McCollum's fat-soluble food accessory. When 2% of butter fat was added to the ration the subjects improved, and with 5% showed absolutely normal appearance and development in every way. This, moreover, proves that the pea nut contains a sufficient quantity of McCollum's water soluble food accessory, as 56% of pea nut in the ration suffices to supply the necessary quantity of this accessory.

If the pea nut is compared with the soya bean (2) it is found to be poorer in mineral matter, especially in calcium, potassium, magnesium and sulphur. If a pea nut ration be completed by the minerals necessary to give it a mineral content equal to that of milk, which has been shown to be adequate for growing animals, a suitable food is obtained. Pea nut meal, which contains a large proportion of hulls, seems to contain sufficient mineral matter to maintain normal growth in young animals if 5% of butter fat be added.

In view of the large acreage suitable to the cultivation of the pea nut

(1) See also R. March, 1918, No 268 — (2) See R. January, 1918, No. 4. (Ed.)

and the fact that there is a tendency to use considerably more plant seeds in the diet, the authors do not hesitate to suggest the use of the pea nut as a human foodstuff. As in the case of the soya bean it is only necessary to add to it those elements in which it is lacking, *i. e.* certain inorganic material and the fat-soluble food accessory, to make it a complete food.

## HORSES

**786 — Potato Peelings and Heather as Coarse Fodder for Horses; Researches in Holland.**

— VAN DRIEST, P. A., in the *Tydschrift voor Diergeneeskunde*, Part 45, No. 10, pp. 286-288. The Hague, May, 1918.

**POTATO PEELINGS.** — According to the author, these constitute an excellent coarse feed for horses. Chemical analysis shows that washed and finely chopped peelings contain 12 % of starch, 1.27 % of albuminoids and 83.4 % of water. Although, according to SJOLLEMA the albuminoids in the peelings are of good feeding value and digestibility, the peelings are principally a starchy food.

As regards solanin, the author found that of 2 samples of peelings, one raw, the other having been boiled for 12 minutes, on analysis by the Meyer method the first was found to contain 80.4 % of water and 0.016 % of solanin, and the second, 90 % of water and 0.006 % of solanin. The increased water content, therefore, results in a reduced solanin content. Further the author has found that solanin is almost completely soluble in boiling water containing a very small amount of vinegar. Therefore, he advises, so as to avoid entirely the bad effect of solanin, that the peelings should be cooked for 10 to 15 minutes in water containing a little vinegar, then immediately removed as, on cooling, the solanin might be precipitated and be deposited again on the peelings.

Cooking the peelings has the advantage that their relatively high potash content, which is supposed to produce bad effects, is considerably reduced. In fact, the author found that a sample of raw peelings contained 1.14 % of ash, while after cooking there was only 0.58 %. As potassium compounds are mostly soluble, it may be admitted that in this way the greater part of the potassium is removed.

**HEATHER.** — To determine its feeding value, 2 pairs of draught horses were used that gave the same amount of work. The first team received each day 6.6 lb. of heather over and above the normal ration; the second team served as control. The animals were weighed every 2 days; the heather did not in any way influence the increase in live weight of the animals.

## CATTLE

**787 — A Study of the Rate and Economy of Gains of Fattening Steers.** — MUM-

FORD, H. W., GRINDLEY, H. S., EMMETT, A. D. and BULL, S., in *University of Illinois Agricultural Experiment Station, Bulletin* No. 197, pp. 567-604. Urbana, Illinois, March, 1917.

This bulletin is one of a series reporting the findings of an investigation in regard to the effect of variations in the amount and character of feed consumed upon the nutrition of two-year-old steers. It gives the results relating to the effect upon the rate and economy of gains: — 1) of variations in the amount of feed consumed ranging from maintenance to full feed rations; 2) of variations in the proportions of roughage and con-

centrates in the ration ; and 3) of the substitution of a nitrogenous concentrate for a part of the grain of a ration of clover hay and ground maize in the ratio of 1 to 5.

*The Experiment.* — Sixteen two-year-old, choice feeder steers were divided into 4 lots of 4 steers each. One lot was given a ration slightly above maintenance, another, an amount of feed equal to the maintenance ration plus one-third of the difference between the maintenance and the full-feed rations, another, an amount equal to the maintenance ration plus two-thirds of the difference between the maintenance and the full-feed rations, and another as much feed as the steers would eat readily.

The experiment lasted for 27 weeks and was divided into five test periods. The first period was 5 weeks in length, the second, third and fourth were each 6 weeks in length and the fifth was 4 weeks in length.

The feeds used were clover hay, ground maize, and linseed oil meal. The ration of the first test period consisted of clover hay and ground maize in the ratio of 1 : 1, that of the second, of clover hay and ground maize in the ratio of 1 : 3, that of the third, of clover hay and ground maize in the ratio of 1 : 5, and that of the fourth and fifth of clover hay, ground maize, and linseed oil meal in the ratio of 1 : 4 : 1.

In periods 1, 2, 3, 4, 5, the average daily gains of the different lots and the individual variations were as shown in Table I :

Lot		Average daily gains	Variations in daily gains
		lb.	lb.
Period 1	Maintenance . . . . .	1.46	0.34 - 1.97
	One-third-feed . . . . .	2.08	1.69 - 2.51
	Two-thirds-feed . . . . .	2.87	2.51 - 3.37
	Full-feed . . . . .	2.98	2.54 - 3.40
Period 2	Maintenance . . . . .	0.00	— 0.12 - 0.07
	One-third-feed . . . . .	1.64	1.31 - 1.98
	Two-thirds-feed . . . . .	1.84	1.57 - 2.24
	Full-feed . . . . .	2.28	1.95 - 2.62
Period 3	Maintenance . . . . .	0.04	— 0.12 - 0.14
	One-third-feed . . . . .	1.12	0.55 - 1.40
	Two-thirds-feed . . . . .	1.48	1.02 - 1.74
	Full-feed . . . . .	1.50	0.90 - 2.12
Period 4	Maintenance . . . . .	0.85	0.74 - 0.95
	One-third-feed . . . . .	1.65	1.36 - 2.17
	Two-thirds-feed . . . . .	2.14	1.74 - 3.07
	Full-feed . . . . .	2.45	1.81 - 2.86
Average of the 4 periods	Maintenance . . . . .	0.70	0.37 - 1.05
	One-third-feed . . . . .	1.32	1.23 - 1.39
	Two-thirds-feed . . . . .	1.79	1.75 - 1.81
	Full-feed . . . . .	2.13	1.98 - 2.29

The consumption of dry substance, digestible dry substance and net energy per pound of gain by one-third, two-third and full feed lots in the 5 periods was as shown in Table II.

Lot		Dry substance per lb. of gain		Digestible dry substance per lb. of gain		Net energy per lb. of gain	
		Average	Variation	Average	Variation	Average calories	Variation calories
		lb.	lb.	lb.	lb.	lb.	lb.
Period 1	One-third-feed . . .	6.61	5.35- 8.17	4.36	3.68- 5.38	4.12	3.50- 5.09
	Two-thirds-feed . .	6.25	5.37- 7.21	3.99	4.41- 4.63	3.76	3.21- 4.34
	Full-feed . . . . .	7.33	6.02- 8.71	4.59	3.82- 5.40	4.32	3.61- 5.06
Period 2	One-third-feed . . .	7.95	6.57-10.12	5.71	4.73- 7.20	5.90	4.88- 7.45
	Two-thirds-feed . .	9.96	7.78-11.85	6.85	5.40- 8.09	7.05	5.54- 8.33
	Full-feed . . . . .	9.86	8.27-12.06	6.36	5.35- 7.24	6.51	5.47- 7.40
Period 3	One-third-feed . . .	10.40	8.05-20.30	7.91	6.10-15.24	8.46	6.53-16.33
	Two-thirds-feed . .	11.08	9.70-16.47	8.15	7.14- 11.71	8.72	7.63-12.53
	Full-feed . . . . .	12.41	7.64-20.16	8.63	5.66-13.16	9.08	6.04-13.65
Period 4	One-third-feed . . .	6.81	5.18- 7.78	5.24	3.98- 6.04	5.53	4.20- 6.38
	Two-thirds-feed . .	7.06	5.11- 8.28	5.30	3.83- 6.22	5.58	4.04- 6.55
	Full-feed . . . . .	7.64	6.94- 8.22	5.79	5.50- 6.50	6.15	5.56- 6.87
Average of the 4 Periods	One-third-feed . .	9.51	9.17-10.04	6.96	6.73- 7.29	7.22	6.97- 7.55
	Two-thirds-feed . .	9.40	8.95- 9.64	6.67	6.48- 6.86	6.90	6.67- 7.10
	Full-feed . . . . .	9.63	8.41-10.47	6.60	5.95- 7.23	6.73	6.10- 7.48

From these results the following conclusions were drawn:—

Two-year-old steers may be maintained on 8 to 9 lb. of dry substance, 0.39 to 0.44 lb. of digestible crude protein and 6.5 to 6.8 calories of net energy per 1000 pounds live weight.

Fattening two-year-old steers may make satisfactory gains over a period of twenty-seven weeks on 14.3 to 22.1 lb. of dry substance, 0.72 to 1.44 lb. of digestible crude protein, and 11.9 to 13.0 calories of net energy per 1000 pounds live weight. Fairly good gains may be made even on less amounts than these.

The rate of gains of two-year-old steers depends upon the amount of feed consumed. However, the amount of feed consumed between one-third feed and full feed apparently has no effect upon the economy of gains as measured by the consumption of feed, of total dry substance, of digestible dry substance, and of net energy per pound of gain.

When a ration consisting of clover hay and ground maize in equal parts is changed to a ration consisting of one part of clover hay and three parts of corn, the amounts of digestible dry substance and net energy remaining practically unchanged, but the protein being reduced 10 to 12 per cent, the rate of gains and the economy of gains are considerably decreased. When a

ration consisting of one part of clover hay and three parts of ground maize is changed to one consisting of one part of clover hay and five parts of ground maize, the digestible dry substance, digestible protein and net energy also being slightly reduced, the rate and economy of gains are decreased.

The substitution of one part of linseed meal for one part of maize in a ration of clover hay one part and ground maize five parts, materially increases the rate of gains and the economy of gains. Steers which have been kept on a low plane of nutrition (maintenance) for a considerable time make more economical gains when put upon a full-feed ration than steers which have been upon full feed for some time. However, steers receiving more than a maintenance but less than a full-feed ration make no more economical gains when put upon full feed than steers which have already been on full feed.

From the results obtained in this investigation it seems safe to conclude that steers may be maintained or fattened with the ordinary rations of the corn belt on less digestible dry matter, on less digestible protein and on less net energy than the amounts prescribed by the generally accepted feeding standards.

**788 - Influence of the Age of the Cow on the Composition and Properties of Milk and Milk Fat.** — ECKLES, C. H. and PALMER, L. S. (Missouri Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. XI, No. 12, pp. 645-658. Washington, D. C., December 17, 1917.

The question of the changes in the composition of milk with successive lactation periods and particularly the question relative to the percentage of fat in the milk of the heifer has been of great practical importance to the dairyman, as a possible index of what may be expected from the mature animals. The conclusions so far reached from data compiled by several investigators have not been entirely uniform. This paper offers new data on the question, taken from the records of the University of Missouri dairy herd, composed of pure-bred animals of the Jersey, Holstein, Ayrshire and Short-horn breeds.

The data showing the average percentages of fat for the successive lactation periods of all animals of each breed and similar data for the entire herd are given in Table I. An examination of the record of the individual animals of each breed, showed rather striking differences among the breeds with respect to the frequency with which the individuals of each breed showed the highest fat test in each lactation period. This frequency calculated as the percentage of cows of each group showing the highest test for each period is presented for each breed in Table II which may be referred to as a frequency table.

These data show that the percentage of fat in the milk of Jersey cows attains its maximum with respect to the average for the entire lactation period during any one of the first three periods, but the chances appears to be greater that this will be attained in the second or third period rather than the first.

Holstein cows on the contrary almost invariably show the highest average percentage of fat for the lactation period during the first period and the conclusion seems justified that this is a breed characteristic.

Ayrshire cows more frequently show a higher average lactation test during the first than during subsequent periods, but less frequently than in the case of Holstein cows.

The variations in the average percentage of fat among the first few lactation periods are not sufficiently great to be of much practical importance, but the gradual decline in average test accumulates to a figure of considerable importance as the number of lactation periods becomes greater.

The fact that certain of the animals of the Jersey and Holstein breeds whose records are included in the data, comprised an experiment to determine the influences of the plane of nutrition during growth and age of first calving upon the dairy qualities of cows, suggested that the two factors may have contributed to the difference in the character of the data from the two breeds.

The data concerning the influence of the plane of nutrition during growth, indicate that this factor may be of importance in connection with the average fat test for the first lactation period. The light-fed Jerseys showed both a lower average test in the first lactation period and also a less frequent tendency for this period to show the highest test, while the heavy fed Jerseys showed exactly opposite results. The strong breed tendency for the Holsteins to show a higher average test in the first lactation period than in any subsequent period was also materially diminished by light feeding during the growth of the animals.

It must also be considered that the light feeding of the animals for both breeds was by no means extreme, although it was widely different from the heavy feeding carried out with the other animals in the experiment.

The data bearing on the age of first parturition indicate that a difference of 16 months between the first parturition of the Jerseys had little influence upon the breed tendency already noted for the higher test to accompany the second lactation period. In the case of the Holsteins, however, calving at a more advanced age seemed to decrease the breed tendency for the first lactation period to show the higher average test. As far as the composition and properties of milk of aged cows is concerned neither the percentage composition of the milk nor the physical and chemical constants of the milk fat of aged cows show any abnormalities attributable to old age.

Butter made from the milk of a cow 19 years old and in her thirteenth lactation period was pronounced to be of excellent quality and kept for a period of three months at a temperature of 8° to 10° C, without showing any marked deterioration.

**789 - Researches on a New Galactagogue, in Italy.** — BRENTANA, D., in the *Rivista di Agricoltura*, Year XXIV, No. 18, pp. 141-142. Parma, May 3, 1918.

The author has studied the effect of injecting the animal with its own milk on the milk produced. The experiments were carried out on various cows and are still in progress. The results so far obtained appear to show that the injections really have an effect on the increase in milk yield of cows. The author, who will shortly deal with the matter more fully, presents the following note.

The best practical application of the method is to give a subcutaneous injection of 10 or 20 cc. of the cow's own milk every 10 or 20 days, commencing the tenth day after calving. The increase in milk production will be about 2 litres a day, and the composition of the milk will hardly vary. The technique of the method is very simple:—

1) Collecting 20-30 cc. of milk in a sterile recipient, after thoroughly cleansing the udder and the milker's hands.

2) Subcutaneous injection, under perfectly aseptic conditions, of 10-20 cc. in the cow from which the milk has been taken.

The author never had any trouble whatever with the injections that he made.

The treatment should be accompanied by adequate feeding for, if the udder can be stimulated, it is still necessary to provide the substances required for milk-formation.

**790 - Breeds of Dairy Cattle in the United States.** — DAVIS, H. P., in the *United States Department of Agriculture, Farmers' Bulletin 893*, pp. 1-36, Washington D. C., November, 1917.

In the United States five breeds of dairy cattle have attained considerable prominence, namely, the Ayrshire, Brown Swiss, Guernsey, Holstein-Friesian and Jersey. These breeds have been developed carefully for a considerable time for the purpose of dairy production and in consequence each transmits its characteristics with regularity to its offspring. Certain distinct features distinguish each breed from the others but all possess ability as milk producers.

**THE AYRSHIRE BREED.** — The first importation of Ayrshires in the

United States was made in 1822, since which time there have been frequent importations into both the United States and Canada. New England, New York and Pennsylvania probably contain the largest number of representatives of the breed. There is a small distribution in the middle Atlantic States and the Pacific Northwest. In Canada Ayrshires have had great popularity and the breed seems able to withstand the rigour of the Canadian climate. In weight the cows vary from 900 to 1300 pounds with an average for the United States of about 1000 pounds; bulls weigh between 1400 and 2090 pounds averaging about 1600 pounds.

Probably none of the other dairy breeds can compare with the Ayrshires in ability to obtain a livelihood on scanty pastures and this ability has made them very useful in sections where there is much rough land in pasture.

Ayrshire milk is only slightly coloured, and the fat is divided in uniformly small globules which on the average are smaller in size than those of any other breed.

The average of the 2598 cows that have completed yearly records for advanced registry to July 1, 1917, is 9555 lb. of milk testing 3.95 % butterfat; amounting to 377.51 lb. of fat.

The 10 highest producers of the breed for butterfat to July 1917 (the milk yields given first being for comparison only) were:— 1) Lily of Willowmoor (22269): 22 596 and 955.56 lb.; 2) Auchenbrain Brown Kate 4th (27943): 23 022 and 917.60 lb.; 3) Imp. Garclaugh May Mischief (27944): 25 329 and 894.91 lb.; 4) Auchenbrain Yellow Kate 3d (36910): 21 123 and 888.33 lb.; 5) Jean Armour 3d (32219): 21 938 and 859.65 lb.; 6) Agnes Wallace of Maple Grove (25171): 17 657 and 821.45 lb.; 7) Netherhall Brownie 9th (23985): 18 100 and 820.91 lb.; 8) Garclaugh Spottie (27 950): 22589 and 816.25 lb.; 9) Gerranton Dora 2d (23853): 21023 and 804.79 lb.; 10) Jean Armour (25487): 20 174 and 774.73 lb.; the *average* being 21356.1 lb. of milk and 855.4 lb. of butterfat

*Families.* On account of the comparatively recent origin of the breed few families have been developed. The more prominent in the United States are the Brownie, Auchenbrain, Finlayston, White Cloud, Jean Armour and Garclaugh May Mischief.

*Bulls.* The 10 Ayrshire bulls having the largest number of daughters with advanced-registry records to July 1917, are listed below, in Table I, together with the average production of their daughters.

The official organization of the Ayrshire breed in the United States is the Ayrshire Breeders' Association, with headquarters at Brandon, Vt. The secretary resides there and has charge of both registration and advanced registry work.

**THE BROWN SWISS BREED.** — The first importation of this breed into the United States was made in 1869 and comparatively few animals have since been brought into the country. The breed is not widely distributed in the United States being found principally in the States of New York and Wisconsin. The cows when mature weigh from 1100 to 1600 lb., with an average for the United States of about 1250 lb.; bulls range from 1500 to 2500 lb.

TABLE I. — *Ten Ayrshire bulls with largest number of advanced-registry daughters.*

Names	Number of daughters	Average pounds of milk	Average pounds of butterfat
g. Imp. Finlayston 882 . . . . .	78	10 513	431
2. Nox'emall 7312 . . . . .	79	9 646	367
7. Earl's Choice of Spring H.11 8 289 . . . . .	58	8 918	375
4. Imp. Morton Mains' Queechy 11 537 . . . . .	40	9 244	374
5. White Cloud of Hickory Island 10 377 . . . . .	36	11 133	435
6. Imp. Mooustone of Drumsnie 8 228 . . . . .	30	8 797	358
7. Imp. Holehouse White King 10 348 . . . . .	35	10 125	397
8. Imp. Howie's Dairy King 9 855 . . . . .	28	11 668	457
9. Benchan Peter Pan 12 971 . . . . .	27	11 414	438
10. Willowmoor Robin Hood 11 900 . . . . .	26	9 621	419

In disposition the cattle are mild and docile and for their size are very active; they are excellent grazers, especially on rough land.

In milk production this breed ranks well in the United States, with a moderate percentage of fat. The average of the 199 cows that have completed yearly records of production to June, 1917, is 10 868.7 lb. of milk testing 3.995 %, amounting to 433.45 lb. of butterfat.

The 10 highest butterfat producers of the breed (the milk yield given first being for comparison only) were:— 1) College Bravura 2d (2577): 19 460.6 and 798.16 lb.; 2) Ethel B. (3842): 18 816.2 and 779.97 lb.; 3) Rosalind B. (3905): 16 804.4 and 727.64 lb.; 4) Lola (3923): 16 844.6 and 685.47 lb.; 5) Edna C. 3d (5092): 16 496.7 and 669.35 lb.; 6) Lottie G. D. (3530): 17 595.3 and 664.25 lb.; 7) Brownie F: 17 420.8 and 662.25 lb.; 8) Kalliste W. (2905): 16 609.2 and 650.32 lb.; 9) Flora Duwire (4105): 16 538.1 and 649.42 lb.; 10) Nau of Lake View (4061): 17 136.4 and 647.30 lb.; the average yield being 170 65.6 and 683.72 lb. respectively.

*Families.* Families of Brown Swiss have not been developed to any great extent in the United States.

*Bulls.* Only few bulls have more than one daughter in the Register of Production; the 11 with the largest number of daughters to June, 1917, are: Mc Avoy, 2068; Zell, 2512; Reuben, 2927; Casper C., 1999; Ben Hanson, 2373; Collier, 2075; Junker, 2365; Mack IV., 2901; Meeta's Son, 1747; Richard Esmond, 1342; Speedwell, 2582. The official organization of the Brown Swiss breed in the United States is the Brown Swiss Cattle Breeders' Association and the secretary for both registration and Register of Production resides at Beloit, Wisc.

**THE GUERNSEY BREED.** — The first representatives of this breed were imported into the United States in the early part of the nineteenth century, but not until the last quarter of that period were efforts made to keep the breeding pure by the establishment of a herd register. Since that time there have been importations almost every year and the breed has grown

steadily in numbers and popularity. At present the largest numbers are found in the Eastern States, the Middle Western States coming next.

Guernseys are medium in size, varying in weight from 900 to 1400 lb., with an average for the United States of 1050 lb.; the bulls range from 1400 to 2200 lb., averaging about 1600 lb.

Guernseys possess a nervous disposition but are very quiet if properly handled.

Milk from Guernsey cows is noted for its extremely yellow colour and high percentage of butterfat. The fat globules are larger than those in milk from either Holstein or Ayrshire cows and consequently the cream rises more rapidly upon setting. The average of 6200 cows that have completed a year's record for the advanced Registry to August 15, 1917, is 8934.44 lb. of milk testing 4.99 %, amounting to 446.01 lb. of butterfat. The 10 highest butter-fat producers of the breed to August 1, 1917 (the milk yield given first being for comparison only), were:—1) Murne Cowau (19597): 24 008 and 1098.18 lb.; 2) May Rilma (22761): 19 673.0 and 1073.41 lb.; 3) Laugwater Hope (27 946): 19 882.0 and 1003.17 lb.; 4) Yeksa's Tops of Gold's Fannie (22362): 19 794.9 and 981.53 lb.; 5) Spotswood Daisy Pearl (17696): 18 602.8 and 957.38 lb.; 6) Julie at the Chêne (30460): 17 661.0 and 953.53 lb.; 7) Belladia (31909): 19 631.9 and 934.05 lb.; 8) Imp. Dairy Moon III (28471): 18 019.4 and 928.39 lb.; 9) Miranda of Mapleton (19606): 16 630.7 and 927.16 lb.; 10) Dairymaid of Pinchurst (24 656): 17285.3 and 910.67 lb.; the average yields being 19 118.9 and 976.75 lb. respectively.

*Families.* There are a number of well-developed families of Guernseys, of which the following are among the more widely known:—May Rose, Glenwood, Masher's Sequel, Governor of the Chêne, Yeksa, Tricksey, and Sheet Anchor.

*Bulls.* Some of the leading sires, with their advanced-registry progeny are given below in Table II. They are arranged according to the number of their advanced-registry daughters to May, 1916.

The official organization of the Guernsey breed in the United States is the American Guernsey Cattle Club, and the secretary for both registration and Advanced Registry resides at Peterboro, N. H.

**THE HOLSTEIN-FRIESIAN BREED.**—The Dutch settlers in the State of New York were probably the first to import individuals of the Holstein-Friesian breed, but the first importations of which records exist were made between 1857 and 1862 and many of the present day animals are descended from these importations.

Holsteins have grown greatly in numbers and popularity in recent years, owing in a great degree to the increased demands in large cities for market milk. Cattle of the breed are most numerous in the Eastern and Middle Atlantic States, with the Middle Western and Pacific sections next in order. With the exception of the Jersey, there are more Holstein cattle in the United States than of any other dairy breed. The Holstein is the largest of the dairy breeds of the United States. Cows at maturity vary in weight from 1100 to 1800 lb., with an average for the United States of about 1250 lb.; bulls range from 1500 to 2600 lb. averaging 1800 lb.

TABLE II — *Sixteen Guernsey bulls, with largest number of advanced-registry daughters.*

Names	Advanced registry daughters	Sons with one or more daughters in advanced registry
1. Masher's Sequel 11 462 . . . . .	63	20

14. Glenwood's Champion 15 639 . . . . .	20	0
15. Justinée's Sequel of the Préel R. G. A. S. 2 119 P. S.	21	1
16. King of the May 9 001 . . . . .	17	9

In disposition Holsteins are docile and rather lazy in general habits as shown in their poor "rustling" ability in grazing scanty pastures. They are large consumers of feed, especially roughage, and do best when plenty is readily available. From the point of view of milk production Holsteins average higher than any other breed. The percentage of butterfat, however, which averages lower than that of any other dairy breed, tends to counterbalance the advantage of a greater production. The 3220 cows that have completed a yearly record for the Advanced Registry to February 19, 1917, averaged 14 622.7 lb. of milk testing 3.424% butterfat amounting to 500.7 lb. of fat.

The ten highest butterfat producers among Holsteins (the milk yield given first being for comparison only), were: — 1) Duchess Skylark Ormsby (124514): 27 761.7 and 1205.09 lb.; 2) Finderne Pride Johanna Rue (121083): 28 403.7 and 1176.47 lb.; 3) Finderne Holingen Fayne (114551): 24 612.8 and 1116.05 lb.; 4) Queen Piebe Mercedes (154610): 30 230.2 and 1111.56 lb.; 5) Ona Button De Kol (115939): 26 761.2 and 1076.44 lb.; 6) Maple Crest Pontiac Application (141158): 23 421.2 and 1075.44 lb.; 7) Banostine Piebe De Kol (90441): 27 404.4 and 1058.34 lb.; 8) Royalton De Kol Violet (86460): 29 949.6 and 1036.45 lb.; 9) Keystone Beauty Plum Johanna (161616): 25 787.5 and 1035.77 lb.; 10) Pontiac Clothilde De Kol 2d (6999r) 25 318.0 and 1017.28 lb.; the averages being 26 965.03 and 1090.98 lb. respectively.

*Families.* The families of the Holsteins are very numerous and it is difficult to determine which are the more important. Probably the following are among the more widely known: — Aaggie, Abbekerk, Artis, Beets,

Burke, Butter Boy, Carlotta, Clothilde Colantha, De Kol, Fayne, Gerben, Hartog, Hengerveld, Johanna, Korndyke, Mechthilde, Mercedes, Mutual, Netherland, Ormsby, Pietertje, Pietje, Pontiac, Sarcastic, Segis, Spofford, Vale, and Veeman.

*Bulls.* The bulls having the largest number of progeny with records, according to volume 27 of the Holstein-Friesian Blue Book, are listed below. (The records are for seven days).

TABLE III

	Number of tested daughters	Number of proved sons	Number of proved daughters

The Holstein-Friesian Association of America is the official organization of the breed in the United States with headquarters at Brattleboro, Vt. where the secretary resides. The headquarters of the Advanced-Registry work of the association is at Delavan, Wis.

**THE JERSEY BREED.** — Jerseys were first imported into the United States about the middle of the last century, and since that time importations have been made practically every year. The breed probably has the largest numbers and widest distribution of all the dairy breeds of the United States. Large numbers of Jerseys may be found throughout New England, the Middle West, the South and the Southwest. Jerseys are the smallest of the dairy breeds. Mature cows range from 700 to 1 300 lb., with an average for the United States of about 900 lb.; bulls vary from 1 400 to 2 000 lb. averaging 1500 lb.

Jerseys have a distinctly nervous disposition and are usually somewhat excitable. Their highly organized nervous system causes them to respond quickly to good treatment and abundant feed.

In natural yellow colour the milk of Jersey cows ranks next to that of Guernsey cows and is usually slightly richer in butterfat. The large fat globules cause the cream to rise readily upon standing. The average of

the 5 244 cows that have completed yearly records for the Register of Merit is 7 792 lb. of milk testing 5.35 %, making 417 lb. of butterfat.

The ten highest butterfat producers among Jerseys (the milk yields being given first for comparison only) were :—

1) Sophie 19th of Hood Farm (189748): 17 557.7 and 999.1 lb.; 2) Spermfield Owl's Eva (193934): 16 457.4 and 993.3 lb.; 3) Eminent's Bess (209719): 18 782.9 and 962.8 lb.; 4) Dosoris Park Lily (233783): 16 728.1 and 957.4 lb.; 5) Jacoba Irene (140443): 17 253.2 and 952.9 lb.; 6) St. Mawes Poppy (219992): 15 782.4 and 952.3 lb.; 7) Olympia's Fern (252060): 16 147.8 and 937.8 lb.; 8) Lass 66th of Hood Farm (271890): 17 793 and 910.6 lb.; 8) Lass 38th of Hood Farm (223628): 15 284 and 890.4 lb.; 10) Spermfield Owl's Temisia (215982): 15 147.1 and 875.2 lb., the averages being respectively 16693 and 943.1 lb.

*Families.* A considerable number of families have been developed and it is difficult to determine which are the most prominent, but probably the following are among the best known:— St Lambert, Rioter, Tormentor, Golden Lad, Flying Fox, St. Helier, Combination, Oxford, Financial King, Owl, Jacoba, St Mawes, Eminent, Diploma and Torono.

*Bulls.* Some of the Jersey bulls having the largest number of Register of Merit daughters to July, 1916, were:—

1) Hood-Farm Pogis 9th 55552 with 78; 2) Hood Farm Torono 60326 with 71; 3) Spermfield Owl 57088 with 48; 4) Loretta's King 65050 with 40; 5) Interested Prince 58 224 with 39; 6) Raleigh's Fairy Boy 83767 with 39; 7) Hector Marigold 59121 with 33; 8) Gomboge's Knight 95 698 with 33; 9) Noble of Oaklands 95700 with 33; 10) Saydus's Heir 45360 with 33; 11) Royal Majesty 79313 with 32.

The American Jersey Cattle Club is the official organization, with headquarters at 324 West Twenty-third Street, New York, N. Y., which is the address of the secretary for both registration and Register of Merit.

791.<sup>1</sup>— **Establishment and Management of the Dairy Farm in India.** — KULKAR, RAO BAHADUR G. K., in *Department of Agriculture, Bombay, Bulletin*. No. 86, pp. 1-60. Poona, 1917.

Since 1908, when a bulletin on the establishment and management of dairy farms was first published by the Department of Agriculture of the Bombay Presidency, the dairy industry has developed considerably all over India, and the Military Department especially has taken up this work very seriously and has opened dairies and dairy farms all over India with up-to-date equipment and machinery. Even with regard to the civil population the question of supplying good milk to cities and towns has come into great prominence at present. This bulletin has been therefore prepared as a guide for people intending to enter this new industry.

**THE DAIRY HERD.** — The common dairy breeds in the Bombay Presidency are :—

*Cows* : Aden, Sindhi or Karachi, Gir or Sorti, Kankrej and Krishna valley. The last two are also good work breeds.

*Buffaloes* : — Jafferabadi, Dehli, Surti or Nadiadi, Deccani, Varadi, and Nagpuri.

The following table will give an idea of the prices, live weight and average annual milk yields as compiled from the records of the Civil Dairy Kirkee:

TABLE I.

Name of Breed	Average price per head in Rs.	Average live weight in lb.	Average number of animals in the herd	Period under observation, years	Average annual yield per head in lb.
<i>Cows :</i>					
Aden . . . . .	75-100	500-600	5	12	1972
Sindhi . . . . .	125-150	650-750	26	12	2022
Gir . . . . .	75-100	700-800	9	10	1604
Kankrej . . . . .	75-100	700-850	—	—	—
Krishna Valley . . . . .	100-125	900-1000	—	—	—
<i>Buffaloes :</i>					
Jafferabadi . . . . .	120-175	1100-1300	11	10	2476
Dehli . . . . .	150-200	1000-1200	11	10	1858
Surti or Nadiadi . . . . .	125-150	900-1100	37	12	2161
Deccani . . . . .	75-100	600-750	6	8	1275
Varadi . . . . .	100-125	800-1000	—	—	—
Nagpuri . . . . .	100-125	800-1000	—	—	—
<i>Bulls :</i>					
Aden . . . . .	100-150	700-850	—	—	—
Sindhi . . . . .	150-200	1000-1100	—	—	—
Gir . . . . .	100-125	1100-1250	—	—	—
Kankrej . . . . .	175-200	1000-1250	—	—	—
Surti . . . . .	100-125	1000-1150	—	—	—
Dehli . . . . .	150-200	1000-1250	—	—	—

POSSIBILITIES OF IMPROVEMENT. — Although the average yield of the Sindhi cows and of the Surti and Delhi buffaloes is 2 022 lb. and 2 161 lb. respectively still there are individuals which give much higher yields than the average as shown by the milk records of the Civil Dairy Kirkee which are given in Table II.

TABLE II.

Name of animal	Name of breed	Years under observation	Average annual milk yield, lb.	Average annual yield of the whole herd of the breed, lb.
Cows :				
Zankar. . . . .	Sindhi	13	3413	2022
Chauguni. . . . .	»	5	3551	
Mohan. . . . .	»	9	2968	
Surti Buffaloes :				
Kaveri. . . . .	Surti	13	3095	2161
Sajani. . . . .	»	9	3526	
Lavangi. . . . .	»	7	3987	

There is a further possibility of improvement by crossing the Sindhi cows with an Ayrshire bull. The results obtained at the Military Dairy Farms, Southern Circle, are encouraging as will be seen from the yields of cows noted in Table III which have completed one lactation period :—

TABLE III. *Military Dairy Farm Kirkee.*

No. of cow	Cross	Average milk yield of the cross per period lb.	Average milk yield of dam lb.	No. of cow	Cross	Average milk yield of the cross per period lb.	Average milk yield of dam lb.
1	Ayrshire × Sindhi	4308	3229	9	Ayrshire × Sindhi	4934	2148
2	»	3450	3229	13	»	8506	2761
3	»	4503	2260	14	»	3547	1986

5	»	4367	1471	26	»	4575	2068
7	»	2170	1076	24	»	5200	1973
8	»	3311	1683	6	Ayrshire × Hansi	4798	2734
14	»	7310	2917	Average	»	4789.5	2358.7

Table IV shows the average analyses of average samples of milk from 9 Sindhi cows and 27 buffaloes milked at the Agricultural College Dairy, Kirkee, between 2 and 4 a. m. in the morning and 12 and 2 in the afternoon.

TABLE IV.

		9 Sindhi cows		Buffaloes herd (27 head)	
		Morning milk	Evening milk	Morning milk	Evening milk
<i>Constituents :</i>					
Water	% . . . . .	86.75	85.91	82.99	81.92
Fat	" . . . . .	4.29	5.42	7.92	8.10
Casein	" . . . . .	3.12	2.95	3.98	4.02
Milk sugar	" . . . . .	5.28	5.40	4.98	5.39
Ash	" . . . . .	0.70	0.69	0.78	0.80

The relative proportion by weight of butter fat to milk in the average daily yield of Sindhi cows and of the whole buffalo herd is shown in Table V.

TABLE V.

Description of animal	Average quantity of milk per head in one day		Average quantity of butter fat per head in one day		Remarks
	lb.	oz.	lb.	oz.	
Cows (Sind) . . . . .	13	14	—	9.87	1 lb. butter from 22 lb. milk
Buffaloes . . . . .	9	2	—	14.37	1 lb. butter from 11 lb. milk

Approximately 1 lb. of cream is obtained from 6 to 8 lb. of buffalo's milk and from 10 to 12 lb. of cow's milk and 1 lb. of butter is obtained from 12 to 14 lb. of buffalo's milk and from 20 to 24 lb. of cow's milk. This standard is, however, found to vary month by month, as will be seen from the figures given in Table VI.

TABLE VI. — *Average number of pounds of buffalo's milk required to make a pound of butter during each month in the year.*

Month	Milk in lb.	Month	Milk in lb.	Month	Milk in lb.
April . . . . .	9.9	August . . . . .	12.1	December . . . . .	11.0
May . . . . .	9.9	September . . . . .	12.2	January . . . . .	11.1
June . . . . .	11.6	October . . . . .	12.1	February . . . . .	10.2
July . . . . .	11.8	November . . . . .	11.0	March . . . . .	10.9

According to Indian processes 15 to 18 lb. of buffalo milk are required to produce one pound of home-made buffalo butter, containing 17.45 % moisture, 81.61 % fat, 0.86 % casein and 0.08 % ash. This butter yields about 80% of "ghee", or clarified butter, obtained by evaporating the water by boiling it on a low fire for about 30 minutes; "Ghee" from fresh buffalo butter can be kept for about 2 to 3 months without any deterioration.

In outlying villages in India, where there is no demand for milk, or "ghee", desiccated milk called "Khawa" is prepared from whole milk from which cream is partially removed by setting it in shallow pans. The milk is boiled in large open vessels, until most of the water is driven off. When the mass is sufficiently thick, it is allowed to cool and is made into balls and sent out to "Halwais" (confectioners) who mix Khawa with fine sugar and turn it into "pedhas" and "burphi" which are the favourite sweetmeats of the Indians.

"Khawa" is also made from separated milk in North Guzerath. About 12 lb. of milk is required to produce one pound of "khawa", but when the whole milk is fresh and unadulterated it takes only 4 lb. to produce one pound of "Khawa".

The business aspect of the dairy industry is discussed by the writers in detail under the following headings: Equipment, machinery and other dead stock, management and labour, dairy buildings, scheme for continuous supply of green fodder, recurring annual expenses, recurring expenditure on feed and maintenance of live stock, and record sheets to be kept on a dairy farm of 200 head of cattle.

792 — Testing of Purebred Dairy Cows in New Zealand. — SINGLETON, W. M., in *The Journal of Agriculture*, Vol. XVI, No 2, pp. 63-75. Wellington, February 20, 1918.

The support accorded by the breeders of purebred dairy cattle in New Zealand to the certificate-of-record testing system, during recent

years evidences an effort that will produce a marked influence on the economic position of the dairy industry in New Zealand.

The following table shows the number of certificates issued during each calendar year since the inception of the system.

Breed	1913	1914		1915		1916		1917	
		Ordinary	Repeat	Ordinary	Repeat	Ordinary	Repeat	Ordinary	Repeat
Jersey . . . . .	67	104	14	91	3	94	11	94	12
Friesian. . . . .	48	67	11	62	9	44	5	62	14
Ayrshire . . . . .	—	17	1	12	1	9	—	4	3
Shorthorn. . . . .	—	—	—	2	—	7	—	21	—
Totals . . . . .	115	188	26	167	13	154	16	181	30

The number of breeders now testing cows shows an increase of 20 per cent over the number testing a year since, and with sufficient testing staff could have been increased to 25 per cent.

The work is destined to make rapid growth in New Zealand, with the coming of normal conditions.

Not a sufficient proportion of the breeders are yet possessed of a due appreciation of the work, and not a sufficient percentage of the dairy herds are yet headed by a purebred butter-fat-record dairy bull. The growth of dairy husbandry in New Zealand, however, suggests that for many years to come the scope for this work will be unlimited. During the year 1917 certificates have been issued for eight Friesian records of production exceeding 600 lb. of butter fat. Three of the class-averages show an increase over the preceding season. The complete figures for 1917 are as follows:—

Class	No. of cows	Average yield for Season		
		Days in milk	Milk	Fat
			lb.	lb.
Junior two-year-old . . . . .	12	346	9 887.60	353.73
Senior two-year-old . . . . .	11	323	9 655.90	326.08
Junior three-year-old . . . . .	4	361	12 797.10	455.98
Senior three-year-old . . . . .	4	343	13 711.84	480.37
Junior four-year-old . . . . .	9	353	13 615.90	475.72
Senior four-year-old . . . . .	6	359	17 250.00	601.57
Mature . . . . .	30	333	14 123.04	495.08

The class production average for the Jersey breed in 1917 was as follows:—

Class	No. of cows	Average yield for Season		
		Days in milk	Milk	Fat
			lb.	lb.
Junior two-year-old . . . . .	39	345	6 429.10	360.62
Senior two-year-old . . . . .	9	323	5 912.40	318.82
All two year-old. . . . .	48	340	6 123.90	352.70
Three-year-old. . . . .	19	328	7 176.40	398.21
Four-year-old . . . . .	9	340	7 926.60	410.53
Mature class . . . . .	31	347	8 454.99	460.92

The Ayrshire class leaders for 1917 were as follows : —

Class	Age at testing	Fat required for certificate	Yield for Season			
			Days	Milk	Fat	
	Years		days	lb.		lb.
Two-year-old . . . . .	2	348	275.3	365	12 583.00	502.55
Three-year-old . . . . .	3	321	309.1	365	11 604.20	426.68
Four-year-old . . . . .	4	348	348.3	365	14 348.60	591.16
Mature . . . . .	6	354	350.0	365	14 636.00	582.47

The work connected with the C. O. R. testing has been much decreased by the cooperation of the secretaries of the several breeders' associations.

**793 — Development of Cow-Testing Associations in the United-States.** — *The United States Department of Agriculture Weekly News Letter*, Vol. V, No. 24, p. 5. Washington, D. C., January 16, 1918.

Cow-testing associations, as a result of work by the Bureau of Animal Industry of the U. S. Department of Agriculture, have continued to increase until there are now 472 active associations composed of 12 088 dairymen, owning 216 831 cows. The past year showed a gain of 37 per cent in number of associations. The cows tested constitute almost 1 per cent. of all the dairy cows in the United States, the total number of milk cows on January 1, 1918, being in round figures 23 284 000. The most noticeable development of cow-testing associations has been in the Western States.

**794 — Goat Milk Records of the New York Agricultural Experiment Station.** — JORDAN, W. H. and SMITH, G. A., in *New York Agricultural Experiment Station Bulletin* No. 429, pp. 1-20. New York, 1917.

For three years an accurate record was kept, at the New York Agricultural Experiment Station, of the individual milk production of the animals included in the herd of milk goats; the cost of maintenance was determined, as well as the cost of milk and the composition of the milk.

The quantity of food consumed by 31 adult and 9 partially grown ani-

mals during the third year was as follows: Dry coarse food 37 740 lb.; Beets, 1 550 lb.; Cut grass, 24 000 lb.; Pasture, 132 days; Grain, 14 688 lb.

The total cost of this food at the prices then ruling was \$ 441.95. The average cost per month per goat varied from \$ 0.481 to \$ 0.992. The average cost of food per goat per year was \$ 11.05 making the daily cost \$ 0.03.

The average yearly yield for 10 animals during 3 years, including 28 lactation periods was 800.4 pounds.

The food cost of the milk per goat for all the goats during the third year was 4 cents per quart, and, for the three years during which the record was kept, 3.4 cents. The lowest cost was with the Saanen goat No. 11, for the second year, which was estimated to be 1.27 cents per quart. The other items of cost, such as care and overhead charges, it is not possible to give with any accuracy. The average food cost for a quart of milk from the Station herd of 25 Jerseys during the three years has been found to be 0.92 cents per quart.

The range of composition of the mixed milk of the whole flock as determined during the third summer was as follows: solids, 11.4 % to 11.9 %; solids not fat, 7.72 % to 8.61 %; fat 3.5 % to 3.8 %.

The composition of milk from individual goats was found to vary in total solids from 9.22 % to 18.55 %; in protein from 2.24 % to 4.96 %; in casein from 1.56 % to 4.6 %; in fat from 1.08 % to 8.4 %; and in ash from 0.43 % to 0.8 %.

A chemical study of goat's milk indicated no essential difference between the constitution of its casein and that of cow's milk. Marked and probably important differences were observed in the salts of the ash as compared with the ash of both cow's milk and human milk.

**795 — Breeds of Pigs in Brazil.** — HUNNICUTT, B. H., in *Chacaras e Quintaes*, Vol. XVII, No. 3, pp. 183-184, 1 Fig. São Paulo, March, 1917.

The native pigs of Brazil are, generally speaking, very good animals. They form more or less fixed types, usually considered as breeds, although they lack certain qualities necessary for this. The chief are:— "Canastrão"; "Canastra"; "Canastrinho" or "Tatù"; "Crioulo". The first three types, which are large, medium and small respectively, are fine fat producers. As they are not pure breeds, they lack fixed characters, and in addition, have the defect of being slow to arrive at maturity.

Foreign breeds have been tried in Brazil, with the results given below.

**Yorkshire**:— very susceptible to skin diseases and suffers from the great heat.

**Tamworth**:— being more suited for meat than lard production, which is the chief aim in Brazil, it cannot be bred on a large scale.

**Berkshire**:— seems suitable for Brazil, but has two serious disadvantages: it easily degenerates and the progeny of crosses with it lack stability.

**Poland China**:— fattens easily, docile temperament, gives good crosses which are not very prolific, lacks hardiness and easily degenerates.

**Large Black**:— suitable for small scale rearing, seems on the contrary to be little suited for large-scale rearing under Brazilian conditions.

PIGS

*Mule foot* ("Casco de burro") :— the statement that it does not suffer from disease appears unjustified.

*Duroc-Jersey* :— large, giving much fat and good meat, very fertile, hardy, good for crossing with native animals, fairly early-maturing.

Systematic selection is indispensable for the creation of a fixed national breed ; but the breeder has, in crossing with improved foreign pure breeds a much surer and more rapid method for increasing and improving the production of butcher's animals.

## POULTRY

**796 — A Study of the Effect of Cottonseed Meal versus Beef Scrap Upon the Egg Production, Fertility and Vitality of Poultry.** — AHRENS, B. A., in *Oklahoma Agricultural and Mechanical College, Agricultural Experiment Station, Stillwater, Bulletin No. 112*, pp. 20 + 21 Tables. Stillwater, January, 1917.

The object of these experiments was to determine the value of cottonseed meal as a feed for egg production when compared with beef scrap, and to determine also the effect of cottonseed meal in moderate as well as in excessive quantities upon the fertility and hatchability of eggs. The discussion of the data from these experiments is divided into two parts: Part I contains all data relating to the breeding; Part II contains data which show the value of the protein from the two sources as a factor in egg production. The conclusions arrived at are as follows :—

1) Cottonseed meal fed in combination with other feeds to form a proper nutritive ratio, or even when fed in excess, does not lower the fertility of domestic fowls, but in many cases the fertility was higher than when beef scrap or animal protein was used.

2) The percentage of fertile eggs hatched shows greatly in favour of cottonseed meal when compared with beef scrap if fed in a properly balanced ration, but when fed in excess gives rather poor hatching results.

3) The percentage of all eggs hatched also shows in favour of cottonseed meal compared with beef scrap when fed in a properly balanced ration, but when fed in excess the results are very poor.

4. As a feed for production of eggs only, and not considering effect on hatchability, beef scrap is superior to cottonseed meal, and more than makes up for its greater cost by apparently causing greater production.

5). The mortality of chicks was a great deal higher in pens fed cottonseed meal, both the normal and excessive ration.

**797 — Capons and Caponizing.** — SLOCUM, R. B., in *U. S. Dept. of Agriculture, Farmer's Bulletin 840*, pp. 15, 10 Fig., Revised Edition. Washington, December, 1917.

A bulletin for the use of poultry-farmers.

Large breeds, such as the Plymouth Rocks, Light Brahmas, Cochins, Indian Games, Langshans, Wyandottes, Orpingtons, and various crosses of these make the best capons. Cockerels should be caponized when they weigh from 1 ½ to 2 ½ lb. or when from 2 to 4 months old. The capons should be sold when 10 months old.

**798 - The Second Rearing of Silkworms in Italy, during Summer and Autumn, 1917.**

— CASELLA, L. G., in *Informazioni Seriche*, Year V, No. 2, pp 19-20. Rome, January 20, 1918.

The propaganda work for the second rearing of silkworms was helped in 1917 by the sale prices for the spring season, as well as by the quantity of unutilised mulberry leaves.

The amount of seed used for that rearing was certainly more than 15 000 ounces of 30 gm., since in Piedmont alone from 8 000 to 10 000 were hatched.

To ascertain the work done in each district by the competent institutions and the rearers, the Minister for Agriculture, who had distributed 1103 ounces of eggs hatching out of season and 463 ounces of eggs preserved by the embryostatic method, distributed a circular accompanied by a number of questions to be answered. The reports received by the Ministry of Agriculture, the most interesting of which were those of the "Associazione serica" of Piedmont, the "R. Scuola di setificio" of Como, the "Comitato per l'incremento della bachicoltura" of Milan, and of the "R. Osservatorio bacologico" of Cosenza, were examined to obtain the conclusions of greatest interest regarding the second rearing.

These reports show that with suitable climatic conditions and where the second rearings were suitably attended to, the rearings were quite advantageous. The cocoons were considered excellent, and were mostly sold at prices above 9 fr. the kg., even 15 fr. in Piedmont, and with a general average of 12.21 fr.

There were yields higher than 40 kg. per ounce, some even reaching 60 kg. On the other hand, under not very favourable conditions many rearings gave limited yields, some even proving failures.

The period indicated as being most suitable, begins at the end of August, and varies according to local conditions.

The studies and experiments on the most suitable varieties of eggs to use should be continued, and a more thorough preparation of the eggs should be encouraged by giving premiums to those who are successful. Intensive propaganda work should be carried out to spread good systems of rearing, and thus decrease the number of failures.

**799 - Sericulture in Cyprus.** — *The Cyprus Agricultural Journal*, Vol. XIII, Part. I, pp. 16-19. Nicosia, January, 1918.

During 1916-1917, the sericultural stations of Nicosia, Paphos, Vialoussa, Lapithos, and Morphon were very active. In these stations the new Cypriot race produced by the cross Japanese X Bagdad was reared, in order to fix and improve it. The breed showed improvement when compared with that of the previous year. The following results were obtained at the Nicosia Station; — *length of cocoon*: minimum = 39 mm, maximum = 44 mm.; *width of cocoon*: min. = 20 mm., max. = 22 mm.; *weight* = 3.07 gm. One ounce of seed produced 39.6 kg of cocoons. To obtain 1 kg. of raw silk 10.02 kg. of cocoons are required.

## FISH CULTURE

800 — **The Problem of the Restocking of the Alpine Lakes.** — GALLI-VALERIO, B., in the *Bulletin Suisse de Pêche et Pisciculture*, Year XIX, No. 2, pp. 18-21. Neuchâtel, February, 1918.

The restocking of the alpine lakes with fish is of considerable economic importance, especially in Switzerland on account of their large number (615 in the canton of Grisons alone). All those that are sufficiently deep are suitable for stocking with trout, as the water does not freeze down to the bottom. Nearly all are of this type, since the thickness of the ice in the alpine lakes does not exceed 32 in. The altitude is of little importance, as lakes over 6500 ft. are well stocked with trout, but on the contrary, the food question is very important. The researches carried out by PERO (*Nuova Notarisia*, 1893, pp. 3 and 47; 1894, p. 135) in the Valteline showed that algae, crustacea, insects, molluscs, and often small fish such as the minnow (*Phoxinus laevis*), are abundant in the lakes of that region and provide the conditions required for feeding trout.

The pests affecting pisciculture in that region are chiefly the otter, a rare animal, the water-shrew (*Crossopus jodiens*), the water-rat (*Arvicola amphibius*), a fish, the bull-head (*Cottus gobius*), that lives in lakes even above 6500 feet, and which devours large quantities of trout-eggs. But according to the author's observations, the greatest enemies of restocking the alpine lakes are the trout themselves, when they have grown too big, for they eat the fry and small trout.

As regards the species to choose for restocking, the author rejects *Trutta lacustris*, because it has the disadvantage that one or two individuals grow more than the others and destroy all the rest. The author tried *T. jario* from the Adda and its tributaries in the Publino Valteline lake, at 6500 ft., but found it had the same disadvantage as the previous species.

For restocking alpine lakes, a breed of *T. jario* should be used that has been bred in those lakes for generations, and which almost constitutes a distinct breed, characterised as it is by an almost black body, with brilliant red dots, almost orange flesh, and which always remains small (7 to 8 in.) so that there is no risk of one or two developing greatly, followed by the destruction of all the others. As the salmon (*Salmo salvelinus*) also occurs in certain alpine lakes, especially in the Tyrol, the author stocked lake Venina, Valteline (6022 ft.), with it, and obtained excellent results. Up to the present the lakes of the Swiss alps have been chiefly stocked with *S. irideus*.

(1) The Minister of Armament has allowed the Service a subsidy of 600 fr. per month per team for spare parts, repairs, etc.

The Department includes:— 1) a *Central Service* divided into several sections: — Secretary's office; Cultivation work; Material; Staff; Accountancy; Studies and Researches; Relations with private persons; 2) an *external Service*, which deals with the teams of 10 tractors supervised by a team-foreman who has under his orders an assistant-foreman, 2 mechanics, 2 smiths and a number of drivers. The technical section is responsible for the upkeep and repairs, as well as the provision of spare parts and tools for 372 tractors of 11 different types or makes, 393 ploughs of 9 different types or makes, 158 harvesters of 4 different types or makes, and 21 cultivators.

The report furnishes information as to spare parts, the service rendered by the central store, the supervision and repair of the tractors, motor lorries, travelling workshops, store cars, to the total number of 72.

After a detailed consideration of the organisation of the staff the report gives the results obtained during July, August, and September, 1917.

During these three months the teams have ploughed 47 577 acres, harvested 6 585 acres, scarified 1 703 acres, broken up 964 acres, and harrowed and rolled 3 188 acres. This work was carried out in 14 422 working days.

In Table I is given the financial statement of the department, whose general administrative expenses are divided among the teams of tractors. The cost per hectare for the different teams is given, the depreciation of the material, however, not being always included.

The report continues the description of the organisation of the Cultivation Department; it gives details as to insurance against accidents and fires; it gives full information as to the work and the section for fuels and lubricants, and concludes by showing the utility of the new Department which, according to the directors of the agricultural departments and the farmers themselves, has assured the re-awakening of agricultural life in the abandoned soils, thanks to the use of tractors. The report also indicates the results obtained by giving the farmers such information as to enable them to choose the tractors best suited to their needs.

TABLE II. — *Yield of the first 3 makes of tractor.*

[Number of days July-August-September]	Number of tractors	Area worked acres	Average yield per day for the whole of the machines. acres	Yield per day and per machine. acres	Average cost per acre, ploughed
1) EMERSON					
92	112	112 31	121.8	1.04	£ 2. 5. 10
2) CASE					
92	110	194 01	210.8	2.10	£ 1. 6. 5
3) MOGUL					
92	54	73 88	78.	1.48	£ 2. 1. 7

II. —The *Génie Rural* in commenting on the financial and technical results obtained by the Department, notes that they varied greatly, not only for the different types of tractors, but also for the various units made up of the same type.

Neglecting the FOWLER units, which proved to be the most economical as regards their yield per acre, it is found that the 32 other units included 116 EMERSON, 100 CASE, 54 MOGUL, 20 AVERY, 10 ROCK ISLAND, 10 TITAN and 10 BULL tractors.

In Table II (page 870) are compared the yields of the first 3 makes, bought in greater number and which have worked through a whole period, thus giving complete information. Table III gives the cost of spare parts.

TABLE III. — *Cost of spare parts.*

III. — The author describes the organisation of State Motoculture in Italy.

The "Ufficio Agrario Temporaneo" (temporary agricultural office), attached to the Ministry for Agriculture, makes out schemes for work in each zone of Italy, with the help of the directors of the Travelling Chairs of Agriculture and the regional delegates for increased food production.

At the request of this office, the "Ufficio Temporaneo degli approvvigionamenti" buys the machines, fuels and lubricators; it is helped by a technical Committee in choosing the types of machine, etc.

The staff (foremen, mechanics, drivers), chosen by the War Ministry from among the soldiers, is trained in two special schools, one at Rome, the other at Foggia.

The work is divided among units of 10 tractors each. Each unit has a foreman, an assistant, 4 to 10 mechanics, 20 to 26 drivers and 2 labourers. Each unit has its own deposit and lodgings for the men, as well as everything required for independent working.

A number of units form a *centre* of motorculture, commanded under military law by a centre commander. Each centre has an office stores, and a workshop for big repairs.

The units consists of tractors suitable for the locality where they work. The State owns numerous types of tractors of a power varying from a minimum of 8-16 HP. to a maximum of 30-40 HP. Besides ploughs the units are provided with harrows, rollers, drills and binders.

Farmers wishing to benefit from State motorculture, apply through the local delegates, paying a certain fee per acre.

802 — Agricultural Tractors in the United States, in 1918. — *Farm Implement News*, Vol. XXXIX, No. 11, pp. 38-66 + 1 Table + 1 Fig. Chicago, March 4, 1918.

A description, with many illustrations, of 161 tractors made by

The Department includes :— 1) a *Central Service* divided into several sections : — Secretary's office ; Cultivation work ; Material ; Staff ; Accountancy ; Studies and Researches ; Relations with private persons ; 2) an *external Service*, which deals with the teams of 10 tractors supervised by a team-foreman who has under his orders an assistant-foreman, 2 mechanics, 2 smiths and a number of drivers. III. — The author describes the organisation of State Motoculture in Italy.

The "Ufficio Agrario Temporaneo" (temporary agricultural office), attached to the Ministry for Agriculture, makes out schemes for work in each zone of Italy, with the help of the directors of the Travelling Chairs of Agriculture and the regional delegates for increased food production.

At the request of this office, the "Ufficio Temporaneo degli approvvigionamenti" buys the machines, fuels and lubricators; it is helped by a technical Committee in choosing the types of machine, etc.

The staff (foremen, mechanics, drivers), chosen by the War Ministry from among the soldiers, is trained in two special schools, one at Rome, the other at Foggia.

The work is divided among units of 10 tractors each. Each unit has a foreman, an assistant, 4 to 10 mechanics, 20 to 26 drivers and 2 labourers. Each unit has its own deposit and lodgings for the men, as well as everything required for independent working.

A number of units form a *centre* of motorculture, commanded under military law by a centre commander. Each centre has an office stores, and a workshop for big repairs.

The units consists of tractors suitable for the locality where they work. The State owns numerous types of tractors of a power varying from a minimum of 8-16 HP. to a maximum of 30-40 HP. Besides ploughs the units are provided with harrows, rollers, drills and binders.

Farmers wishing to benefit from State motorculture, apply through the local delegates, paying a certain fee per acre.

802 - Agricultural Tractors in the United States, in 1918. — *Farm Implement News*, Vol. XXXIX, No 11, pp. 38-66 + 1 Table + 1 Fig. Chicago, March 4, 1918.

A description, with many illustrations, of 161 tractors made by

104 American firms, giving the chief characteristics and noteworthy details of the construction :—size ; number of driving and steering wheels, or if on chain-track system ; H.P. ; draw-bar pull ; speeds ; number of ploughs that can be hauled ; size of thresher that can be driven ; engine ; cylinders and bore ; stroke ; carburettor ; ignition ; pumps ; drive ; shaft-speed ; fuels that can be used ; tank capacity ; total weight ; works price at date of publication and liable to alteration without previous notice. The characters of the 161 tractors described in the text are summarized in table form.

803 — **Traction on Bad Roads or Land.** — LEGROS, L. A., in *Engineering*, Vol. CV, Nos. 2717, 2718, 2719, 2720, 2721, 2722, 163 Figs., 2 Tables + an Historical and a Bibliographical Appendix, London, January 25 to March 1, 1918.

The author deals with the problems involved in the design of vehicles for hauling goods or agricultural implements over the land or bad roads. He chiefly deals with tractors having more than 2 driving wheels or provided with a chain track. These two classes of tractor are applicable to different conditions, and while the methods cannot be considered as competitive, the limitations of each can be best appreciated by direct comparison of their respective peculiarities and advantages.

In the first part the author, while considering various types, deals successively with four-wheel driving, four-wheel steering, four-wheel braking, automatic differential locking gears, and the application of the four driving wheels for bad roads and arable land. Comparative figures for the different types of vehicle, their horse-power, speeds, load weight, wheel base, track width, turning radius, and overall dimensions are given by the author in a table.

The author concludes that for the transport of goods over bad roads on gradients varying from 1 in 15 on roads in which the tyres sink 2 in. to 3 in. in depth to 1 in. 5 on hard roads with bad surface, and for speeds varying from 1.5 m. p. h. on grades to 12 m. p. h. on fairly level roads, the four-wheel drive tractor has great advantages over the ordinary two-wheel drive tractor.

In the author's opinion it may be expected to rank as an important factor in the development of districts overseas not far removed from railroads, but having only primitive roads.

In part 2 of the paper chain-track tractors are dealt with and classified. The author considers methods of springing, truck frames and track-frame connections, steering, driving gear, engines, ignition and starting, radiators, speed, draw-bar pull, climbing power, etc., and he describes various English, American and French tractors, the various types being shown in illustrations. Chain-track tractors have been built in the U. S. A. and used for hauling logs since 1904, some of the original ones being still in use ; these machines have intermediate roller chains ("Phoenix", ALLIS-CHALMERS, and DIPLOCK). The author gives, in a second table, a summary of the various chain-track tractors, afterwards giving details of their construction.

The tractors described are : —

The Log-Hauler, Phoenix, of 100 H.P. ; the Centiped Truck, Phoenix,

of 50 H.P.; the 68 H.P. ALLIS-CHALMERS tractor; the HOLT Caterpillar tractors of 18, 45, 75 and 120 H.P.; the CLAYTON tractors (1) of 35 and 110 H.P.; the Tracklayer (C. I. BEST) of 16, 30, 75 and 90 H.P.; the Creeping-Grip tractors (BULLOCK) (2) including the 75 H.P. Giant, the 50 H.P. Senior, the 30 H.P. Junior, and the 16 H.P. Baby; the 15 and 35 H.P. AUSTIN tractors; the 25 and 50 H.P. STRAIT (KILLEN-STRAIT) tractors; the 25 H.P. MARTIN's agricultural tractor (3); the 30 and 40 H.P. Lefèvre (4) tractor; the 12 H.P. WOLSELEY motor sleigh.

The author gives numerous examples of the use of chain-track tractors for ploughing and for transport on bad roads unsuited for the conveyance of heavy loads. He calculates that the cost of traction is  $\frac{1}{3}$  to  $\frac{1}{5}$  that by means of horses or mules. Besides their use for cultivation and road haulage, the author mentions the use of chain-track tractors for excavating drainage trenches (5); amongst these, the PARSONS excavators (20, 30, 45, 62 and 80 H.P.) and AUSTIN excavators (15 to 85 H.P.) are described.

The author concludes that where a track can be found 7 ft. wide which does not present rocky obstacles over 10 in. high, whether over sand, ash, clay, marsh, snow or ice, on the level, or on gradients up to 30 per cent., the chain track tractor has proved itself capable of travelling and performing useful work beyond the capacity of animal haulage. For this reason the chain-track tractor may be expected to occupy a position of ever-increasing importance in the development of new countries and in places where it is necessary to transport machinery and stores over roadless country many miles from the railway. Mr. LEGROS does not regard any one of the existing systems as perfect and expects that much will be done to improve the vehicles in the near future.

There is probably room for considerable improvement in the chain-track itself as well as in its supports and its anti-friction devices. The variation in resistance to haulage is so great as between one system and another, not merely in static resistance to starting, but in dynamic resistance to haulage, that, as the author has already suggested, the various track systems should form the subject of comparative tests at some of the great agricultural colleges. One feature that is particularly remarkable is the small amount of power lost in compressing soft marshy land under the feet of the track chains.

804 - **The Ford Tractor (6) and the Oliver M. O. M. Plough in England.**—*The Journal of the Board of Agriculture*, Vol. XXIV, No. 12, pp. 1456-1457. London, March, 1918.

In the Letter No. 79/M. 1, dated February 26, 1918, the Food Production Department of the Board says that is essential that the Ford tractor should be used only with the new type Oliver M. O. M. plough which was specially designed to work with it, and which is supplied with each Ford tractor. The tractor and plough together form a unit, and on no account must this tractor be used with any other type of plough.

(1) See R. 1918, No. 678; — (2) See B. 1915, No. 1912; — (3) See R. 1918, No. 678; — (4) See R. August, 1917, No. 753; — (5) See R. 1917, No. 1053. — (6) See R., 1917, No. 755. (Ed.)

The new Oliver plough is giving great satisfaction for both grass and stubble ploughing.

According to trials carried out on the farm of the Haiper Adams Agricultural College in February, 1918, the Ford tractor and the new Oliver plough gave good results in breaking up a grass field not previously ploughed for about 20 years. The special features of the Ford tractor are:—extreme accessibility of the engine parts; reduction of the lubrication parts to 11 oil-holes and grease-cups; the possibility of turning in a minimum space; direct attachment of the plough to the tractor; only one operator is required, the control levers of the plough being easily accessible to the tractor driver from his seat. As regards the Oliver plough the outlift at the end of the furrow is automatic, and the depth at which the plough is working can be easily regulated.

The plough has a skim coulter that turns in the upper layer of the turf, and at the same time keeps clean the surface of a swivel disc coulter replacing the usual knife-form of coulter. The mouldboards are well shaped and turn the furrow slice satisfactorily to a good depth. A depth of 8-9 in. was maintained satisfactory on level ground, second speed being used on the tractor. The mouldboard is of a type and setting unusual in England. Longitudinally it is concave, and transversely convex, while it is set out at an angle of 45°. The work done by the plough resembles that of fallow land ploughed with a digging plough. The land is left very light, and it is obvious that the ploughing must be followed by a discing to secure the necessary compactness, but an abundance of loose mould is produced which is not the case with the older system of ploughing. The character of lea ploughing produced is revolutionary, but there is every reason to anticipate that this type will be superior to the type of ploughing generally adopted.

805 - **Disc-Harrow Trials at Montpellier, France.**—CLAROT, C., in *Le Progrès Agricole et Viticole*, Year XXXIX, No 15, pp. 343-350, 3 Figs. Villefranche, April 14, 1918.

Disc-harrows were introduced into France a long time ago, and they are now much in favour as they are of great interest to farmers and southern winegrowers.

The author gives the results of trials that he carried out at the Montpellier School of Agriculture with the disc-harrow under widely different conditions. The trials were made a "Cotton" 6-disc harrow, supplied by the firm of BOMPARD, at Montpellier. The machine is 49 in. wide, 28 in. high without the seat, 51 in. long without the shaft, and 14 ft. with the shaft. Its total weight is about 660 lb.; the discs are 17.32 in. in diameter.

The machine was tested in a vineyard. But owing to its dimensions, and the space required for the team, it can only be used where there is at least a space of 79 in. between the vines; space is also necessary to allow for turning at the end of each row.

1) *Trial at Mas de Rochet (near Castelnaud) February 23.*—The harrow worked in a recently-ploughed sandy soil at its maximum depth of 4 to 5 in. on the first turn. There was no weight on the machine, as the

"Cotton" harrow has no arrangement to allow of this. The work was done along the furrow slice and was well done. Cultivation was not necessary as the soil was already well broken up.

2) *Trial at Mœstroun (Farm of the School of Agriculture at Montpellier), March 7.* — The Mœstroun vineyard had not yet been ploughed and the harrow turned the soil under; its work was comparable with that of an ordinary vineyard hoe. The ground was sloping; during the descent the discs did not enter the soil sufficiently, while in ascending the work was good. The tilth obtained with the pulveriser in the first turn was the same as that given by the hoe. After the first turn the pulveriser worked more deeply than the hoe. The depth was 3 in. during the first turn. The work was hard on the horses. A one horse hoe passes among all the vines but the harrow hauled by 2 horses requires 6 ft. 6 in. between the vines.

The great advantage of the pulveriser is that, in passing twice over the same ground, it would replace the plough; and that in two turns it does sufficient work almost equal to 6 furrows of the plough. In addition the grass was destroyed much better than with the hoe.

3) *Trials at Mandou (Land near the School of Agriculture at Montpellier), March 6.* — The soil was loamy, with abundance of couch-grass, and had already been ploughed and cultivated. The harrow did not destroy the couch-grass very satisfactorily. The spring-tine harrow had given much better results. Another turn with the plough would probably have been much more useful.

At Mandou the harrow was coupled to a 5-10 HP. Avery tractor, a dynamometer being placed between to register the draught of the one and the power of the other. A width of 47 in. was cultivated at each turn. The results of the trials are given in the following table.

*Comparative draught of a disc-harrow and a spring-tine cultivator.*

Disc-harrow				Cultivator		
Depth metres	Type of work done	Tractive effort in kg.	Tractive effort per metre (1) in kg.	Type of work done	Tractive effort in kg.	Tractive effort per metre (1) in kg.
0.02	Incomplete . . . .	130	110	— . . . . .	115	115
0.03	Incomplete . . . .	160	130	— . . . . .	125	125
0.04	Good . . . . .	200	160	Good scratching . .	150	150
0.06	Does not break soil up . . . . .	225	185	Excellent work . .	200	200

(1) Tractive effort per metre of width worked.

It will be seen from this table that at equal depths the draught of the 2 machines is practically the same; but the machines are not made

to work at the same depth. If the harrow goes deeper than 5 cm., it does not work well at all.

4) *Test at Bellevue (Commune of Montpellier), March 8.* — Field spring and autumn-ploughed; compact, damp soil, with occasional big clods left by deep ploughing and untouched by other hoe or roller.

The most suitable average depth was found to be 6 cm. for the pulveriser. The work was not too heavy for the horses; in 80 minutes 0.4 hectare was worked; which is equivalent to 3  $\frac{1}{2}$  hours per hectare. Normally, 2 to 3 hectares could be done a day. The results obtained were the best of the 4 trials.

The model tested was not suited for vineyard work, as a 6-disc harrow requires 2 horses. This prevents the use of the machine in vineyards having less than 6 ft. 6 in. between the rows. It is, however, very suitable in new vineyards with a width of from 6 ft. 6 in. to 7 ft. 4 in.; 8-disc harrows might even be used, and with vines on iron wire, even 10-disc harrows. The author considers that the harrow is interesting and that, used at the right moment under suitable conditions, it might be of great service to farmers for destroying weeds, etc.

806 — **A Weeding Rake for Low Vines.** — SAVASTANO, L., in *R. Stazione sperimentale di Agrumicoltura e Frutticoltura, Acireale, Bollettino No. 34*, pp. 1-2 + 1 Fig. Acireale, April, 1918.

The author has invented this tool so that women and children can weed low vines more easily in summer.

*Weeding rake for low vines.*

A  
type with broad, flat teeth.

B  
type with round or square teeth.

If, instead of using the hoe, an ordinary rake is used, many of the weeds are removed, but those with tap roots remain with the root intact, so that they quickly grow again. To avoid this, the two end teeth of the rake have been modified by making them like a knife blade with an external cutting edge. The dimensions are: —length of blade 14 in.; length of teeth 5 in.; length of handle about 5 ft. so inclined to the blade that no stooping is required when using the rake. When a tap-rooted plant comes under the rake, the tool is lifted and the root struck with the blade.

Of the 2 types of rake shown on the figure by the letters *A* and *B*, the first has broad, flat teeth, and the second round or, better still, square teeth. One or the other is used according to the kind of soil.

**807 - Economic Advantages Resulting from the Use of Machinery in Harvesting Wheat.** — See No. 812 of this *Review*.

**808 - A Hemp Harvester.** — *The Implement and Machinery Review*, Vol. XLIII, No. 516, p. 1291, 1 Fig. London, April 1, 1918.

This harvester is made by the INTERNATIONAL HARVESTER CORPORATION, Chicago, U. S. A., being devised with idea of enabling hemp to be grown on a large scale notably for the manufacture of binder twine. In 1917, the Ridge Land & Navigation Co., of Stockton, California, raised 4 000 acres of hemp and handled the whole crop by machinery.

This hemp harvester is of necessity much larger and heavier than a grain binder, for hemp may grow from 6 to 9 ft. high. Hemp of this height is most desirable and produces the best fibre. Because the hemp grows so high a wider platform has to be provided and the reel has to be much higher and fitted with special fans. A heavy knife, with special guards, is also essential.

Hemp harvester.

In order that the hemp may be spread on the ground so as to ret properly, and so that each swath may be moved out of the way of the horses and harvester on the next round, the hemp is moved to the right and placed down at right angles to the machine. A circular carrier accomplishes this, as shown in the appended illustration, the mechanism laying the hemp in a nearly straight line, and at almost perfect right angles to the harvester.

The retting of hemp requires from 2 to 3 weeks to 2 or 3 months, depending on the humidity and the temperature. Three machines are required to complete the cycle of harvesting hemp and producing the fibre. When the retting is complete the hemp binder picks up the hemp and ties it into bundles, which are shocked similarly to maize, with the difference that the shocks are made more open to permit a free circulation of air. When the shocked hemp is ready, it is taken to the braker, from which it passes to the scutcher.

### 809 - Review of Patents.

**TILLAGE MACHINES AND IMPLEMENTS.** — *Italy*: 158480 Rotary motor-plough; 159764 Rotary plough.

*United Kingdom*: 113684 Agricultural skimmer plough; 114028 One way motor plough.

*United States*: 1258109 Rotary cultivator; 1258286 Multiple disc plough for mechanical traction; 1258287. Disc cultivator attachment; 1258681 Plough; 1258951 Lister plough; 1259174 Agricultural implement frame; 1259511 Power lift tractor lister; 1259638 Traction plough; 1260079 Cultivator; 1260318 Harrow; 1260497 Disc harrow; 1260573 Landroller; 1260738 Power propelled agricultural machine; 1260752 Plough coulter.

**DRAINAGE AND IRRIGATION.** — *Switzerland*: 77759 Drainage pipe.

*United States*: 1258240 Irrigation water elevating device; 1258759-1259746 Ditch or drain forming device; 1259211 Irrigation apparatus; 1259684 Drainage pipe.

**MANURES AND MANURE DISTRIBUTORS.** — *France*: 486840. Physiological manure composed of the plant's natural salts for directly and locally fertilizing any agricultural seed or plant.

*United Kingdom*: 113571 Process and apparatus for producing a nitrogenous manure from straw or other material containing fermentable carbohydrates by fixation of atmospheric nitrogen; 113648 Process for producing calcium superphosphate.

*United States*: 1258378 Straw spreader; 1259456 Harvesting and reduction apparatus for sea kelp; 1259457 Kelp incinerator; 1259739 Spreader; 1260219 Fertilizer spreader; 1260332 Combined cultivator and fertilizer distributor; 1260777 Apparatus for distributing fertilizers.

**DRILLS AND SEEDING MACHINES.** — *Netherlands*: 2378 Bulb planter.

*United States*: 1259033 Seed planting attachment for cultivators; 1260174 Ridging attachment for planters; 1260808 Planter.

**VARIOUS CULTURAL OPERATIONS.** — *France*: 486641 New system of cultivation.

*United States*: 1258085-1259940 Cultivators; 1258275 Portable machine for fastening vines to supports; 1258340 Cotton chopper; 1258680 Wheeled cultivator; 1260332 Combined cultivator and fertilizer distributor; 1260746 Sugar cane cultivator.

**CONTROL OF DISEASES AND PESTS OF PLANTS.** — *France* 486556 Regulator for dusting and similar machines.

*Switzerland* : 77763 Process for manufacturing a product for destroying pests.

*United States* : 1258504 Insect catcher ; 1258930 Quack-grass destroyer.

REAPERS, MOWERS AND OTHER HARVESTING MACHINES. — *France* : 486735 Improved motor-binder.

*Italy* : 159363 Lifter for harvesting lodged cereals.

*Switzerland* : 77881 Fruit picker.

*United Kingdom* : 114082 Flax pulling machine.

*United States* : 1257972-1259767 Maize harvesters ; 1258277 Cotton picker ; 1258671 Chain sickle mower ; 1259465 Reaper ; 1259647 Shock binder ; 1259803 Self cleaning rake ; 1260031 Gang mower ; 1260410 Butt adjuster for maize harvester ; 1260906 Rake.

MACHINES FOR LIFTING ROOT CROPS. — *United States* : 1258456-1258818-1260715 Beet topping machines ; 1258819 Beet digging machine ; 1259178 Beet harvester.

THRESHING AND WINNOWER MACHINES. — *United States* : 1258354 Separator ; 1258858 Forced straw stacker for threshing machine ; 1260014 Band cutter and feeder for threshing machine ; 1260227 Grain separator.

MACHINES AND IMPLEMENTS FOR THE PREPARATION AND STORAGE OF GRAIN, FODDER, ETC. — *France* : 486822 Fodder loader.

*Italy* : 160096 Improvement to machines for grinding cereals, oats, chestnuts, etc.

*Netherlands* : 2371 Latex coagulating apparatus.

*Switzerland* : 77880 Process and apparatus for ventilating haystacks.

*United Kingdom* : 113700 Apparatus for packing grains, etc.

*United States* : 1258125-1259678 Peanut shellers. 1258142 Shock loader ; 1258217 Seed maize drier ; 1258245 Pepper peeling machine ; 1258848-1259961 Baling presses ; 1258958 Fruit sizing machine ; 1259034 Attachment for gin-feeder ; 1259081 Variable speed drive mechanism for cotton gin ; 1259613 Fruit packing press ; 1259905 Fruit and melon grader ; 1260059 Beet loading machine.

FORESTRY. — *France* - 486895 Heath grubbing machine for animal traction.

*Switzerland* : 77761 Plant for cutting and bundling twigs.

TRACTION AND STEERING OF AGRICULTURAL MACHINERY. — *France* : 486651 Motor-windlass car ; 486767 Tandem tractor.

*Italy* : 156674 Driving wheel for tractor and motorplough.

*United Kingdom* : 113497-114109 Power cultivation of land (haulage by cables).

*United States* : 1257976 Power attachment for automobiles ; 1257999 Farm and road tractor conversion attachment ; 1258221-1258362-1258512-1258973-1260259 Tractors ; 1258288 Chain track drive and support for tractor ; 1258329 Truck for converting an autocar into a tractor ; 1258489 Tractor gearing ; 1258501 Tractor wheel rim ; 1258502 Agricultural tractor ; 1258601-1258612-1258613 Track chains ; 1258602-1258605 Endless trackbelt tractors ; 1258603 Traction engine with a pair of endless tracks and one steering wheel ; 1258607 Wheel for tractor truck

mechanism; 1258608 Track link construction; 1258611 Support for chain track; 1260402 3-horse draft equalizer.

FEEDING AND HOUSING OF LIVESTOCK. — *Italy*: 159264 Liquid, concentrated or solid animalized vegetable milk for rearing stock.

*United Kingdom*: 113988-114115 Horseshoes.

*United States*: 1259071 Hay distributor; 1259084 Calf feeder; 1259112 Hog trough; 1260339 Fly catcher for stables and barns.

POULTRY FARMING. — *United States*: 1258037-1259726 Incubators; 1258069 Mechanism for feeding device.

FISHING. — *United States*: 1258213 Fish hook.

INDUSTRIES DEPENDING ON PLANT PRODUCTS. — *Italy*: 159569 Bolt-ing machine drive.

*Netherlands*: 2427 Improvement to sugar cane crushers.

*Switzerland*: 77926 Hand mill with two superimposed plates for treating fruit stones.

*United Kingdom*: 113486 Bakers' yeast; 113530 Apparatus for extracting oils from seeds, etc., by solvents; 113558 Conveyor for mechanical bread making; 113628 Rotary filtering drum for pressing yeast; 113997 Process for reduction of grain in view of increasing the yield of flour from wheat and other cereals; 114024 Apparatus for depericarping palm nuts, olives, etc.

*United States*: 1258571 Apparatus for decorticating, washing and drying sisal and other fibrous materials; 1258866 Machine for working dough or other plastic substances; 1258981 Fruit juice extractor; 1259213 Fruit slicing machine; 1259483 Milk substitute composed of edible oil, flour, glucose, salt and water; 1259774 Apparatus for drying tomatoes and fruit; 1260053 Fruit press; 1260399 vegetable slicing machine.

INDUSTRIES DEPENDING ON ANIMAL PRODUCTS. — *Italy*: 159839. Process and apparatus for the rapid tanning of skins.

DAIRYING. — *United States*: 1258036 Milkcan; 1258095 Churn-dasher; 1258902 Milk sterilizer; 1258996 Method of making composition butter; 1258997 Artificial butter composed of cream and condensed skimmed milk; 1259047 Ventilating cream can cover; 1259323 Combined stool and milk pail; 1260127 Milk pasteurizer.

FARM BUILDINGS AND EQUIPMENT. — *Italy*: 159799 Bottom drained MARIANECCI silo for storing sugar beet pulp.

*United States*: 1259021 Grain elevator structure; 1259039 Farm gate; 1259080 Portable shelter.

VARIOUS. — *United States*: 1258048 Orchard-ladder on truck; 1258198 Adjustable horse collar; 1259055 Horse collar; 1259239 Orchard ladder; 1259669 Soil testing machine.

#### FARM BUILDINGS

810 — Movable Pig-Houses. — I. EDWARD, J. M. and DAVIDSON J. B., extracted from *Agricultural Experiment Station, Iowa State College of Agriculture and the Mechanical Arts, Bulletin No. 152, Ames, Iowa, U. S. A.*, published in *Missouri State Board of Agriculture Monthly Bulletin*, Vol. XIV, No. 5, pp. 54 + 37 Figs. + 2 Tables. Columbia, Missouri. May, 1916. — II. MAC VEAN, J. D. and HUTTON, R. E., in *U. S. Dept. of Agriculture, Office of the Secretary, Circular No. 102*, pp. 8 + 6 Figs. Washington, February, 1918.

I. — Movable pig-houses of suitable construction are of great use if

they are adapted to local conditions. The model pig-houses described in the bulletin under consideration were tested at the Iowa agricultural experiment station. These pig-houses are practical and based on long study of pig-rearing in the United States.

After describing the requirements for the site and the construction of pig-houses, the authors give the advantages and disadvantages of pig-houses consisting of single, isolated and portable sties as compared with central permanent piggeries containing many sties with or without movable partitions. Among the advantages claimed for single-sty pig-houses each containing a sow and her litter, are :—

- 1) the ease with which the house may be taken down and moved about to suit the needs of the farm ;
- 2) the rapid isolation either for sows about to farrow, for protecting the young, or for the growth of young pigs, and for selection ;
- 3) improved sanitary conditions, both for the prevention of disease and rotation of pasture ;
- 4) simplicity of construction.

These pig-houses are more practical and cheaper for beginners or breeders on a small scale, and they are more suitable to farming conditions, being portable. A limited number of the houses can be warmed with oil-lamps, and the risk of fire is less. The single-sty, portable pig-house combines perfectly with permanent piggeries by acting, when required, as a supplement to the latter. Amongst the disadvantages, it should be noted that :—

more labour and time is required for tending the herd as the houses are scattered about ; they do not last as long ; it is difficult to heat many houses at the same time ; the lighting and ventilation are imperfect ; the manure is often not removed on account of the distance between the sties ; the care, feeding and watering are more difficult.

A larger number of types of portable pig-house have been constructed by the live-stock and farm engineering departments. Many of them only differ as regards the placing of the doors and the provision of hinged walls to serve as shelter, ventilators and windows.

The authors describe the various types, giving plans and estimates for the 6 chief single pig-houses tested.

Among these the " Iowa Gable Roof House " was used successfully by the Iowa agricultural experiment Station. As is shown in fig. I, it is of simple construction ; its vertical walls can be lifted up, thus giving a greater area for shelter ; one of the sides of the roof, which should face either to the east or south, has two flaps which open or close like a door, so as to uncover or cover two glazed windows. The entrance can be either in front or at the side. The frame and walls are of wood ; there is a floor of 2 in. planks, but this can be omitted if the site is sufficiently dry.

The construction of the house is shown in a design, the various dimensions being given. It is about 9ft. long, 7ft. wide and 4ft. 6 in. high to the ridge. In Iowa the wood and labour required cost \$ 8.94.

Figure 2 shows the " A " pig-house, so-called from its resemblance to

that letter. The sides have a hinged division that can be lifted up to give shade in summer. In another "A" type of pig-house one of the sides has a leaf that can serve as a door.

Fig. I. — Iowa gable roof house (spring and autumn).

Fig. II. — "A" house with lateral flaps (summer).

The "A" pig-house is of simple construction and can be erected very quickly. It is highly favoured by a large number of breeds. It is made in varying sizes, the one illustrated being 9ft. long, 7ft. wide at the base and

6ft. 6 in. high to the ridge. The doors may be placed so as best to suit local conditions. On the side opposite to the door is a ventilator, which may be opened or closed according to the weather. This type is made of wood and costs about the same (\$ 8.94) as the Iowa gable roof house. The ever-increasing cost of wood has led to the construction of type "A" pig-houses in metal. The experience obtained under Iowa conditions show that the metal houses are warmer at noon and colder at night than the wooden houses.

II. — Portable pig-houses which can be taken to pieces are of great use especially in regions having mild winters and serve to shelter the pigs against both the summer sun and winter damp and storms. These single pig-houses can be moved from one pasture to another when the pigs are changed to fresh pasture.

These shelter-houses form an important factor in the development of pig breeding, for they are suitable for housing the spring litters and are cheaper than larger buildings. The circular contains instructions, figures and plans for building 2 ordinary types of portable, single pig-house. The type "A", is about 8 ft. wide at the base and 6ft. long and the lateral flaps that forms the gables are 8 ft. long.

The type "A" is very suitable for fattening spring pigs, or for housing a sow and her litter in warmer climates. In cold regions where it snows and there is much wind, the house should be made as warm as possible by covering it with tarred paper. This is especially necessary in the north if the house is to be used for farrowing. The interior heat may be conserved by covering the house with straw, leaves, etc. In hard weather, a couple of lamps could be lit and hung from the roof of the house.

## RURAL ECONOMICS.

### 811 — Important Factors in the Operation of Irrigated Farms in Utah, U. S. A. —

BROSSARD, E. B., in the *Utah Agricultural College Experiment Station Bulletin* No. 160, pp. 48, 49 Tables, 16 Figs. Logan, September, 1917.

In order to promote the maximum economic agricultural production of existing farms and the agricultural development of many thousands of acres of new land, the Utah Agricultural College, in collaboration with the U. S. Dept. of Agriculture, has carried out an inquiry to determine, according to the experience of practical farmers, the most profitable systems of farm management on irrigated Utah farms and which can be applied by those wishing to obtain farms in Utah, and also to furnish bankers, officers of loan associations, and other capitalists who loan money on irrigated farms in Utah useful information regarding the average value of such securities. The inquiry is based on records from 309 irrigated Utah farms for 1914. The records were taken in 7 typical general farming areas in 7 typical counties of Utah. The climate, crop, and livestock conditions in Utah in 1914 were about normal.

The following facts were brought out by this investigation :—

I. — FARM CAPITAL. — 1) A greater percentage of the capital is di-

rectly productive on farms with large capital than on farms with small capital.

2) There is less waste land in proportion to the total farm area on the farms with large capital.

3) A large farm capital is usually accompanied by a greater number of acres and crop acres. The proportionate area cropped is about constant.

4) On the average, crop yields are a trifle better on farms which have a large capital. This seems true, however, only when farm capital is less than \$ 20 000.

5) A large farm capital is usually accompanied by large numbers of productive animal units.

6) The farms with large capital are usually the most intensely stocked.

7) A large farm capital is usually accompanied by a comparatively high value per acre of land and buildings.

8) A large farm capital is on the average accompanied by a decrease in the value of machinery per crop acre, and by an increase in the number of crop acres per \$ 100 worth of machinery.

9) Horse labour is more efficient on the farms with large capital.

10) When the same farm crops are raised man labour on crops is more efficient on farms with large capital than on farms with small capital.

11) When approximately the same kind of livestock is kept, man labour with livestock is more efficient on farms with large capital than on farms with small capital.

12) Farms with large capital have more capital per man than farms with small capital.

13) As a result of the foregoing economies, farms with large capital are more profitable than farms with small capital, as shown by the increase in the farmers' labour income.

14) The total net income from the average of 309 irrigated Utah farms was about as follows, in 1914:—

5 % interest on average capital of \$ 11 886. . . . .	\$ 594
Average farmer's labour income . . . . .	\$ 541
Value of farm products consumed by average farm family . . . . .	\$ 600
11.625 % of \$ 7482, increase in value of average irrigated farm land on 309 irrigated Utah farms, 1914. . . . .	\$ 870
Total net income . . . . .	\$ 2 605

15) Labour income is less in proportion to farm capital on farms with large capital than on farms with small capital.

16) Labour income increases in the same ratio as farm capital until farm capital reaches \$ 20 000 or over. Beyond this, as capital increases 1 %, labour income increases only about 0.33 %.

II. — SIZE OF FARM — 1) There are more acres of crops, on the average on the large farms than on the small farms. But, the proportionate area cropped is less on the large farms than on the small farms.

- 2) A larger percentage of the farm capital is employed in directly productive enterprises on the large farms than on the small ones.
- 3) The shelter cost per unit of livestock is lower on the large farms than on the small farms.
- 4) Each \$ 100 worth of machinery is more efficient on the large farms in that it cultivates more acres of the same kind of crops and consequently lessens the value of machinery per crop acre.
- 5) Horse labour with crops and livestock is more efficient on the large farms.
- 6) Man labour with crops and livestock is more efficient on the large farms.
- 7) As a result of the foregoing economies on the large farms, they are more profitable as shown by the greater size of the farmer's labour income. This is \$ 336 for farms of from 10-39 acres and rises as the size of farm increases till it attains \$ 991 for farms of from 300-500 acres
- 8) The farmer's labour income is less in proportion to the total farm capital on the large farms than on the small farms.
- 9) Over half of the labour income from the average irrigated Utah farm is increase in inventory of farm capital. The most important increases in the farm inventories are in livestock and feed. This seems to indicate that Utah farmers realise the advantage of increasing the number of livestock on their farms.

III. — OTHER IMPORTANT FACTORS. — 1) On an average the farms with the highest crop yields per acre are the most profitable.

2) When average crop yields are maintained, the size of the irrigated Utah farm influences the labour income of the farmer more than increased crop yields per acre.

3) The number of livestock and the net livestock receipts per productive animal unit affect directly the farmer's labour income—as either increases the farmer's labour income increases. Both are important factors in the operation of irrigated Utah farms.

812 - Cost of Harvesting Wheat by Different Methods in the United States. — YERKES, A. P. and CHURCH, L. M. in *U. S. Dept. of Agric. Bulletin No. 627* (Office of Farm Management), pp. 1-24. Washington, D. C., February 13, 1918.

By far the largest percentage of the wheat of the United States is to-day harvested with the binder, the use of this machine being almost universal. The only wheat-growing sections where the binder is not used on the greater part of the crop are in the States of Washington, Oregon, and California and parts of Idaho; Utah, Wyoming and Montana, where much of the wheat is cut and thrashed with combined harvesters although even where these outfits are commonly used binders also are employed to some extent.

The cost of harvesting may be somewhat greater where the binder is used than where the work is done with headers or combined harvesters. The binder, however, has a distinct advantage over these machines in that the work of harvesting may be begun from one to two weeks earlier with the binder than with either the header or combine, since wheat can be cut with a binder while in the early dough stage and placed in shocks to

complete ripening, thus requiring fewer horses and men to harvest a given acreage. The cost of harvesting wheat with a binder varies considerably being influenced by several factors, *i. e.*, size of the outfit used, yield per acre, especially of the straw, the character of the soil, whether soft or firm, rough or smooth and the topography of the farm, whether level or hilly, the working ability of the horses used and the condition of the working parts of the machine. The figures given in Table I approximate the average conditions as far as possible, assuming man-labour to be worth \$2 per day and horse-labour \$1.20 per day.

TABLE I. — *Average acres cut by 6, 7 and 8 foot binders in a 10 hour day (235 Reports) and labour cost of cutting one acre of wheat with binders of different sizes.*

Width of cut and number of horses	Acres cut			Cost per acre		
	per binder	per horse	per foot of cutter bar	total labour \$	man labour \$	horse labour \$
6 foot, 3 horses . . . . .	10.90	3.63	1.82	0.51	0.18	0.33
6 foot, 4 horses . . . . .	12.10	3.03	2.02	0.57	0.17	0.40
7 foot, 3 horses . . . . .	12.50	4.17	1.79	0.45	0.16	0.29
7 foot, 4 horses . . . . .	15.10	3.78	2.16	0.45	0.13	0.32
8 foot, 4 horses . . . . .	17.00	4.25	2.13	0.40	0.12	0.28

*Interest and Depreciation.* — The cost for interest and depreciation on binders, based on tabulation of 235 Reports, was \$0.24, 0.16 and 0.125 per acre annually, for the 6, 7 and 8 foot binders respectively with a life of the binders of 15, 11 and 10 years and 750, 1100 and 1500 acres respectively.

The acres cut annually by a binder do not seem to have a very direct influence upon its life except where the acreage is extremely large. There is a certain deterioration due to age which appears to limit the length of life in years whether the binder does a fair amount of work each season or not.

*Repairs.* — Many farmers have reported the use of a binder for several years without a cent being spent for repairs, whereas in other cases repairs have ranged from \$10 to \$15 annually. As a rule the most expensive item of repairs is the canvas. If properly protected when idle, a binder canvas should cut from 400 to 800 acres. It is believed that 20 per cent. of the first cost for six-foot binders, 25 per cent. for seven-foot and 30 per cent. for eight-foot machines will approximate the average repairs required for these outfits.

The cost for shelter has been omitted because this item varies so greatly and in many cases is insignificant, since a great many binders, particularly in the West, have no shelter whatever except for the canvasses and sickles, which usually are taken off and stored in a dry place during the winter.

*Auxiliary Binder Engines.* — The use of binder engines furnishing power to operate the mechanism, which is ordinarily driven by power from

the horses through the medium of the bull wheel, has increased considerably during the last two or three seasons particularly in certain sections where wet ground has made the operation of the binder difficult. These engines cost about \$ 150 but their use is not confined to the binder alone, being utilized for belt power. Under these conditions their estimated average life is about 9 ½ years. In some instances the engines are used practically every day of the year for pumping water, except while on the binder.

The owners of these outfits report that from 2 to 5 gallons of gasoline are required to operate the engine per day, while about 1 pint of lubricating oil per day appears to be a fair average. With gasoline at 20 cents per gallon and lubricating oil at 40 cents this would make the daily operating expense about 85 cents. Reports from farmers indicate that an increase of from 4 to 5 acres per day may be expected in the area covered with the binder under unfavourable conditions previously mentioned. The repairs on the outfits averaged \$ 3 annually.

*Shocking.* — The practice of shocking wheat after being cut with a binder is almost universal. The average acres shocked per day per man and cost per acre and per bushel in relation to yield per acre are shown in Table II.

TABLE II. — *Acres shocked per day per man and cost per acre and per bushel in relation to yield per acre (Based on labour at \$ 2 per day, 264 Reports).*

Yield per acre	Average yield per acre	Acres shocked per day man	Cost per acre	Cost per bushel
Under 20 bushels . . . . .	15	12 ½	\$ 0.16	\$ 0.01
20 bushels . . . . .	20	12	0.16 ½	0.008
21 to to 30 bushels . . . . .	26.2	8 ¾	0.23	0.009
31 bushels and over. . . . .	37.4	7 ½	0.26 ½	0.007

*Comparison of Costs — Old methods versus new.* — It is very interesting to compare the costs of cutting wheat as it is usually done to-day, with the methods in use 75 years ago, according to the *Transactions of the New York State Agricultural Society* (Vol. 10, 1850). Based on labour at \$ 2 per day, the cost per acre by the hand method, with an average yield of 16 bushels per acre, would have been approximately \$ 1.60 75 years ago as against \$ 1.23 with the binder. But to-day two men (one shocking) with three or four horses will cut, bind and shock about eight times as much wheat as two men cutting with a cradle and binding by hand. Taking wheat prices and labour prices into consideration, the cost of harvesting in recent years has represented about one eleventh of the selling price of the crop, whereas in 1850, when hand methods were used, the cost of harvesting represented less than one thirtieth of the selling price.

*Stacking.* — Six acres per day for two men and one team appears to be a fair day's work in stacking wheat under most eastern conditions, whereas in the western sections, where the more efficient methods are employed,

8 acres per day for two men and two horses and 10 acres per day for two men and four horses would appear to be a fair average. Based on these figures the cost of stacking per acre for man and horse-labour would be as shown in Table III.

TABLE III. — *Labour cost per acre and per bushel of stacking wheat with man-labour at \$ 2 and horse-labour at \$ 1.20 per day of 10 hours.*

Operation — No. of horses	Acres covered per day	Labour cost per acre			Cost per bushel (16 bushel yield)
		Man	Horse	Total	
1 man pitching and 1 loading (1 wagon) 2 . . . . .	6	\$ 0.66 1/2	\$ 0.40	\$ 1.06 1/2	\$ 0.06 1/2
2 men pitching (1 wagon) 2 . . . . .	8	0.50	0.30	0.80	0.05
2 men pitching (2 wagons) 4 . . . . .	10	0.40	0.48	0.88	0.05 1/2

TABLE IV. — *Cost of harvesting an acre of wheat with headers of various sizes and different size crews, with man-labour at \$ 2 and horse-labour at \$ 1.20 per day of 10 hours.*

Size of header and crew	Daily cost of operating the outfit				Cost per acre	Cost per bushel	
	Total	Man labour	Horse labour	Interest, depreciation and repairs on headers		Based on 11 bushel yield	Based on 30 bushel yield
12-foot, with 5 men and 10 horses (1) . . . . .	\$ 25.40	\$ 10.00	\$ 12.00	(2) \$ 3.40	\$ 1.06	\$ 0.07	—
12-foot, with 6 men and 14 horses (3) . . . . .	» 32.20	» 12.00	» 16.80	(2) » 3.40	» 1.34	—	\$ 0.045
14-foot, with 6 men and 12 horses (1) . . . . .	» 29.75	» 12.00	» 14.40	(5) » 3.55	» 1.06	» 0.07	—
14-foot, with 8 men and 16 horses (6) . . . . .	» 38.55	» 16.00	» 19.20	(3) » 3.35	» 1.38	—	» 0.046

(1) Crew made up as follows: 1 driver and 6 horses with header; two header wagons with 2 drivers and 4 horses; 1 man loading wagon and 1 man on stack.

(2) Based on annual duty of 300 acres and 24 acres per day.

(3) Crew made up as follows: 1 driver and 8 horses with header; 3 wagons with 3 drivers and 6 horses; 1 loader and 1 man on stack.

(4) Crew made up as follows: 1 driver and 6 horses on header; 3 wagons with 3 drivers and 6 horses; 1 loader and 1 man on stack.

(5) Based on annual duty of 450 acres and 28 acres per day.

(6) Crew made up as follows: 1 driver and 8 horses on header; 4 wagons with 4 drivers and 8 horses; 1 loader and 2 men at stack.

The cost of stacking is little if any greater than the cost of hauling from shock to the separator when thrashing. Having the grain in stocks ex-

pedites thrashing somewhat and at the same time reduces the number of men and horses required.

*Headers.* — Thousands of acres of wheat are harvested annually by means of the header in the Pacific Coast States and in the Middle West. The sizes of headers most commonly used are 12 and 14 feet. A six-horse team is found most commonly on the twelve-foot machine, although eight horses are sometimes employed where the grain is particularly heavy or where the land is in such condition as to make a very heavy draft. On the fourteen-foot machine eight horses are used most frequently. The approximate cost of harvesting an acre of wheat with twelve and fourteen-foot headers, with two common-size crews each is given in Table IV.

Table IV shows that there is generally a saving in harvesting with a header when the cost of shocking and stacking, or hauling to the separator is considered.

*Combines.* — By far the cheapest method of harvesting and threshing wheat practised in this country at present is by means of the combined harvester, a machine that cuts the heads from the wheat and thrashes them at the same operation.

The use of this outfit has been limited to certain sections where the grain ripens on the stalk.

"Combines" as they are commonly called in the sections where they are used, vary considerably in size and weight according to the type and make. The amount of work done per day with the different sized outfits is shown in Table V.

TABLE V. — *Acres cut and bushels threshed by different sized combines "in a 10 hour day (65 reports).*

Width of combines and horses used	Acres per 10-hour day			Bushels thrashed per day (30 bushel yield)	Usual number of men in crew
	Per combine	Per horse	Per foot of cut		
7 feet, 8 horses . . . . .	12.4	1.55	1.77	372	2
9 feet, 10 horses . . . . .	13.6	1.36	1.51	408	2
12 feet, 22 horses . . . . .	19.9	0.90	1.66	597	4 or 5
14 feet, 24 horses . . . . .	20.6	0.86	1.47	618	5
16 feet, 28 horses . . . . .	27.0	0.96	1.69	810	5
18 feet, 30 horses . . . . .	31.0	1.03	1.72	930	5
20 feet, 30 horses . . . . .	34.0	1.13	1.70	1020	5 or 6
24 feet, 36 horses . . . . .	42.0	1.17	1.75	1260	5 or 6

There is considerable irregularity in the number of acres cut per day by the different sized outfits, due probably to the small number averaged in most of the groups.

Depreciation, interest on investment, repairs, and operating expenses of these outfits are shown in Table VI and VII.

TABLE VI. — *Overhead expenses per year, per day, per acre and per bushel; average cost and estimated life of, and acres cut annually by different sized combines (65 reports).*

Width of swath feet	Average annual overhead expenses on combines				Total per			Average cos	Estim- ated life in years	Average acres cut annually to date
	Total	Depre- ciation	Interest on investment at 6 %	Repairs	Day	Acre	Bushel (30 bushel yield)			
	\$	\$	\$	\$	\$	\$	\$	\$

9	184.04	112.04	36.00	36.00	9.30	0.684	0.0228	1200	10.71	269
12	233.36	115.41	50.55	67.40	8.95	0.450	0.0150	1685	14.60	519
14	233.31	114.59	50.88	67.84	9.73	0.472	0.0157	1696	14.80	494
16	209.05	87.95	51.90	69.20	6.58	0.244	0.0081	1730	19.67	858
18	269.37	127.06	60.99	81.32	8.35	0.269	0.0090	2033	16.00	1000
20	310.05	146.25	70.20	93.60	7.93	0.233	0.0078	2340	16.00	1330
24	425.00	250.00	75.00	100.00	8.92	0.213	0.0071	2500	10.00	2000

TABLE VII. — *Labour costs per day, per acre and per bushel for different sized combines and crews, man-labour being considered as worth \$2 and horse-labour \$1.20 per day of 10 hours (65 reports).*

Width of cut and crews most commonly used with each outfit	Labour cost per day			Labour cost per acre			Total man and horse labour cost per bushel
	Total	Man labour	Horse labour	Total	Man labour	Horse labour	
7 feet; 2 men, 8 horses.	\$ 13.60	4.00	9.60	1.10	0.32	0.78	0.0365
9 feet; 2 men, 10 horses.	16.00	4.00	12.00	1.18	0.30	0.88	0.0392
12 feet; 4 men, 22 horses.	34.40	8.00	26.40	1.73	0.40	1.33	0.0576
14 feet; 5 men, 24 horses.	38.80	10.00	28.80	1.88	0.48	1.40	0.0628
16 feet; 5 men, 28 horses.	43.60	10.00	33.60	1.61	0.37	1.24	0.0538
18 feet; 5 men, 30 horses.	46.00	10.00	36.00	1.48	0.32	1.16	0.0495
20 feet; 5 men, 30 horses.	46.00	10.00	36.00	1.35	0.29	1.06	0.0451
24 feet; 6 men, 36 horses.	55.20	12.00	43.20	1.32	0.29	1.03	0.0438

From these figures it appears that the total cost of cutting and threshing a bushel of grain with a combine varies from about 5.1 cents per bushel for the large outfits to a fraction under 8 cents for the 14-foot size. Six cents per bushel is probably a fair general average cost representing one-third and one-fourth of the cost in sections where the wheat is cut and thrashed at two separate operations with a consequent increase in man and horse-labour. At present most combines are still drawn by horses, although auxiliary gasoline engines are frequently used to operate the mechanism, the horses merely moving the outfit. Modern combines are expressly designed and built for the complete operation of cutting and threshing the grain and gasoline engines either in form of tractors or mounted on the combines themselves as single units.

813 — **A Farm Accounting and Statistics Bureau for British Columbia, Canada.** — TWEDDLE, A. B. (Statistician), in *The Agricultural Journal of the Department of Agriculture of Victoria, B. C.*, Vol. 2, No. 10, pp. 197. Victoria, B. C., December, 1917.

The Department of Agriculture of British Columbia, following the example of the Ontario Agricultural College at Guelph, has instituted a Farm Accounting Statistics Bureau for the study of Farm Management, in consideration of the beneficial results similar work has been obtaining in the United States, which proved to be useful not only to farmers themselves but to legislators and colleges as well. It is not intended, nor is it possible at this time, to include all the farmers in the Province, but a limited number will be asked to cooperate with the Department of Agriculture. The necessary diaries and forms will be delivered free of charge to those farmers expressing a willingness to cooperate. In these diaries the farmers will be required to record daily operations and transactions along the lines shown in accompanying forms, which, in brief, relate to crop yields and sales, feed and supplies, fertilizers, live-stock sales and purchases, by-products sales and receipts, expenses of various kinds, capital investment and depreciation, etc. The forms will be distributed merely for the purpose of a guide to the farmers in making entries in the diaries.

The work does not require the knowledge of book-keeping, the farmers being asked to give the simple facts in the diaries. At the end of the twelve months these diaries will be collected by the Department of Agriculture where the data will be compiled.

Such work need not interfere with regular daily duties on the farm, and on the other hand will provide profitable employment for the members of the families for the entire year. All diaries and records will be numbered and so dealt with throughout that during compilation no names will be disclosed to the public, or any member of the Government except the official in charge of the work. Not under any circumstances will the information received by the Department of Agriculture be allowed to be used for any purpose relating to taxation in any form.

Immediately the information has been compiled the diaries will be returned to the farmers, along with a copy of the compiled statements, which may be used for their future reference and guidance.

## AGRICULTURAL INDUSTRIES.

814 — **The Cream of Tartar in Plastered Wines.** — BORNTAEGER, A.: I. Plastered Wines and the (Italian) Official Method for Estimating the Cream of Tartar and the Free Tartaric Acid, in *Le Stazioni sperimentali agrarie italiane*, Vol. I, Pt. 11-12, pp. 576-590, Bibliography of 23 Publications. Modena, 1917. — II. On the Yield in Tartrate of Wines Plastered during Winter, *Ibid.*, pp. 610-612, Bibliography of 19 Publications.

I. — After having given an historical review of the question, quoting the chief work done on the subject since PASREUR, the author describes his own experiments on plastered wines. He has found that the actual yield in cream of tartar during the winter did not agree with the yield calculated by deducting the result obtained in the following spring (March, 1917) from

INDUSTRIES  
DEPENDENT  
ON PLANT  
PRODUCTS

the result of the estimation of the bitartrate obtained by the alcohol-ether method carried out in autumn (November, 1916). The actual yield found was higher than that calculated by difference.

II. — Wines made from well ripened, white Vesuvius Catalanesca grapes and plastered on pressing gave a higher yield of cream of tartar (1.25-1.50, 2.10 times) than that given by control wines made at the same time with similar grapes, but not plastered. For the 1913 wines the results were: — natural, 1.00 %; plastered, 1.26 %; another wine plastered more than the previous one, 1.53 %; and for the 1916 wines: — natural, 0.77 %; plastered, 1.63 %.

815 — **The Balance of Some Constituents of the Sugar Beet During the Manufacture of Sugar.** — SAILLARD, EMILE, in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 17, pp. 697-699. Paris, April 29, 1918.

On account of the increased price of certain constituents of the sugar beet, especially potassium and nitrogen, the author thought it might prove useful to study these constituents during the process of sugar-making. He gives the results of his investigations as the averages of numerous analyses made during about 15 years, and draws from them the following conclusions.

**NITROGEN.** — The nitrogen from the diffusion pulp and carbonated cake may be recovered, but that which is given off as ammonia during the heating of the juice, syrup and cooked mass, which are alkaline, is lost in the condensation waters or the condenser; this represents about 17 % of the total nitrogen.

At the present time almost all the molasses from sugar factories are used for the manufacture of alcohol and brines (the remainder is used for molasses feeds). The nitrogen they contain, representing about 30 % of that of the beet, is lost during the burning of the residue.

About 50 % of the total nitrogen of the beet is, therefore, lost. This loss is equivalent to 2.2 lb. of nitrogen per metric ton of roots, or about £ 2.10 per acre.

**POTASSIUM AND SODIUM.** — These are contained almost entirely in the molasses and brine. Nevertheless some loss occurs during the burning of the residue.

**PHOSPHORIC ACID.** — This remains chiefly in the carbonated cake.

It is seen that as the beet is converted into molasses, then into residue and brine, the quantity of nitrogen per 100 of potassium decreases. For 100 parts of potassium, the beet contains about 75 of nitrogen; molasses 32, distillation residue a little less than 32.

It was once proposed to absorb the ammonia given off by the heated juices with sulphuric acid; at the present price of nitrogen (4s. 9d. as compared to 11 ½ d. to 1s. 1 ½ d. before the war) this proposal would be more valuable. The loss of nitrogen during the burning of the residue deserves attention for the same reason.

816 — **Estimation of the Water Content of Products of the Sugar Industry by the Distillation Method.**—LINDEN, T. VON DER, KAUFFMAN, M., and LEISTRA, F. (Proefstation voor de Java-Suikerindustrie), in *Archief voor de Suikerindustrie in Nederlandsch-Indië*, No. 22, pp. 951-962 + 6 Tables + 1 Fig. Soerabaja, May, 1917.

Apart from JOSSE's well-known method for determining the water content, and consequently also that in dry matter, in agricultural commercial products, there is another, less exact but more rapid, which has been applied in the analysis of matters differing widely one from the other. This method consists in the *distillation* of the matter to be analysed in the presence of a liquid insoluble in water, such as benzene, toluene, xylene, amyl acetate, paraffin, etc. The steam, carried over with the other vapours is condensed in a eudiometer, thus allowing the water content of the product analysed to be determined immediately. GOGELA applied this method to the analysis of products of the sugar industry in 1915 (*Centralblatt für die Zuckerindustrie*, p. 228, 1915).

The work on this subject is first reviewed, including that of HOFFMAN, the first to apply the method; GRAY, who applied it to the analysis of butter and other foodstuffs, using as insoluble liquid, acetate, valerianate or amyl butyrate; MARCUSSEN (fat, mineral oils, soap and resins); THÖRNER (butter, margarine, meat, milk, vegetables, bread, flour); GRÄFE and SCHWALBE, MAI and RHEINBERGER who used paraffin for fibrous matter and cheeses; FABRIS, with essence of turpentine, for honey; GADTLER, with benzene, for cheese, white of egg, etc.; MICHEL, who made a close study of the method and found that the best results were obtained with a mixture of toluene and xylene as an insoluble liquid.

The authors studied at the Experiment Station of Java the application of this method to the products of the sugar industry and compared their results with those obtained by JOSSE's method. They concluded that:—

1) *With benzene* distillation is too slow, and necessitates the use of too large a quantity of distilled liquid, which remains cloudy; this justifies the opinion of MICHEL, who recommended the use of an insoluble liquid lighter than water and with a higher boiling point.

2) *Paraffin* can hardly be recommended because it causes reactions and then shows too high a water content.

3) *Toluene* gives good results, though it is still necessary to collect excessive quantities of the distilled liquid.

4) *Xylene* is the best liquid; it allows an easy and rapid distillation, and relatively small quantities may be used, According to the author, the mixture of xylene and toluene advised by MICHEL is not appreciably superior to xylene used alone.

Various analyses of molasses made with the use of xylene gave results agreeing with those of other methods so long as certain precautions were taken and corrections made:—1) Readings from the eudiometer a quarter of an hour and an hour after distillation (the average value between the two readings always corresponds best to that obtained by other methods); 2) correction of errors caused by the meniscus of the eudiometer.

The authors do not consider it advisable to adopt this method generally for the analysis of products of the sugar industry, but it gives practical results of sufficient exactitude to be applied now and again, on account of its rapidity, in laboratories where numerous determinations of water content have to be made.

**817 — Bacterial Deterioration of Bread in Rome.** — PEROTTI, R and COMANDUCCI, J., in *Atti della Reale Accademia dei Lincei*, 5th. Series, *Rendiconti, Classe di Scienze Fisiche, Matematiche e Naturali*, Vol. XXVII, Pt. 7, pp. 258-261. Rome, April 7, 1918

In the spring of 1917 a ropiness was observed in the bread of some bakeries in Rome which was attributed by the authors to a form resembling *Bacillus mesentericus vulgatus* Flügge, perhaps identical with VOGEL's *Bacterium mesentericum*, and differing slightly from FÜHRMANN's *Bacterium panis*. The chief condition under which this deterioration occurs is the chemical composition of the flour. The agent, at least in the case studied by the author, is infected yeast. To avoid the injury it is necessary to disinfect the vessels and the rooms in which infection has occurred, use controlled, well-prepared yeast, and keep the bread at a rather low temperature.

With reference to another deterioration of bread caused by *Oospora variabilis* and studied by one of them (1), the authors note that the organism survives baking much more frequently than had been supposed, and that this must be borne in mind, not only to obtain good bread, but also to prevent the spread of organisms of infectious diseases.

**818 — The Agen Plums and Prunes.** — CARLES, P., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 13, pp. 429-432. Paris, April 10, 1918.

The author (fellow of the Faculty of Medicine and Pharmacy of Bordeaux) summarises a pamphlet published by him under the title of "*The Agen Plum and Prunes*". In the preparation of the Agen prune there are four chief points for the biologist to consider:— 1) the destruction of the relative tartness of the ripe fruit; 2) its desiccation; 3) elimination of moulds; 4) constant preservation of its normal water content.

**1st. Phase.** — The action is exclusively *chemical* or, more correctly, *biological*. The agent is an oxydase which, when helped by gentle heat and a moisture-saturated environment, quickly destroys the tannic matter ferrous salts, etc., and changes the fruit juice into a very delicately flavoured and sweet juice.

**2nd. Phase.** — This is purely *physical* and consists of the transformation of the juice into a true syrup by the elimination of its excessive water. To do this the temperature is gradually and regularly raised while a drying air current is set in motion. The process must be stopped at the moment when the remaining sugar transforms this intracellular juice into an ordinary preserving agent, an auto-antiseptic. The prune is ready when the natural moisture is thus reduced to 30 %.

**3rd. Phase.** — These are various methods of eliminating moulds and the author discusses their scientific side.

(1) See R. Sept., 1917, No. 852. (Ed.)

*4th. Phase.* — Dryness must be avoided. When, to eliminate the danger from moulds, the 30 % moisture content is by chance allowed to fall too low the sugar of the normal syrup crystallises on the surface. The fruit turns first grey, then white, like figs, and loses its plasticity, delicate flavour and 50 % of its commercial value. If the sterilised prune with its normal water content is placed where the water cannot evaporate, it will keep its qualities indefinitely. It is yet better to pass a well-adjusted supply of hot steam into a store where evaporation is very slow ; by this means the moisture equilibrium is re-established and the prune assumes the black colour characteristic of its normal water content.

Producers, buyers and exporters should give greater attention to selecting varieties instead of sacrificing all else for the weight of the fruit. Weight is far from being a definite proof of the excellent quality of certain plums with small, light yellow stones and greenish-yellow flesh of average volume. The smell of these varieties is so pervasive, yet so delicate, that when the fruit is eaten the smell spreads all around.

**819 - The Pasteurization of Sour, Farm-skimmed Cream for Buttermaking.** — HUNZIKER, O. F., SPITZER, MILLS, H. C. and SWITZER, H. B., in *Purdue University, Agricultural Experiment Station, Bulletin* No 208, Vol. XX, pp. 76, 54 Tables, Lafayette, Ind., September, 1917.

INDUSTRIES  
DEPENDENT  
ON ANIMAL  
PRODUCTS

The purpose of the experiments recorded in this bulletin was :—

- 1) To determine the effect of pasteurization of sour, farm separator cream on the flavour, keeping quality and market value of butter.
- 2) To study the effect of different processes of pasteurization on the bacterial count of cream and butter and on the flavour and keeping quality of butter.
- 3) To study the effect of pasteurization on the chemical properties of fresh and stored butter.
4. To determine the causes undertaking the changes of the flavour of raw and pasteurized cream butter in storage.

The results are summarized as follows :—

Fresh butter made from sour cream pasteurized at 145° F. and held for 20 minutes, scored 2.9 points higher than fresh butter made from raw sour cream. Fresh butter made from sour cream pasteurized at 165° F. flash and at 185° F. flash respectively, scored practically the same as fresh butter made from raw sour cream.

After 30 days cold storage, the butter made from sour cream pasteurized at 145° F. holding, and 165° F. and 185° F. flash process, scored 3.9 points, 2.0 points and 2.4 points higher, respectively, than the butter made from raw sour cream.

After 90 days storage, the pasteurized cream butter scored 4.5 points, 2.9 points and 3.2 points, respectively, higher than butter made from raw cream.

On the basis of a difference of two cents between extras and firsts, and two cents between firsts and seconds, and assuming that extras are worth 30 cents, the holding process butter would sell at 1.6 cents, 1.7 cents, 1.7 cents and 2.0 cents higher when fresh and when 30, 60 and 90 days old, res-

pectively, than the raw cream butter. On the same basis, butter from the flash process at 185°F. would sell at 0.2 cent, 0.9 cent, 1.1 cents and 1.3 cents higher when fresh and when 30, 60 and 90 days old, respectively, than raw cream butter.

The holding process at 145° F. for 20 minutes proved more efficient in its germ killing effect than either of the two flash processes, averaging a germ killing efficiency of over 99.9 per cent. The flash process at 185°F. showed a slightly lower germ killing efficiency than the holding process, and the 165°F. flash process had a germ killing efficiency of not more than 90 per cent. The minimum temperature and time at which the holding process insures maximum germ killing efficiency and keeping quality is 145° F. for 20 minutes. Nothing is gained by longer exposure to 145°F.; in fact, excessive exposure is undesirable, because it tends to give the butter a mealy body.

The butter made from cream pasteurized at 185° F. flash showed the best keeping quality. This is probably due to its power, not only to destroy germs, but also to inhibit the action of enzymes.

The 185° F. flash process proved unsuitable for pasteurization of sour cream, causing the butter to have a distinctly oily flavor. This appears to be due to the combined action of high heat and high acid. In the case of sweet cream or sour cream in which the acid has been properly reduced by neutralization before pasteurization this oily flavor is much less pronounced.

The germ killing efficiency of pasteurization in summer is greater and the keeping quality of such butter is better than that of winter cream and butter showing that winter cream contains more resistant and undesirable ferments than summer cream.

The quality and sweetness of cream affect both raw and pasteurized cream butter, but pasteurization is capable of producing marked improvement in the quality of butter even from inferior cream.

In order to reap the full benefit of pasteurization, cream and butter must be guarded against re-contamination after pasteurization. An unclean vat may reduce the efficiency of pasteurization 50 per cent. Pure air, sanitary condition of sewers, freedom of the factory from flies, cleanliness of vats, pipes, conduits, coolers and churns, purity of starter and wash water, and the sanitary condition of the packing equipment are all essential in safeguarding the benefits of pasteurization.

When cream is put in proper condition for pasteurization, and other conditions are as they should be, there is no danger of excessive loss of fat in the buttermilk from pasteurized cream. Pasteurization of mixed sweet and sour cream without giving the acid in the sour cream time to act normally on the curd in the sweet cream, pasteurization of excessively thin sour cream, the churning at too high temperatures or not holding the cream long enough at the churning temperature, and the overcrowding of the churn, are bound to reduce the exhaustiveness of the churning and to cause heavy loss of fat in the buttermilk.

Pasteurization does not materially effect the chemical composition of butter. It has a tendency, however, to lower slightly the per cent moisture

curd and acid in butter. During storage, the per cent. lactose in butter decreases and the acidity increases. These changes are greater in raw cream butter than in pasteurized cream butter. The increase in acidity is not proportionate to the decrease in lactose. The fat constants in butter in storage undergo but very slight changes. These changes are greater in raw cream butter than in pasteurized cream butter, but they are too far within the limits of experimental error to permit of serious comparison. The fat constants in butter fat held at room temperature for 11 months showed slightly greater changes, but even these changes were in no way commensurate with the intense deterioration of the flavour of the fat. These results suggest the probability that some of the flavour defects in storage butter may be due, at least in part, to hydrolysis or oxidation of some of the fats and that very slight changes in the fat constants may create most intense depreciation in the flavour of butter fat and butter.

All butter held in cold storage showed an increase of cleavage products of the proteins as determined by proteins not precipitated by bromine, copper sulphate, phosphotungstic and tannic acid. This increase in protein decomposition was much more rapid after butter had been transferred from cold storage to room temperature. The protein decomposition was greatest in the raw cream butter and least in the butter made from cream pasteurized at 185°F. flash process, showing that this process proved most efficient in retarding protein hydrolysis, probably due to its power to destroy the activity of enzymes contained in cream. Protein hydrolysis in butter may be brought about by such agents as ferments, both micro-organisms and enzymes, acids, salts and metals through catalytic action. Cream of poor quality and old cream furnish favourable conditions for rapid protein hydrolysis in butter. Protein hydrolysis plays a prominent part in the deterioration of butter in storage. It can be minimized by improving the quality of the cream, proper pasteurization, reduction of acidity, discarding of rusty cans, protection of cream and butter against contamination with metals and metallic salts, sanitary equipment, thorough washing of the butter, proper treatment of liners and wrappers, cleanliness of packing and printing equipment and guarding butter against exposure to high temperatures in storage and in transit.

## PLANT DISEASES

### DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

#### GENERAL

821 - Sooty Moulds of Southern France. — ARNAUD, G., in the *Bulletin de la Société de Pathologie végétale de France*, Vol. IV, Part 2, p. 95. Paris, 1917.

The author gives the results of his observations on sooty moulds collected by M. MAZADE at Mougins (Alpes Maritimes), etc., in March, 1915.

On branches of olive attacked by *Lecanium oleae* were perithecia of *Capnodium meridionale*, already reported on various plants.

Branches of fig heavily attacked by *Ceroplastes rusci* were covered with numerous perithecia of *Ceratocarpia Cactorum*; the same fungus was also very abundant on the branches and less commonly on the leaves of the orange tree. The latter plant was chiefly attacked by *Lecanium hesperidum* with a few *Pulvinaria camellicola*. Up to the present the fungus had never been reported on the leaves.

The perithecia of the two species in question were often accompanied by the pycnidia and elongated spermagonia found in the majority of the sooty moulds.

This information shows that the sooty mould fungi are not in close relation with any particular species of plant or honeydew-producing insect.

#### MEANS OF PREVENTION AND CONTROL

822 - Simple Solutions of Copper Sulphate against Vine Mildew. — CAMPREDON D'ALBARETTO, E., in *Annali della R Accademia d'Agricoltura di Torino*, Vol. XI, (1917), pp. 13-19. Turin, 1918.

At Ponzano Monferrato (province of Alexandria) the author carried out spraying experiments to compare the action and efficiency of Bordeaux mixture containing 1 % copper sulphate and 1 % lime with those of a simple solution of copper sulphate containing 250 gm. of sulphate per hectolitre of water and made adhesive by the addition of 500 gm. of dextrin previously dissolved in hot water. The results showed that simple 2.5 % solutions of copper sulphate are more efficient and act more rapidly than those of Bordeaux mixture. Nevertheless, even when dextrin is added to these simple solutions to make them more adhesive and to increase the duration of their action, this action decreases rapidly and a few days after spraying the vines have as low a resistance to adverse conditions and attacks of mildew as those treated with ordinary Bordeaux mixture.

Simple 2 % solutions can, therefore, be used as a rapid cure, but Bordeaux mixtures containing 1 % copper sulphate and 1 % lime have a more lasting and more certain preventative action.

From these results the author deducts the following practical rules:—

Simple solutions are not to be recommended in the ordinary control of mildew because of the short duration of their action, which though very effective immediately after spraying, weakens rapidly and disappears in a few days, leaving the vines unprotected. They should only be used in exceptional cases, especially for treating large vine-growing areas when mildew appears suddenly and labour is lacking, as they rapidly check the attack. Once infection has been stopped by easy and economical spraying with a simple solution there is ample time to spray again with Bordeaux mixture, the application of which is slower and more expensive, the curative action slower, but more lasting and capable of protecting the vine against subsequent attacks of the disease.

DISEASES  
OF VARIOUS  
CROPS

825 — Diseases of Parsnips in England. — CORTON, A. D., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 1, pp. 8-21 + 2 Figs + 2 Plates. London, 1918.

The attention of the Board of Agriculture and Fisheries was recently drawn to a disease of the roots of parsnips (*Pastinaca sativa* = *Peucedanum sativum*) well known to English farmers as "parsnip canker", or "parsnip rust". This disease does not appear to have been studied hitherto.

The very serious loss in roots, especially in Worcestershire, and also in Gloucestershire and Somersetshire, lead to a careful investigation. Two visits were paid to the district most affected (that of Evesham, Worcestershire). Besides field observations, experiments were made at Kew with diseased roots and infected soil from Evesham and Somersetshire. At the same time certain secondary diseases of the parsnip were noted, three of which are new for Great Britain, and one of which appears capable of causing serious damage.

Parsnip canker, *i. e.*, the decay of the upper part of the roots during late summer and autumn, is caused by a physiological phenomenon which cracks the outer skin, and not by invasion by a parasitic fungus. The cracks occur during growth, especially when heavy rain follows a period of drought; the parts attacked are the periderm and the outer layers of the cortex. The cracks, mainly horizontal round the upper part of the root but also vertical, are from  $\frac{1}{2}$  to 2 inches long, and expose the cortex. The resulting canker or decay is caused by the inability of the root to form a layer of wound cork. Although the outer cortical cells exposed to the air suberise and there are but few cell divisions, no definite phellogen is formed and the cracks are not protected as in the case of other fleshy roots. The protection is insufficient to keep out micro-organisms, which probably

enter by the inter-cellular spaces and cracks caused by drying and destroy the tissues of the root more or less rapidly. Although canker is more serious in some districts than others, it seems to occur everywhere as a result of the cracking of the root-skin. No specific microorganism has been isolated in connection with this decay.

With respect to the conditions causing the formation of cracks, investigations show that while these cracks are due to an unequal rate of growth of the tissues — the inner tissues growing more rapidly than the outer ones — and are largely influenced by weather conditions, their formation may be favoured by certain methods of culture, chiefly overmanuring, neglect of liming and early sowing, which causes premature ripening. The variety of parsnip grown may also be responsible for the appearance of the disease, a high quality parsnip with bulky top, abundant flesh, and small core being very largely grown in the worst infected areas.

As preventative treatment it is advisable:— 1) to avoid growing parsnips in too rich a soil 2) to sow late, 3) not to neglect liming, 4) to apply potash and salt to the soil to retard ripening, 5) to adopt a suitable rotation, never growing parsnips two or three consecutive years on the same land.

Besides canker, parsnips are attacked by the following diseases:

1) *Erysiphe Polygoni* D. C., a fungus occurring in large numbers in market gardens round Evesham and Wisbech, and elsewhere; the attack is not sufficiently severe to call for special treatment.

2) *Phyllachora Pastinacae* Rostr.; a species new to Britain; the conidial form (*Cylindrosporium Pastinacae* Lind.) attacked very severely the foliage of a certain number of parsnips in a market garden at Mickleton (Glos.). Although neither the ascigerous nor conidial stage of *Phyll. Pastinacae* had been previously reported in the country, there is little doubt that it occurs frequently but has been overlooked. It is also probable that *Phyll. Pastinacae* is synonymous with *Phyll. Heraclei*, a fungus not uncommon in England on cow parsnip, *Heracleum Sphondylium*. There is no doubt that the parasite passed from the wild to the cultivated plant.

3) *Ramularia Pastinacae* Bubák, new to Great Britain, found on parsnip leaves generally in Worcestershire, but also in Gloucestershire and Cambridgeshire. It is probably spread widely over England, but has been overlooked. In crowded gardens and allotments the fungus weakened the plants considerably, but in the open fields the damage was insignificant.

4) *Cercospora Pastinacae* Karst., new to Great Britain; found on parsnip leaves closely associated with *Ramularia Pastinacae*, but much less common than this fungus.

5) *Plasmopara nivea* Schroet., a species observed in large numbers on parsnip leaves near Wisbech at the end of September, 1917. In October it was found on material from Ashford and Haslemere, and later signs of its presence were noted in several other localities. In a garden near Wisbech where parsnips were grown between trees a considerable amount of the foliage was destroyed by this fungus.

826 - The Control of a Disease of the Japanese Medlar caused by *Fusicladium pirinum* var. *Eriobotryae* (1). — SAVASTANO, L., in the *R. Stazione di Agrumicoltura e Frutticoltura, Acireale, Bollettino* No. 33, pp. 2. Acireale, 1918.

In 1917-18, the experiments with lime-sulphur mixture, begun in 1916 to attempt to control the disease (called "brusone" by the author) were continued.

Summer sprayings were tried, with the object of controlling the disease in the branches, as well as 2 winter sprayings for the purpose of protecting the medlars from the parasite.

As the result of these experiments, the following method is advised for the treatment of the disease:—

1) Summer spraying: in August, with 10-12 % lime-sulphur mixture, normal density 1.25; this spraying is only given when the disease is present in the branches.

2) Winter sprayings. The first at the end of December or beginning of January, *i. e.*, when the disease begins to appear, and the second in February; both of 12 %, normal density.

The spray should be applied liberally so as to wash the vegetative parts requiring protection against the fungus.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

828 - The Value of the Coleopteron *Chilocorus bipustulatus* as a Destroyer of Scale Insects (1). — CORTE, J., in *Bulletin de la Société de Pathologie végétale de France*, Vol. IV, Pl. 2, pp. 86-88, Paris, 1917.

The author collected notes on the attack of the ladybird *Chilocorus bipustulatus* L. on the scale insect *Chrysomphalus dictyospermi* Morg., which is becoming a serious pest in eastern Provence on account of the swarms in which it occurs. His observations do not agree with those of TRABUT, according to whom the ladybird, in Algeria, attacks nearly all scale insects, especially *Ceroplastes rusci* L. of the fig tree, and is able to prevent *Aspidiotus hederae* Vallot from ruining the carob crops.

The author first observed *Chilocorus* larvae and adults feeding on *Chrysomphalus dictyospermi* on a mandarin tree in a garden at Nice, as well as on a neighbouring orange tree. In another garden near the same species was found on a clump of rose-bay the leaves of which were covered with the scale. The research included direct observation and breeding of the insect. Direct observations could only be made during July and were frequently interrupted. During this time *Chil. bipustulatus* was the only coccinellid observed on the mandarin tree and continued to live on it. *Toxoptera aurantii* Fonsc. attempted to invade the bush several times; very small colonies of the aphid formed at the extremities of the twigs,

MEANS  
OF PREVENTION  
AND CONTROL

(1) See R., May, 1918, No. 599. — (2) See B. Apr., 1915, Nos. 451 and 452; B. March, 1916, No. 368; R. June, 1916, No. 707; R. Oct., 1916, No. 1140, R. July, 1917, No. 691; R. Jan., 1918, No. 118. (Ed.)

under the very young leaves which curved round them. These small colonies were destroyed as soon as they appeared, not one being able to establish itself on the tree under observation. The author was unable to catch the ladybird in the act of destroying the insect, but the relative abundance of *Chilocorus* on the bush and the absence of any other coccinellid seem to leave no doubt that the destruction was due to this coleopteron.

If this be correct it shows that the scale is not the food preferred by the ladybird, which only attacks *Crysomphalus* when its customary food is lacking. Nevertheless *Chilocorus* is not considered a large eater of aphids. On the other hand there were on the mandarin tree some specimens of *Saissetia oleae* Bern. in various stages of development, but none appeared to be attacked. The same thing applies to some *Pseudococcus adonidum* (L.) Westw. which the author brought into contact with the ladybird, which seemed to ignore them. It was also noted that *Chrysomphalus* multiplied actively on the mandarin tree and rose-bay under observation, especially on the bay, in spite of the many ladybirds on them.

The author placed four specimens of *Chilocorus* in a large tube and fed them with rose-bay leaves on which were *Chrysomphalus*. With the help of a magnifying glass it was easy to see how the ladybirds attacked the scale insects. They attack the edge of the shield, break it, and feed on the exposed body of the female. Sometimes the *Chilocorus* specimens were not fed for two or three days. Under these conditions they were seen on one occasion to make vain attempts to break the edge of the shield of large *Ceroplastes sinensis* Del Guercio, which they would certainly not have touched had they not been starving. On the other hand, some weeks later, young *Ceroplastes* mixed with *Chrysomphalus* were continually left untouched in spite of their thin shields. This also happened in the case of young *Ps. adonidum* but *Asp. hederae* was found to be a very acceptable food.

The observations, started during the first fortnight of July, were still being continued during the beginning of December, when two of the ladybirds died and the appetites of the two others decreased considerably. After the end of December they only received scale insects on ivy, and died in the middle of April.

The direct observations and breeding tests therefore proved that, in the Nice district, *Chil. bipustulatus* attacks *Chrys. dictyospermi*, which suffices to keep it in normal condition, but does not appear to be its normal food. Agriculturists cannot rely on *Chil. bipustulatus* for the efficient control of swarms of *Chrys. dictyospermi*.

829—The Toxicity to Insects of Various Organic Compounds. — See No. 771 of this Review.

INSECTS, ETC.,  
INJURIOUS  
TO VARIOUS  
CROPS

830 — *Dysdercus scassellatii* n. sp., a Bug Observed on Cotton in Southern Italian Somaliland. — DEL GUERCIO, G., in *L'Agricoltura coloniale*, Year XII, 1st. Half-Year, No. 1, pp. 5-20, 6 Figs. Florence, 1918.

A detailed morphological description of the new species *Dysdercus scassellatii* (Hemiptera Heteroptera), collected on cotton in southern Italian Somaliland by Dr. G. SCASSELLATI-SPORZOLINI.

Up to the present there has been no precise information as to the biology of the hemipteron.

In some nymphs of this *Dysdercus* some unidentified forms of mycetozoa have been found, as well as two different bacteria not yet identified. No internal parasite was found in the nymphs and adults examined.

Together with the nymphs were sent rare forms of large spiders, regarding whose importance, according to the author, nothing definite can be said.

831 — *Megastigmus ballestrerii*, a Hymenopteron Living on the Pistachio Tree and Turpentine Tree, in Sicily. — DE STEFANI, T., in the *Bollettino di studi ed informazioni del R. Giardino coloniale di Palermo*, Vol. IV, Pt. 1-2, pp. 101-131 + 24 Figs. Palermo, 1917.

After reviewing the various insect and arachnid pests attacking the pistachio tree (*Pistacia vera*) and turpentine tree (*P. Terebinthus*, used not only a stock, but also for fertilising the pistachio) in Sicily, the author confines himself more particularly to the chalcid *Megastigmus ballestrerii* Rond. (syn. *Trogocarpus ballestrerii* Rond.).

The larva of this insect, called by the author "verme dei frutti del pistacchio", destroys the pistacchio seed. In 1916 more than 70 % of the fruit were lost by the action of *M. ballestrerii* in some plantations.

The morphology of the insect is minutely described and information on its biology and habits given. The author believes its natural host to be the turpentine tree, and that it has gradually adapted itself to the pistachio.

The best method of controlling *M. ballestrerii* is to collect carefully and burn all infected pistachio fruit either on the plant or on the ground; such fruit is easily recognisable.

To prevent contamination the same procedure should be applied to the fruit of all turpentine trees in or near pistachio plantations. As the collection of the small turpentine fruit from the tree and the ground would be very difficult, the author recommends the destruction of the female inflorescences in April and May as a quicker and more certain method.

FIRST PART.

### ORIGINAL ARTICLES

#### **Mechanical Ploughing. Handling of the Machines.**

BY

A. TARCHETTI

*Engineer in Charge of the Mechanical Department  
of the "R. Stazione Sperimentale di Riscoltura" of Vercelli, Italy.*

At present the use of machinery for ploughing is spreading so rapidly, especially in France, Great Britain and Italy, that it will be necessary to modify the usual methods of cultivating the soil in such a way as to utilise the machines in the best possible manner.

This modification is all the more necessary in Italy since the greater number of the machines had to be hastily — and consequently not always so carefully as was desirable — ordered from the United States, a country having different soil conditions and methods of cultivation, as well as of purchase and use of the machines.

Unfortunately, on the contrary, many farmers, obstinately clinging to the old customs or slaves of routine, thought they could simply use the machine to replace the ordinary plough, thus obtaining an unsatisfactory yield of work, imperfect ploughing, and sometimes running the risk of having unpleasant surprises while the work was in progress.

However, it must be admitted that, though much progress has been made in the construction of machines for motorculture, and though there is an abundance of publications dealing with the subject, yet very little attention has been paid to practical instruction on their application to the soil, except for a few publications by experts dealing with special aspects of the vast problem (1) and for pamphlets and catalogues — not always disinterested — published by the makers of such machines.

(1) For example, see the articles by Prof RINGELMANN in the *Journal d'Agriculture pratique*, 1916, p 135 and 1917, p 103

It is, therefore, not surprising that, owing to lack of more complete and detailed information, farmers are perplexed when about to buy new machines, or are embarrassed when using them on the farm.

The present notes are intended to provide new material for the study of this important question, by considering a series of data and practical rules concerning the new technique of cultivation.

A description will be first given of the handling of the machines in the field, following by a more detailed consideration of the way they should be used in ploughing according to the various methods of preparing the soil.

Leaving aside balance machines (with cable or direct traction), the handling of which is reduced to engaging and lifting out the ploughs at the beginning and end of each furrow, only motor ploughs and tractors will be considered, as their handling is much more complicated, both during the work (ploughs in the soil) or when the ploughs are lifted.

**HANDLING DURING WORK.** — It is very easy to guide the machine during ploughing when the furrow is rectilinear, but it must be very straight. For this reason the first furrow should be turned most carefully with a team, for the perfection and easy working of all the following furrows depends on its straightness.

Handling becomes much more complicated when the furrow is curved. Let us take the example of a tractor with one driving wheel working in the furrow (Fig. 1).

The coupling  $\gamma$ , usually attached at about the middle  $a$  of the back-axle, can turn round this point, describing an arc of radius  $r$  (length of coupling). When the tractor turns, describing an arc of radius  $R$ , the chain and, consequently, the plough-beam, should take up the position  $ac$ , in order that the width ploughed should remain constant. On the contrary, however, owing to the pull being on a curve the chain tends to assume the position  $ac_1$  (normal to  $R_1$ ), so that there is a tendency for the ploughs to be displaced towards the centre  $O$  of the curve.

This tendency, whilst hindering the steering by causing a lateral com-

Fig. 1 — Ploughing on a curve with a tractor with one driving wheel running in the furrow.

Fig. 2 — Ploughing on a curve with a tractor with one driving wheel; effect of moving the coupling to  $a_1$ .

ponent  $f$  to act on the driving wheels which causes the rear wheels of the tractor to be displaced transversely to the direction of movement, prevents the ploughing of a uniform width, as the ploughs tend to be displaced towards the ground already ploughed and to enter into the preceding furrows, while the displacement is all the greater as the chain  $r$  is the longer and the turning radius  $R$  is shorter.

When the point where the chain (Fig. 2) is attached is moved to  $a$ , or as far as  $a''$ , (as is done for hauling military lorries on the road), the difficulty is lessened, but not eliminated, for such a displacement should vary with the radius of the curve (1).

This difficulty is also not eliminated when ploughing on an *internal* curve, i. e., when the driving wheel  $M_1$  runs in the furrow. In this case the ploughs tend to move away from the ploughed land, thus covering a larger width and leaving strips unploughed.

This disadvantage is less noticeable with machines of the *MOLINE* type (front driving wheel) or with motor-ploughs of the *PAVESI-TOLOTTI* type.

With machines working, not in the furrow, but on the firm land, there is no difficulty in ploughing external curves, because their freedom of movement on the soil allows of the ploughs being guided into the correct position; on the other hand, the disadvantage is accentuated when working on an internal curve, the steering wheel  $D$  being obliged to run on the ploughed ground.

In any case ploughing curves is always very difficult, and results in a poor yield being obtained from the engine on account of the greater passive resistance, while the machine (even with a differential) wears more owing to the abnormal strain on gears and bearings. Work done on such curves can never be regular or perfect.

It can be easily understood why circular ploughing is often practised in North America (the *FELLENBERG* method and its modifications) on account of the usually light soils and the fact that a depth greater than 5 to 6 in. is rarely ploughed. The regularity of the work in this case becomes merely a side-issue when compared with the benefit obtained by eliminating turning at the end of the furrows, the ploughing thus being continuous.

But, in Italy the more intensive cultivation, which requires better and deeper ploughing, the more compact soils, and the absence of vast plains, indicate the inadvisability of curvilinear ploughing, which should be reserved for indispensable work such as finishing off the corners of the field.

For example, let us assume that a corner of a field, forming an acute angle (Fig. 3), to take a simple case, has to be finished. It should be finished on a curve of the shortest radius compatible with the turning of the

(1) Theoretically, the constance of the relative positions of the (rigid) coupling and the beam can be obtained for any turn by making them both of the same length, or by using a double (rigid) coupling crossed X-wise. In practice, however, this is not easy, on account of constructional difficulties and even of the ploughing, especially with gang-ploughs.

machine, *i e.*, along the curve *acb* (shown as an arc to simplify matters) so as to reduce to a minimum the space *Oacb* which has to be left to be finished by hand. But this is not possible because, whether working on internal or external curves there would be unploughed strips on the curves, given that the widths *L* of the first furrow are so much greater than the normal width *l* as the angle of the field is more acute.

The ploughing must, therefore, be done in *concentric* curves (Fig. 4); the part of the angle left untouched will, it is true, be greater, but the rest will be completely and uniformly ploughed.

The attention of the drivers should be drawn to this simple fact, especially when they wish to close the furrows by proceeding from the exterior to the interior of the field (as is done in rice fields where the golden rule is to heap the soil against the banks that surround the field, so as to strengthen them), in order that they may not open the first furrow with the maximum turn, then find that they cannot turn symmetrically on the curves of the subsequent furrows.

Fig. 3 — Ploughing a corner of a field, bad method.

Fig. 4 — Ploughing a corner of a field, good method.

**HANDLING WITH THE PLOUGHS LIFTED.** — Handling with the ploughs lifted is much lighter and easier than during ploughing, but it is much more frequent, particularly when there are short furrows or irregular plots, so they they tire the driver the most. From this point of view, they thus deserve special consideration.

Turning is easier with 2 steering wheels mounted on a loose axle, turning like the front-wheels of an ordinary four-wheeled cart. It is less easy when the 2 wheels are turned as in the automobile type, and still less easy when there is only one steering wheel. In the last two cases turning on the spot is very tiring if the tyres of the wheels are very prominent and it is almost impossible on very compact soils.

The turning should, therefore, be done while moving, and gradually, without pushing the turn to the maximum, for handling is nearly always more tiring on narrow curves; but, on the other hand, it should be done energetically and so, as to save time (thus obtaining more work).

and a smaller consumption of fuel) and space (smaller breadth of the headlands).

It is thus of interest to see how the machine can be handled in the field, while conciliating the opposite requirements of less fatigue with greater speed, in the narrowest space.

When it is said that a machine *turns* in a radius, of 5 metres for example, it means that the machine can, at the maximum, turn in a circle of 10 metres in diameter, but not that it could do the whole turn in a space of 10 metres except by doing the maximum turn *on the spot*, which never happens in practice.

For example, take a machine moving along a straight line  $AB$  (Fig. 5) and which, when at  $B$ , should turn to the right. The driver, letting the machine move forward, commences to turn gradually towards  $C$ , the maximum turning point, after which the machine would advance automatically, describing an infinite number of circles of centre  $O$  and radius  $OC$  corresponding to the minimum possible to the machine. The trajectory  $BC$  of the machine is evidently a polar curve, for, supposing that the turning could increase still more after the point  $C$ , the radius of curvature would be reduced to zero, *i. e.*, would attain the pole; the amplitude or development of the trajectory in the field depends, for the abscissae  $BD$  and the ordonates  $CD$ , on the ratio between the two speeds of advancing and turning (1) simultaneously.

Fig. 5 — Mathematical analysis of a turn.

If this ratio is constant, *i. e.*, if the machine moves forward uniformly and if it turns gradually, as in the cases when it would be obtained mechanically with a uniform movement, then the curve has a well defined equation: that of the logarithmic spiral, as is shown by the mathematical analysis.

Figures 6 to 16 represent by one of these spirals (the same in each figure, and on the same scale), a few of the commonest evolutions carried out in the field by tractor ploughs (usually with ploughs turning the earth on one side only), in order to compare the length covered (space covered as a function of time employed, and, consequently, of fuel consumed) and the total amplitude of the turnings (sum of work or effort expended by the driver).

These figures show the form of the evolutions, *carried out with constant speed in the minimum space*, given: — *a*) the maximum width of a headland, or the space in which the evolutions must take place included between the lines  $xx$  (end of the furrows) and  $yy$  (edge of the field) (Fig. 6); *b*) as unit  $P$  of effort, making a complete turn (to pass from  $B$  to  $C$ , Fig. 5);

(1) In Fig. 5,  $B$  is a point of the curve placed so that the tangents at  $B$  and  $C$  are normal to one another; this is an example of one of the commonest practical applications. But  $B$  could also be placed either above or below the line  $BD$ .

c) as unit  $S$  of space, the corresponding trajectory, that is, the length of the spiral  $BC$ .

*Minimum turn with curve of  $180^\circ$ , or half-circle turn (Fig. 6).* — When the last plough is about to reach the line  $xx$  at  $A$  (end of furrows) the steering wheels have reached  $B$ , where the turn to the right, for example, commences. Once the maximum turn has been reached at  $C$ , the driver begins to turn to the left until the machine reaches  $D$ , afterwards starting the return trip at  $A_1$ . *Total journey =  $2 S$ ; total work =  $2 P$ .*

Fig. 6 — Minimum turn at  $180^\circ$

Fig. 7 — Minimum turn at  $90^\circ$  repeated.

*Minimum turn with curve of  $90^\circ$  (Fig. 7).* — To reach half the turn (angle of  $45^\circ$ ) at  $C$  the machine had to turn about  $\frac{1}{4}$  to the right, travelling a distance of  $0.7 \times S$ ; it has to turn the same distance to arrive at  $D$ . *Total journey =  $1.4 S$ ; total work =  $1.4 P$ .* This turn usually serves to fix the breadth of the chief headland.

If it is desired to return to the furrows (turn of  $180^\circ$ ) from  $D$  (or from

Fig. 8 — Circle of  $180^\circ$  with minimum turn.

Fig. 9 — Manoeuvre for decreasing the turning.

$D_1$ , after a rectilinear journey along the edge of the field), the same manœuvre must be repeated, *i. e.*, that  $D_1E$  = about  $\frac{3}{4}$  of the right-hand turn, and  $EF$  = about  $\frac{3}{4}$  of the left-hand turn. *Total journey* =  $2.8S + DD_1$ ; *total work* =  $2.8P$ .

*Curve of 180° with minimum turn* (Fig. 8). — From  $B$  to  $C$ , half-turn

Fig. 10 — Orthogonal turn.

Fig. 11 — Finishing work on a curve of two headlands with orthogonal turns.

Fig. 12 — Method of ploughing without headlands, eliminating orthogonal turns.

to right; from  $C$  to  $C_1$ , arc of circle (without turning manœuvre) of centre  $O$ , angle about  $120^\circ$  and length about  $1.75S$ ; from  $C_1$  to  $E$ , half-turn to right to straighten out. *Total journey* =  $2.75S$ ; *total work* =  $1P(1)$ .

These results show that the turns should be kept within the limits of Figs. 6 and 8 (*i. e.*, between 5 and 8 metres with the ordinary American

Fig. 13 — Double turn within the breadth of an ordinary headland.

machines) and that it is a mistake to think that very wide ridges (as in Fig. 7) save the driver trouble; he certainly has an period of rest (in the journey  $DD_1$ ) but there is waste of both time and fuel, while the fatigue caused

(1) In the case of Fig. 7, the turning curve can be diminished as shown in Fig. 9, but a wider headland will be required (by the quantity  $a$ ). In this case, for a curve of  $90^\circ$  or  $180^\circ$ , where are the values: — *Total journey* =  $1.5S$ , or  $3S + DD_1$ ; *total work* =  $1P$  or  $2P$ .

by each evolution is, on the contrary, greater than that resulting from narrower, or at least equal, turns. Moreover, the repeated passage of the wheels over the length  $DD_1$  damages the soil so much that there is very poor grip when turning the last furrows on the edge of the field.

*Orthogonal Turn or at  $270^\circ$*  (Fig. 10). — From  $B$  to  $C$ , complete turn to the right; from  $C$  to  $C_1$ , without a manœuvre, a quarter circle with the smallest turning radius  $OC$ ; from  $C_1$  to  $D$ , complete turn to the left. *Total journey* =  $2.5 S$ ; *total work* =  $2 P$ .

This manœuvre, useful for hauling mowers or harvesters, is recommended by several authors for ploughing also, for preparing the finishing curves at the headland (Fig. 4), turning the head furrows  $m, m, m...$  and the side furrows  $n, n, n...$  which permits of shortening the furrows by diminishing the work on the curve (Fig. 11). But it is advisable: — 1) either to eliminate these difficult orthogonal turns, by arranging that the first furrow should end in  $M$  (Fig. 12) from the beginning of normal ploughing and that the subsequent furrows should be gradually prolonged until they describe the curve  $M N$  suitable for turning the machine; 2) or to replace the orthogonal turns by figure-of-8 turns (described later) limited to the chief headlands when they must be reduced to the same breadth as the side headlands.

*Double or figure-of-8 turns* (Figs. 13, 14, 15, 16). — These are necessary (if the machine has no reverse, or if, having one, the coupling to the ploughs is not rigid) when the machine has to turn in a space narrower than  $BD$  of Fig. 6 (*i. e.*, usually less than 6 metres), as when the first furrow is being opened or the ploughing finished.

Fig. 14 — Another example of a double turn within the headland, symmetrical to the axis of the furrows.

Figures 13 and 14 give examples of two double turns in the limits of breadth of the ordinary headland. That of Fig. 13 is longer and more difficult, as it requires: *Total journey* = about  $6.15 S$  and *total work* =  $4.5 P$ , while the turn in Fig. 14 requires: *Total journey* =  $5 S$  and *total work* =  $4 P$  and it is easier to carry out, being symmetrical to the axis of the furrows.

Figures 15 and 16 show two double turns inside the field, with no head-

land, as in ploughing without ridges or by the Fellenberg method. The turn of Fig. 15 is symmetrical to the axis of the furrows but is much longer than that of Fig. 16. The respective values are : — *Total journey* = 6.75 S and 3.8 S; total work 3 P.

The various evolutions illustrated by these figures illustrate special problems, for, in practice, freedom in turning allows the driver to enlarge or diminish the curve of the turns at will by decreasing or increasing the turning speed, but the relation of the journey and especially of the total work remains practically the same.

Fig. 15 — Double turn inside the field, symmetrical to the axis of the furrows.

Fig. 16 — Double turn inside the field, not symmetrical to the axis of the furrows and shorter than that of Fig. 15.

This is why, when buying a ploughing machine, it is very important to study and observe its behaviour in the field, by means of repeated turning trials on the field with the ploughs lifted, not only with the object of exercising the driver and making the turns more exact and sure, but also on account of the need for arranging the division of the field and even the choice of the methods of ploughing so as to suit the type of machine.

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

DEVELOPMENT  
OF  
AGRICULTURE  
IN VARIOUS  
COUNTRIES

832 - The Agricultural Development of the East Coast of Sumatra. — BLINK, H., in the *Tydschrift voor Economische Geographie*, Nos. 3 and 4, pp. 100 + Figs. + Tables. The Hague, April, 1918.

The paper under review contains an historical, geographical and economical survey of the Island of Sumatra, with a general historical introduction. It includes the hydrography, geology, climatology, ethnography, general economic development, agriculture, industry, and commerce of the district.

In the chapter on AGRICULTURE a special study is made of the cultivation of tobacco, one of the most important crops of the island. It was first started on a large scale and organised by Europeans towards the middle of the 19th. century. Several companies were formed, most of which cultivated rubber as well as tobacco. The development of tobacco was extraordinarily rapid in certain years; the total crop which, in 1864, was 460 cwt., rose in 1913 to 3955 113 cwt. The first plantations were on cleared forest land. The produce was of a dark shade much in demand. To avoid continual clearing a rotation system was adopted including a tobacco crop every 6 or 8 years, followed immediately by a rice crop, after which the ground is left fallow for some time; as green manure *Crotalaria striata* is grown. The subsequent adoption of modern cultural methods produced a tobacco of lighter colour but fortunately without modifying appreciably the flavour or aroma. The tobacco is sown early in the year under frames ("pajongs") and when the plants have developed sufficiently they are transplanted. After a few months the plant is about 8 feet high and has 40 to 50 leaves, the longest of which are 19 ½ to 23 ½ inches long. The drying-rooms can hold an average of 1 million leaves, which are afterwards piled up so as to attain the necessary suppleness. In sorting preference is given to Chinese workers who are more apt than the natives to distinguish differences in the shade and consistency of the leaves. The sorted packets are compressed hydraulically into bales of 176 lb. The cultivation of tobacco has changed the appearance of the country, formerly covered with virgin forests, which have given place to plantations and dwelling. The swamps have been

drained, roads and bridges built, sanitary conditions improved, and an agricultural experiment station ("Deli-Proefstation te Medan") established at Medan.

The more recent crops as yet cultivated to a smaller extent than tobacco are then described :—

1) RUBBER. — The cultivation of rubber on a large scale was started towards 1902, and has since developed rapidly. The plantations, which did not exceed 435 acres, in 1916 covered an area of 259 999 acres with a production of 15 265 metric tons. A yield of 45 000 metric tons is anticipated for 1921, and the district will then be able to supply an important percentage of the world production. Exportation was formerly chiefly to London, Antwerp, Amsterdam and Hamburg, but since the war it is more largely to America. In 1916 the exportation of *Hevea* rubber was :— United States, 112 936 cwt; United Kingdom, 95 404 cwt.; Singapore, 20 878 cwt.; Penang, 11 219 cwt.; Java, 117 105 cwt; Netherlands, 435 cwt. The soil, usually white clay in the plains and darker on the hills, and the even, rainy climate without long periods of drought, favour the cultivation of *Hevea*, which supplies most of the rubber.

2) COFFEE. — In 1903 the average production was 42 600 *picol* (41 761 cwt.). Most varieties of coffee-plants only begin to yield 3 years after planting; they are grown between the trees in the rubber plantations, which usually only begin to yield after 4 or 5 years. The varieties mostly grown are *Robusta* and *Liberian*, as well as *Javan*, and *Quillou* from the French Congo. In 1916 the exports amounted to 73 600 cwt.

3) TEA. — The district is fairly well adapted to tea-growing, which requires a moist atmosphere and continuous and regular rains. The exports, mostly to London, were 30 096 cwt. in 1916.

4) COCONUT. — This is grown particularly in the valleys and low districts along the coast as the sea assures the necessary humidity and constant temperature. In 1916, 90 348 cwt. of copra were exported.

5) OTHER CROPS. — In 1916 *oil-palms* were grown over 9 000 acres and this acreage will certainly be extended in view of the increasing demand for palm oil for making candles, vegetable butter, soap and glycerine. As there is a crop only every 3rd or 4th year coffee is also grown here between the trees. The *sago-tree* is partly cultivated, partly wild; the exportation of sago amounted to 2 621 cwt. The *gambier* gives a resinous gum used for tanning and dying, of which 44 361 cwt. were exported in 1916, chiefly to Great Britain. *Betel* is obtained from the fruit of *Areca Catechu* L. The cultivation of *pepper*, once very flourishing, has greatly decreased. New crops have recently been attempted, particularly *agave*, *sesame* and *sugar-cane*. *Soya* has been introduced in the tobacco rotations.

6) FOREST TREES. — Before the arrival of Europeans most of the district was covered with forests, and wood was one of the most important branches of native trade. The exportation of forest produce has much decreased but is still fairly important. The extension of modern agricultural enterprise has spared only those forests on ground inaccessible for cultivation. For this reason the forests are found now especially on the mountains or hills. The principal trees are :—

*Azelia palembanica*, which gives an excellent wood for building; *Sloetia Sideroxylon* which yields a reddish wood which turns brown when exposed to the air; it is the most solid in the district. There is no very marked limit between the species of the plains and those of the hills, but there is transition, the larger specimens being found in the mountains. In the plains it is only in the relatively wild districts, interspersed with marshes, that forests are still found. Most of the species belong to the Dipterocarpaceae family; two Oleaceae — *Scorodocarpus borneensis* and *Ochanostachys amentacea* — give a good quality wood; one Loganiaceae — *Fagraea fragrans* — gives an almost white wood. *Cerriops Candolleana*, *Rhizophora conjugata*, *Brugniera gmnorhiza*, etc., should also be mentioned.

The felling of wood is particularly along the water-courses and tends to increase more and more. The local consumption of building wood increases continually near the agricultural estates, and the authorities have taken steps to form reserve forests in the mountains.

#### RURAL HYGIENE

833 - The Influence of Specific Carbohydrates and Grains, Other than Oats, on the Development of Scurvy. — PRIZ, W. (University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 3, pp. 471-482 + 12 Charts, Bibliography. Baltimore, 1918.

I) *Effects of Carbohydrates and specially of Lactose*. — In a previous paper (1) MCCOLLUM and PRIZ had put forth the theory that scurvy in the guinea-pig results from the absorption of toxic substances arising from putrefaction in the cœcum due to undue retention of fœces.

HULL and RERTGER showed with white rats and also with men fed on a high protein diet that the bacterial flora of the intestine could be changed from a putrefactive flora to an acidophilus flora by the ingestion of lactose in the diet. Other carbohydrates as sucrose, dextrose, maltose, etc., produced a similar, but less pronounced, effect. It results from this that any substance that will thus change the intestinal flora should prevent the onset of the symptoms of scurvy. In order to test this supposition guinea-pigs were fed oat meal and whole milk, plus a carbohydrate. The results obtained show that a subject already affected begins to recover, while healthy subjects are completely protected by adding lactose to their diet. Excepting dextrose, which has only a slight action, the other carbohydrates had also a partially preventive action which, although less than that of lactose, maintains the animals in much better condition than when they are fed on oat flour and milk alone.

II) *Influence of Grains, other than Oats*. — The author fed guinea-pigs on ground grains of barley, wheat and maize, together with as much milk as they would consume (which favoured constipation). The barley grains caused scurvy after 4 weeks, those of maize after 5 to 6 weeks and those of wheat after only 3 weeks.

It may be concluded that grains of barley, wheat, and maize fed with large quantities of milk, so as to produce constipation caused scurvy,

(1) See R., 1914, No. 547. (Ed.)

but did not favour it as much as oats. In fact, for these grains, 10 per cent of lactose added to them was just as effective in preventing scurvy as was 20 per cent when fed with oats.

834 - **An Experimental Chronic Beriberic Syndrome**(1). — WEILL, E. and MOURIQUAND, G., in the *Comptes Rendus des Séances de la Société de Biologie*, Vol. LXXXI, No. 8, pp. 432-435. Paris, April 27, 1918.

As the result of experiments made on pigeons, the authors have concluded that by the side of an acute beriberic syndrome (EYKMAN'S syndrome appearing about the 20th or 25th day) there exists a chronic beriberic syndrome that appears much later and which can be caused especially by a partially deficient diet (in the present experiments by a mixture of  $\frac{1}{3}$  of wholly raw seeds with  $\frac{2}{3}$  of sterilised seeds). This syndrome is characterised by incipient paralysis of the wings, which may be followed by paralysis of the claws; it is completely resistant to treatment with raw epidermis, considered to be a specific.

In the experimental, acute, beriberic syndrome, recovery is obtained in a few hours by administering raw epidermis or by injecting vitamines, as if the paralysis was solely due to a chemical change in the nerve centres. The chronic cases that are almost entirely resistant to treatment with epidermis appear to be caused by profound nervous lesions (a natural consequence of the chemical change). The clinically "functional" paralysis of the former cases should be clinically "lesional" in the latter.

In a note on the previous communication, M. L. LAPICQUE records similar results that he has obtained with mice fed exclusively on white wheat flour. After a few days the young mice showed serious disorders, which were at once cured with whole wheat. When fed with white flour the adult mice only showed the characteristic neuritis after several weeks, and when once the disorder was manifest, recovery could not be obtained by adding either casein or whole wheat to their diet.

835 - **The Value of the Yeast Vitamine Fraction as a Supplement to a Rice Diet.** — EMMETT, A. D. and MCKIM, L. H., in *The Journal of Biological Chemistry*, Vol. XXXII, No. 3, pp. 409-419 + 4 Diagrams + Bibliography of 9 Publications. Baltimore, Md., December, 1917.

In the present paper the authors report the first of a series of investigations that deals more particularly with the efficiency of the vitamines from autolysed brewer's yeast (2), in respect to their value as an *adjuvant* to a diet that has been shown to be deficient in some particular vitamine.

From these studies, which have extended over a much longer period of time than any of those previously reported on this subject, it appears: —

1) That ordinary fuller's earth, ground to a definite fineness, absorbs the yeast vitamine fraction from the autolysed yeast filtrate as readily as the special form of fuller's earth, called Lloyd's reagent. Further, the

(1) See *R.*, 1916, No. 415; *R.*, 1917, Nos. 260 and 566. (Ed.). — (2) See also *R.*, March 1918, n. 341. (Ed.) See also: *B.* 1912, No. 1130; 1914, No. 871; 1915, No. 1239; 1916, No. 612 and 1254. (Ed.)

"Kieselguhrs" (infusorial earth, "celite B," and "filtercel") do not absorb the yeast vitamine.

2) That these two forms of activated fuller's earth are equally potent and very efficient as therapeutic agents in the treatment for typical attacks of avian polyneuritis.

3) That silicates in the form of ordinary fuller's earth, Lloyd's reagent or infusorial earth, when added to a polished rice diet, do not inhibit or accelerate the onset of avian polyneuritis; and that lactose, used in making the vitamine tablets, is also inert in this respect.

4) That the activated fuller's earth when given as a rational supplement to a polished or a brown rice diet, acts as a partial stimulant to increase the weight of the treated polyneuritic pigeons; it does not, however, in the case of the polished rice, accelerate the increase in weight to anything like that which is produced under similar conditions with brown rice alone, corn, barley, or hulled oats; and comparatively speaking, this activated yeast vitamine is not a complete supplement to a polished rice diet.

5) That there are apparently two so-called vitamins associated with rice polishing, one which cures polyneuritis and one which produces weight, and of these two the SEIDELL yeast vitamine preparation contains chiefly the curative fraction, along with a small per cent of the other.

Finally, it is evident, that while this activated yeast vitamine product is a valuable adjuvant to the diet in the case of convalescents from avian polyneuritis, yet for the best results, the diet should, in addition, be made up in part at least of vitamine-containing foods, not for the purpose of preventing the recurrence of typical attacks of this dietary deficiency disease (for the preparation is able to do this) but with the object of bringing about normal gains in weight and complete recovery.

836 - Studies on the Digestibility of Some Nut Oils. — HOLMES, A. D. (Office of Home Economics), in the *U. S. Department of Agriculture, Bulletin No. 630*, pp. 19 + 7 Tables + Bibliography of 20 Publications. Washington, April 16, 1918.

The author undertook a series of studies on the oils of several nuts in order to determine their digestibility as compared with those of animal or vegetable fats commonly used as foods.

All the oils were administered in the same way and with the same rations, so that the results as to their digestibility were directly comparable. A blancmange, or cornstarch pudding, was used as the basis of the ration and contained the oil for experiment; wheat biscuit, oranges and sugar were also given. All the food was cold with the exception of tea or coffee (without milk) which the subjects were allowed to take with their meals if they liked. The subjects were adult men between 20 and 40 years of age, mostly engaged in mental work, but taking sufficient exercise to make their energy requirement greater than that of most people with sedentary professions.

The experiment lasted 3 days and included 9 meals. The faeces were carefully analysed. The oils tested, the average daily amount consumed, and their coefficient of digestibility were:

1) Almond oil from *Prunus Amygdalus*, ration 70 gm., coefficient of digestibility 97.1 %.

2) Black-walnut oil, *Juglans nigra*, ration 56 gm., coefficient of digestibility 97.5 %.

3) Brazil-nut oil, *Bertholletia excelsa*, ration 81 gm., coefficient of digestibility 96.3 %.

4) Butternut oil, *Juglans cinerea*, ration 43 gm., coefficient of digestibility 95.4 %.

5) English-walnut oil, *Juglans regia*, ration 78 gm., coefficient of digestibility 97.6 %.

6) Hickory-nut oil, *Carya ovata*, ration 95 gm., coefficient of digestibility 99.3 %.

7) Pecan oil, *Carya Pecan*, ration 104 gm., coefficient of digestibility 96.8 %.

The average daily amounts given above are not maximum and may be exceeded.

These oils have about the same digestible qualities as the common vegetable oils (cottonseed, groundnut, olive oils, etc.). They are all liquid at ordinary temperatures. The data obtained with regard to the digestibility of the protein and carbohydrates consumed with these oils show them to have no abnormal influence on the digestibility of other foods eaten with them. The results shows that, as these oils are very well assimilated by the human body, they may be used freely for food purposes.

**837 - Experiments on the Digestibility of Fish.** — HOLMES, A. D. (Specialist in Charge of Digestion Experiments, Office of Home Economics), in *U. S. Department of Agriculture, Bulletin No. 649*, 14 pp. Washington, April 13, 1918.

In the study of the digestibility of the protein and fat supplied by some common varieties of fish, fish in the form of "fish loaf" was served as the major part of a simple mixed diet, which also included potatoes, crackers, fruit, sugar, and tea or coffee. Considering the experiments as a whole, the total diet supplied on an average 99 gm. of protein, 60 gm. of fat, and 160 gm. of carbohydrates daily, the fuel value being 1576 calories. The low amount of fat and of carbohydrates was due to the fact that butter and similar fats were omitted and the foods other than fish loaf which supplied both protein and carbohydrates, were limited in order that both the fat and the protein in the diet might be contributed in as large proportion as possible by the fish.

The principal results are summarised in the following table : —

Number of experiments	Kind of fish	Average amount of fish eaten per man per day	Digestibility of fish protein	Digestibility of fish fat
		grams	per cent	per cent
3	Mackerel ( <i>Scomber scombrus</i> ) . . . . .	448	93.1	95.2
3	Butterfish ( <i>Peronatus triacanthus</i> ) . . . . .	471	91.9	86.4
8	Grayfish ( <i>Squalus acanthias</i> ) . . . . .	440	92.8	94.3
4	Salmon ( <i>Oncorhynchus tshawytscha</i> . . . . .	355	93.2	93.7

As these figures show, the average coefficients of digestibility for fish proteins are in close agreement, therefore it would seem, from a dietetic standpoint, that the different fishes studied would supply protein in equally available form. The fats were well assimilated in the case of the mackerel, grayfish, and salmon, which, according to the usual custom, are to be regarded as "fat fishes". Considering the experiments as a whole, the very complete utilisation of the protein and fat supplied by the fishes studied offer additional experimental evidence that fish is a very valuable food and that its extensive use in the dietary is especially desirable.

## CROPS AND CULTIVATION.

SOIL PHYSICS,  
CHEMISTRY  
AND  
MICROBIOLOGY

838 - Movement and Distribution of Moisture in the Soil (1). — HARRIS, F. S. and TURPIN, H. W. (Utah Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. X, No. 3, pp. 113-155, 31 Figs., Bibliography of 35 Publications. Washington, D. C., July 16, 1917.

During recent years considerable difference of opinion has arisen regarding the importance of the capillary movements of soil moisture and also regarding the laws governing the final distribution of moisture in the soil. In order to solve this problem the authors carried out a series of laboratory and field experiments under irrigation and dry-farming conditions. The experiments represent several thousand moisture determinations. The field studies include the effect of fallow, kind of crop, manure, irrigation water, surface mulches, cultural methods, and seasonal conditions on the movement and distribution of soil moisture. The laboratory studies include the effect of the initial percentage of moisture, gravity, soil type, source of supply, etc., on the movement and distribution of moisture in the soil.

RESULTS. — In field soils the moisture content of the fallow soils averaged greater than that of the cropped soils.

Unmanured irrigated land showed less difference in moisture between cropped and fallow than did the manured.

Irrigation influenced the top feet of the cropped plots proportionately more than the fallow, but water did not appear to penetrate the fallow plots below 7 feet as readily as it did the cropped ones. Under dry farming conditions the difference in moisture between cropped and fallow plots was not noticeable until after June 16. Cropped plots showed more fluctuation than fallow ones. Wheat, maize, potatoes, and peas drew most of their moisture from the first 4 feet in depth. The wheat land contained less moisture in the autumn than the other cropped soils, with maize following.

The increase in moisture due to applications of 5 to 7  $\frac{1}{2}$  inches of irrigation water was felt to depths of 10 feet in 24 hours, although most of the increase was in the first 4 feet.

(1) See also B. April 1914, No. 308; R. January 1916, No. 8; R. Dec. 1917, No. 1111; R., February 1918, No. 128. (Ed.)

The effect of mulches in preventing moisture loss under both irrigation and dry-farming was noticeable several feet below the surface of the ground, but the surface foot showed the greatest benefit from mulches. A straw mulch proved considerably better than a 2-inch soil mulch.

Mulches on irrigated plots appear to influence the moisture content of the soil to greater depths than do those under dry-land conditions. A dry-farm plot kept free from weeds in 1916 but not mulched lost very little more water than one mulched 2 inches deep. A 6-inch cultivation on spring-ploughed and a 2-inch cultivation on autumn-ploughed dry-farm land seemed to conserve the moisture best.

Subsoiling 15 inches deep had little influence on the moisture; spring discing was rather a distinct benefit.

An 8-year average shows that spring ploughing under dry-farming conditions at Nephi conserves moisture better than autumn ploughing. This difference in favour of spring ploughing is shown more below the first foot than in the first foot, and more in summer and autumn than in spring.

A precipitation as small as 0.1 inch under dry-farming conditions could not be detected in moisture determinations soon after, but, when as much as 0.5 inch fell within a short time, an increase in moisture was noticed to a depth of 6 feet.

When freely supplied with water, a soil with a high initial percentage of moisture will come to a moisture equilibrium sooner than a drier one, but if given time the drier soil will absorb a greater quantity through a long distance either upward or downward than will the wet one.

The rate of moisture penetration in the first 10 days was nearly twice as great with initial percentages above 15 as with 5 or below, and nearly twice as rapid after a 15-inch irrigation as after a 5-inch one. Under the most favourable conditions 7 feet was influenced in 10 days.

Moisture movement from soils of optimum moisture content into soils of differing initial percentages varied to an extent inversely as the initial content of the dry soil. At the end of six weeks, however, the amount of water actually in the soils still varied directly as the initial percentage.

The higher the percentage of moisture in the soil supplying the water to a dry-soil, the more rapidly and farther from the source of water did the moisture move.

Even when the source of water was an unsaturated soil, greater and faster movement took place when the water was moving downward than upward. When the quantity of soil yielding the water was so small as to make the total moisture content of both moist and dry soils very low if equally distributed, the effect of gravity was not great.

Moisture from a nearly saturated soil moved a greater distance into loam than into sand in 139 days and into sand farther than into clay. The clay, however, contained more moisture in the layer of soil next the water supply than the others and sand contained by far the least.

Sand, with 7.77 per cent of moisture, gave up its moisture to loam much more readily than did loam with 31.09 or clay with 24.62 per cent of moisture.

The rate of rise of moisture from soils of varying fineness when used either as water sources or water absorbers varied inversely with the fineness. Water rose to a height of over 30 inches in a loam soil from a moist sand in 94 days, while from a moist clay it rose little more than 6 inches in this length of time. In all soils the most rapid rise of the water was during the period soon after being placed in contact with the water.

Although the rise of the moisture was more rapid in the sand and loam than in the clay, the rise continued steady longer in the clay than in the others.

**839—Studies in Soil Reaction as Indicated by the Hydrogen Electrode (1).**—I. PLUMMER, J. K. (North Carolina Agricultural Experiment Station), Studies in Soil Reaction as indicated by the Hydrogen Electrode, in the *Journal of Agricultural Research*, Vol. XII, No. 1, pp. 19-31, + 8 Tables + Bibliography of 13 Publications. Washington, D. C., January 7, 1918. — II. HOAGLAND, D. R. and SHARP, L. T. (Agricultural Experiment Station of the the University of California), Relation of Carbon Dioxide to Soil Reaction as Measured by the Hydrogen Electrode, in the *Journal of Agricultural Research*, Vol. XII, No. 3, pp. 139-148 + Bibliography of 11 Publications. Washington, D. C., January 21, 1918.

The hydrogen electrode has been used by the author for indicating soil reaction on a number of untreated soils in suspension. The soils experimented with represent a wide range in texture of those common to the area of the southeastern portion of the United States, extending from and including the Appalachian Mountains to the Atlantic Ocean. The H-ion concentration varies from almost "true neutrality" to rather excessive "true acidity" in the soils.

With the Morgan apparatus for extracting film water from soils, it was shown that its reaction is the same as the free water, differing only in intensity.

The effects of certain fertilisers on the H-ion concentration of long-time-treated plots of three soils were measured, with the following results: — 1) ammonium sulphate materially increased the H-ion concentration of all plots which received applications of this material. The acidity thus developed often extends to the subsoil; 2) sodium nitrate slightly reduced the acidity of the plots to which it was applied; 3) potassium sulphate increases the "true acidity" when applied to soils, though not as greatly as ammonium sulphate; 4) acid phosphate does not appear to affect in either direction the H-ion concentration of field soils. 5) Lime materially increases the OH-ion concentration of field plots to which it has been added.

The acidity developed from ammonium sulphate was more intense in the film than in the free water of the three soils.

Monocalcium phosphate does not change in any way the soil-film water until excessive amounts are added.

(1) Though the hydrogen electrode has been used for some time in indicating changes in reaction, GILLESPIE was the first to use it on an extended scale as an indicator of reaction in soils (See R. 1916, No. 733). Later SHARP & HOAGLAND measured the hydrogen-ion concentration of numerous soils in suspension and they also applied the method to the study of other phenomena of the soil.

II. — In a previous article (SHARP, I. T. and HOAGLAND, D. R., Acidity and Absorption in Soils as Measured by the Hydrogen Electrode, *Journal of Agricultural Research*, Vol. VII, No. 3, pp. 123-145) the authors have presented data concerning the question of soil reaction as determined by the hydrogen electrode. Since this work did not include direct measurements of the effect of carbon dioxide on the reaction of soils, it was thought desirable to carry out further experiments on this point.

The H-ion concentrations of soil suspensions were measured under various partial pressures of carbon dioxide, with the following results: —

The H ion concentration of suspensions of acid soils is not markedly affected by increasing the content of carbon dioxide up to 10 per cent. The H-ion concentration of slightly alkaline soils is slightly increased by such treatment. A notable increase in H-ion concentration is observed when soils containing alkali carbonates are similarly treated.

It has not been found that any treatment with carbon dioxide can produce an alkaline reaction in the suspension of an acid soil.

When the original conditions are restored, no permanent change in soil reaction could be attributed to the carbon dioxide.

Further experiments with the hydrogen electrode have confirmed the point of view that solutions in equilibrium with acid soils contain H-ion in excess of OH-ion.

840 — **Humus in Mulched Basins, Relation of Humus Content to Orange Production, and Effect of Mulches on Orange Production.** — JENSEN, C. A. (Bureau of Plant Industry, U. S. Dept. of Agric.), in *Journal of Agricultural Research*, Vol. XII, No. 8, pp. 505-518, 8 Tables, Bibliography of 10 Publications. Washington, D. C., February 25, 1918.

This report presents a study on: — a) the changes in humus content in soils in basins mulched with different organic substances; b) the effect of lime on humus content in soils in mulched basins; c) the relation of humus content in the soil to orange production.

By "humus" is meant the brown- to black-coloured organic extract obtained from soil leached with 1 per cent hydrochloric acid to remove the calcium completely and the soil residue boiled for two minutes in a 7.5 per cent sodium hydrate solution.

Humus determinations in mulched basins in citrus groves showed a fluctuation in the percentages of humus from time to time. The average percentage of humus increased more in basins on clay loam soil than in basins on lighter soils, with manure and alfalfa as mulching materials. Usually the percentage of humus in basins increased more when manure was used as mulch than when alfalfa was used as mulch. This seemed, however, to be due more to the humus added with the manure, than to the greater "humification" of the manure over the alfalfa. When manure alone was used as mulch in basins the increase in humus was greater than when lime was added with the manure. In most cases when lime was added to alfalfa in basins greater increase in the humus content occurred than when alfalfa alone was used. Blood, acid phosphate, bone meal, tankage, or sulphur did not show any appreciable influence on the changes of humus content in mulched basins. It was not evident that there was any appreciable accu-

mulation of humus in the lower depths of soil due to the leaching of humus from the surface foot of soil. There was no evident correlation between the amount of humus in the soil in mulched basins and the amount of fruit on the trees. There was no evident effect of lime on orange production in these experiments. Alfalfa and bean-straw mulch in basins on the heavier soil types produced from 30 to 100 per cent more oranges per tree than manure mulch. Manure mulch produced more oranges per tree than either barley hay, sweet clover, bur clover, or pine shavings. These differences were obtained in the summer following the application of the mulches in the preceding autumn. Alfalfa mulch and manure mulch in basins on the lighter types of soil produced no observable differences on fruit production of lemons in the course of one year. In all experiments so far conducted by the Office of Biophysical Investigations, Bureau of Plant Industry, in the Riverside area, the mulched-basin system on the heavier soil types has produced favourable growth response in a few months. It usually takes longer to produce appreciable response on the lighter soil types. It appears that the degradation products from freshly decomposing organic substances are more effective in orange production than the amount of "humus" formed. And the value of a given mulch does not necessarily depend upon its being a legume or non-legume.

**841 - Formation of Black Alkali (Sodium Carbonate) in Calcareous Soils.** — BREAZEALE, J. F. (Biophysical Investigations, Bureau of Plant Industry, U. S. Dept. of Agric.), in *Journal of Agricultural Research*, Vol. X, No. 11, pp. 541-589, 26 Figs., 48 Tables + 1 Plate, Bibliography of 7 Publications. Washington, D. C., September 10, 1917.

With the exception of an adequate water supply, the presence and accumulation of alkali is probably the most important problem that confronts the man engaged in farming under irrigation in the arid and semi-arid regions of the West.

As ordinarily used, the term "alkali" indicates the salts of sodium, together with calcium and magnesium salts in lesser amounts. In this paper the term includes all the water-soluble salts of the soil, whether organic, or inorganic. This paper discusses only one specific phase of alkali formation and that is that which takes place when sodium salts are present in a calcareous soil. The conclusions arrived at are as follows: —

- 1) In the reaction between sodium nitrate (or sodium chloride or sodium sulphate) and calcium carbonate, resulting in the formation of sodium carbonate, the presence of relatively small amounts of calcium nitrate or calcium chloride in the reaction impedes and may prevent the formation of sodium carbonate.

- 2) The presence of a saturated solution of calcium sulphate in this reaction does not entirely stop the formation of sodium carbonate.

- 3) Sodium nitrate, sodium chloride and sodium sulphate in the presence of carbon dioxide react with calcium carbonate with the formation of sodium bicarbonate.

- 4) The presence of relatively small amounts of calcium nitrate or calcium chloride in this reaction impedes and finally prevents the formation of sodium bicarbonate.

5) The presence of calcium sulphate has no effect in preventing the formation of sodium bicarbonate when sodium sulphate or a mixture containing sodium sulphate reacts with calcium carbonate.

6) A field application of gypsum will probably have no effect in overcoming black alkali if the soil already contains soluble sulphates in appreciable amounts, or if the irrigation water contains these salts.

7) Sodium nitrate, sodium chloride, and sodium sulphate increase the solubility of calcium carbonate in the soil.

8) Sodium nitrate, sodium chloride, and sodium sulphate react with calcium carbonate in the soil with the formation of sodium carbonate ("black alkali").

9) Sodium carbonate, formed by the above reaction, decomposes the organic matter of the soil.

10) Calcium carbonate has a slightly destructive action upon the organic matter of the soil.

11) Sodium carbonate is much more destructive to organic matter than sodium bicarbonate.

12) The alkali crusts that accumulate upon the soil in some irrigated regions are due in part to the action of sodium salts upon calcium carbonate with the formation of sodium carbonate.

13) Barren, or "slick", spots are often due to the action of sodium nitrate, sodium chloride, or sodium sulphate upon calcium carbonate with the formation of sodium carbonate.

14) Sodium chloride and sodium sulphate have a protective action upon organic matter in the presence of sodium carbonate.

15) A calcareous hardpan often produces black alkali.

842 - **Influence of Carbonates of Magnesium and Calcium on Bacteria of Certain Wisconsin Soils.** — FULMER, H. L. (Wisconsin Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. XII, No. 8, pp. 463-504, 19 Tables, 11 Figs., Bibliography of 64 Publications. Washington, February 25, 1918.

It is a well-established fact that the majority of the changes of soil constituents are brought about by microorganisms and are influenced by the number and kinds of bacteria. The beneficial effect of lime, calcium carbonate, and magnesium carbonate on the growth of higher plants is generally preceded by an increase in the number of bacteria. An increase in the number of soil microorganisms is usually reflected in a more rapid decomposition of organic matter and a greater liberation of the inorganic soil constituents, chiefly potassium and phosphorus.

Although many important data have been obtained in relation to the effect of liming on the bacteria in soil, there still remain problems which deserve careful investigation — for example, the amount and kind of lime and calcium and magnesium carbonates that can be applied most economically and yet give the best results. The investigations described were undertaken with the hope of throwing some light upon the problem of soil bacteria and their response to applications of magnesium carbonate, calcium carbonate and limestone. The effect of these substance on pure cul-

tures of bacteria and on the ordinary soil flora was observed in: — a) acid Colby silt loam soil; b) acid Plainfield sand; c) neutral Miami silt loam.

From a brief review of certain of the more important papers relating to the effect of lime ( $\text{CaO}$ ), calcium carbonate and magnesium carbonate on soil microorganisms it appears that the addition of calcium and magnesium, either in the form of oxide or carbonate, to soil, and especially to acid soil, brings about conditions favourable to the growth of certain groups of microorganisms. There are many factors which have been given little or no consideration — for instance, what relationship exists between the total number of bacteria in soil and the quantity of soil acid neutralized? With few exceptions, little attention has been directed toward the relative effect of calcium and magnesium carbonates on the soil flora. There exists a diversity of opinion with regard to the relation of bacteria to these two compounds. This lack of harmony may be due to the difference in the soil types which have been studied. Again, it seems that no one has tried to measure the effect of calcium and magnesium carbonates on pure cultures of bacteria in sterilized acid soil. To obtain information with regard to these points, a series of experiments was planned.

Each of the 3 experimental soils was passed through a 4 mm. sieve and mixed. The calcium carbonate requirement of the 2 acid soils was determined: — to correct the active acidity of 100 gm. of soil on the dry basis 1.05 gm. were required for the Colby silt loam and 0.21 gm. for the Plainfield sand. Three bases were used to neutralize the acidity in these soils: — 1) pure precipitated calcium carbonate; 2) pure precipitated magnesium carbonate; 3) commercial ground limestone with 53 per cent of calcium and 43 per cent of magnesium oxide. They were added in amounts sufficient to neutralize  $\frac{1}{4}$ ,  $\frac{1}{2}$  and the total active acidity. In certain experiments varying amounts of monocalcium phosphate were added to the soil, alone and in various mixtures with calcium carbonate. The mixtures of soil and bases were poured into earthenware jars and the moisture content raised to one-half saturation with distilled water. At definite intervals samples were drawn and plate counts made. At regular intervals the effect of these compounds on the total number of bacteria in the soil, on ammonification and on nitrification was studied. The results were as follows: —

The number of bacteria in acid Colby silt loam and acid Plainfield sand is increased by the application of calcium carbonate, magnesium carbonate, or limestone. Magnesium carbonate increases the number to a much greater extent than does either calcium carbonate or limestone. Monocalcium phosphate and dibasic magnesium phosphate slightly increase the total number of bacteria in neutral soil.

Nitrification is benefited by limestone, calcium carbonate, and magnesium carbonate treatment. Magnesium carbonate in soil to which no nitrogenous substance was added favours nitrate accumulation more than does either calcium carbonate or limestone. The phosphates increase the accumulation of nitrate nitrogen to a very small extent. When gelatin was applied to the soil, magnesium carbonate did not benefit nitrification any more than calcium carbonate or limestone.

Ammonification in Colby soil is benefited by all three forms of the carbonates, while in Plainfield sand a decrease in ammonia is shown. Monocalcium phosphate increases ammonification in both soils.

Pure cultures of *Bacillus tumescens* and *B. subtilis* ammonify blood meal better when sterile Colby soil is treated with any one of the three forms of carbonates. A culture of *B. azotobacter* in the two soils treated with the carbonates and mannite fails to show an increase in total nitrogen in the sand and only a slight gain in the Colby soil. Pure cultures of *B. radicicola* of both alfalfa and lupine strains, and *B. azotobacter* are greatly benefited when inoculated into sterile Colby soil previously treated with magnesium or calcium carbonate. Limestone barely increases the number of *B. azotobacter* in Colby soil. In neutral and acid soils treated with magnesium carbonate until they were strongly alkaline, *B. azotobacter* greatly increases in number in comparison with that of the untreated.

From the data considered as a whole, magnesium carbonate is superior to calcium carbonate or limestone in stimulating the reproduction of bacteria in Colby silt loam and Plainfield soils. In general, the smaller applications of either compound give better results than do the heavier applications. Magnesium carbonate appears to play an important part in the development of soil bacteria, much more so than does calcium carbonate. Magnesium phosphate, when applied to neutral soil, caused an increase in the number of bacteria. In the neutral soil magnesium phosphate proved superior to calcium phosphate in stimulating the bacteria; in acid soil neither compound appeared to benefit the soil flora.

843 - The Gases of Swamp Rice Soils. — Part III. A Hydrogen-Oxidising Bacterium from these Soils. — Part IV. The Source of the Gaseous Soil Nitrogen. — HARRISON, W. H. and SUBRAMANIA AYER, P. A., in *Memoirs of the Department of Agriculture in India*, Chemical Series, Vol. IV, No. 4, pp. 135-148, 1 Fig., 9 Tables; Vol. V, No. 1, pp. 1-31, Figs. and Diagrams. Calcutta, 1916.

In a preceding memoir (1) published by the authors dealing with the relationship between the gases of swamp rice soils and the organized film present on the surface of the soil, it was shown that the latter possessed the power of oxidising hydrogen. This oxidation was further demonstrated to be due to the activities of certain bacteria and crude cultures were obtained and their action studied. A pure culture of a specific bacterium has been obtained and it is with this organism that the third part deals. It contains a description of the hydrogen-oxidising organism, together with the effect of different concentrations of various nitrogen containing chemicals upon its power to oxidise hydrogen. No name is assigned to the organism, but it is said to be different from previously described hydrogen-oxidising bacteria.

Part IV deals with explanations for the variation in quantity and composition of gases evolved from cropped and uncropped soils during different stages of growth. The authors demonstrate that a very considerable proportion of the gaseous nitrogen normally found in swamp paddy

(1) See R., 1914, No. 119; 1915, No. 490. (Ed.).

soils is produced through the decomposition of organic matter. The nitrogen thus liberated is derived from two distinct sources: *a*) from the decomposable organic matter of the soil or of the green manure used, and *b*) from a certain proportion of the roots of the crop which die and subsequently decompose. The production of gaseous nitrogen from soil organic matter and green manure persists throughout the growing season, but is most prominent during the earlier period, whereas that derived from root decomposition is most prominent during the later stages of growth and persists after harvest time. The crop does not interfere with, or materially alter, the normal course of the fermentation of the soil organic matter and green manure. The difference in the rate of evolution of gases from cropped and uncropped soil is due to a matted root condition existing near the surface which in conjunction with the fine soil particles mechanically hinders the escape of gases on cropped soil. After appreciable quantities of gas accumulated and the roots began to decay, which occurred about the time rice was jointing, the accumulated gas began to escape in large quantities, whereas on uncropped soil the escape was very uniform throughout the growing period. The difference in composition was found to be due to the influence of the same factors. The methane and hydrogen retained near the organised surface film was oxidised thus giving to the gas finally escaping from cropped soil a much higher per cent of nitrogen and lower per cent of methane and hydrogen.

IMPROVEMENT,  
DRAINAGE  
AND  
IRRIGATION

844 - Artificial Glaciers for the Irrigation of Mountain Pastures, in India. —

I. DAINELLI, G., in the *Rivista del Club Alpino Italiano*, Vol. XXXVII, Nos 1, 2, 3, p. 30. Turin, January, February, March, 1918. — II. LUIGGI, L., in the *Annali d'Ingegneria e d'Architettura*, Year XXXIII, No. 9, pp. 139-140. Rome, May 1, 1918.

I. — Sig. G. DAINELLI, who explored the Caracoram hills in 1913-1914, records that the inhabitants of Cunis built an artificial glacier so that they could extend their fields and have sufficient water to irrigate them. The method was to choose a spot as high and elevated as possible and well protected from the sun; on a bed of straw they next placed a layer of gourds filled with water following with alternate layers of gourds and straw. If possible the straw is mixed with briars and wood charcoal. At the beginning of winter stones are laid on the upper layer, then a number of wide-necked earthenware pots full of water, which naturally freezes. After 2 or 3 months, when the great winter falls of snow have ended, the snow is covered, first with straw, then with earth, thus covering all the preceding material. The inhabitants repeat the same procedure the second and third years, extending the area each time. If, for example, 200 gourds are placed the first year, the second year 400 are placed, and so on. At the end of the fourth year the glacier is ready, and grows spontaneously each year, while each summer it furnishes the water required for the fields. The author has heard of artificial glaciers that have been working for over 40 years. The preservation of the initial glacier, i. e., that produced artificially by the 4 year's work, is easily explained as the materials that protect the successive masses of winter snow both above and below are bad conductors of heat. It is more difficult to explain how the glacier continues to work

afterwards without the addition of fresh insulating material. Very probably the fresh snow fallen on the system, while free from the warming action of the soil, melts in the summer on account of the air temperature, but freezes again on coming in contact with the underlying artificial layers at a very low temperature; the snow thus feeds the lower layers and compensates for the losses due to melting in summer. It is these losses that are used for irrigating the fields lying at a lower level. The fact recorded by the author was briefly described in 1867 by Mr. JOHNSON (1) in the description of his exploration journey across the Himalayan mountains.

II. — Prof. LUIGI LUIGGI, pointing out the construction of these artificial glaciers, is of the opinion that their construction as artificial lakes in the mountains would help to make the water supply more regular, and would lead to a more complete and better utilisation of the natural supplies of water of Italy.

845 — **Leakages from Irrigation Canals and Reservoirs in the U. S. A.** — DAVIS, A (Director and Chief Engineer, U. S. Reclamation Service), in the *Engineering News-Record*, Vol. LXXX, No 14, pp. 663-665. New-York, April 4, 1918.

In numerous cases in the United States the admission of water into irrigation canals and reservoirs has disclosed the existence of subterranean cavities not previously observed. The author quotes three examples of canal troubles (those of Flathead; Grand Valley Lands, Colorado; and Spanish Fork Canal, Utah) and six of difficulties with reservoirs (Jerome and Deer Flat reservoirs, Idaho; Lake McMillan and Hondo reservoir, New Mexico; Walnut Cañon reservoir, Arizona; and Tumalo reservoir, Oregon). For each of these he describes the difficulties and the remedies applied, discussing the successes or failures.

Some of the difficulties encountered, especially in canal building, are of such nature that no method of foreseeing them appears to be possible.

In the case of canals, however, these difficulties are usually easily remedied, either by puddling the cavities that appear, as at Flathead and Grand Valley, or by relocation, as at Caislsbad. Remedies in the case of reservoirs are not so easy. Puddling is useless if the subterranean conditions are such that the seepage of water can get away and thus let the seepage continue. No reservoir in earth is of much value if it continuously seeps at the rate that water can pass vertically through puddled earth. The problem then is to avoid regions where subterranean conditions are such that the water can escape. A few rules of caution may be of value:—

- 1) Avoid reservoirs adjacent to gypsum deposits and to limestone deposits which show evidence of caves.
- 2) Examine critically reservoirs in volcanic rock, as a few have failed in such locations. Coarse-grained sandstone seems to be an object of suspicion and should be carefully examined.
- 3) Natural depressions are treacherous and should be examined with

care, and if they are near deep cañons or underlain with coarse material where water might readily escape, no superficial tightness will avail to make them effective.

MANURES  
AND MANURING

846 - **New Deposits of Guano in the Philippines.** — In the *Philippine Agricultural Review*, Vol. X, No. 3, p. 301. Manila, 1917.

Owing to the inability to secure fertilizer material by even those planters who have learned the value of fertilizer for the growing of sugar cane, extensive search has been made for deposits of bat guano in the various parts of the Philippine Archipelago. In several instances, particularly in the southern provinces of the Island of Luzon, these searches have resulted in the location of extensive guano deposits. This material, however, has invariably contained a low percentage of nitrogen which condition was due no doubt to the extremely soluble substance containing that element having leached away during the rainy seasons. Analysis of this material showed the following average result: — Nitrogen 1, phosphoric anhydride 15, and potash 1 per cent.

847 - **Fertilising Value of Ammonium Nitrate.** — SCHOESING, TH. JR., in *Le Progrès Agricole et Viticole*, Year 35, No. 22, pp. 517-519. Montpellier, June, 1918.

Ammonium nitrate, hitherto little known by farmers because it has never been available in large quantities, will be able to be supplied liberally to them when no longer used for the purposes for which it is required under present circumstances. For this reason the author made tests of its fertilising value by pot experiments. Maize seeds of equal weight were sown in each pot, which contained about 17 lb. of soil with an initial moisture percentage of 12.0, and 15 gm. bipotassium phosphate as basic fertiliser. Except in the two control pots the nitrogenous fertiliser added to each contained 3.37 gm. of nitrogen; four pots contained ammonium sulphate and four ammonium nitrate. The plants were cut down to the ground at the beginning of earing and the following average weights per pot of the air-dried crop were obtained:—Control pots, 87.6 gm.; pots with ammonium sulphate, 106.8 gm.; pots with ammonium nitrate, 108.4 gm. Ammonium nitrate thus gave an increase in the dried crop almost equal to that of ammonium sulphate.

The soils in the pots was kept very moist. It was found that, although nitric nitrogen fertilisers give slightly heavier crops than ammoniacal nitrogen fertilisers, there is little difference in yield in very wet years.

It is usually admitted that the nitrogen of ammoniacal fertilisers must be nitrified before it can be used by plants. Several workers (MÜNTZ, MAZÉ, SCHLOESING JR.) have, however, shown that absorption occurs in the ammoniacal form as well as in the nitric one. The only difference is in the rate of absorption, a difference which might be explained by an influence of the absorbing properties of the soil on the ammonia. Till it is nitrified ammonia will also be less mobile. For this reason an excess of water, while favouring the equilibrium movements which cause the dissolution of new quantities retained in the soil in proportion as absorption progresses, exercises a very good influence in this case.

848 - **The Potassium Problem (1) and the Utilisation of Olive Oil Residue, in Italy.**—  
L'ABATE, G., *Il problema della potassa e l'utilizzazione delle "morchie"*, pp. 8. Bari,  
Laterza & Figli, 1918.

The potassium question is one of the most serious problems for all agricultural countries, especially Italy, which consumes much less than other states using it, though they may be less agricultural. Among the various types of fertilisers, some of which, the superphosphates, have developed greatly, potassium is not yet very largely used by Italian farmers. As sources of potassium in Italy there are the mother-lyes of the salt-springs; the leucites of Latium, the ashes of wood and other vegetable products (almond shells, exhausted olive cake). Taking the whole as a sole source of potassium salts for agriculture, there only remains at present, according to the author, distillery residue, and, as a less limited and hitherto untested source, the residue ("morchie") from the manufacture of olive oil.

Samples of olive oil residue from the province of Bari showed the following composition, in grams per litre:— water, 884.891; mineral, 30.65-35.48; organic matter, 79.85-80.60; fat, 10.50; nitrogen, 10. These results led to a comparison between the residue from olive oil with that from distilleries and molasses, with a view to using it, like these products, for extracting potassium salt, of the following composition:— water-soluble matter, 80.31 %; matter insoluble in water (carbon, silica, lime, magnesia and 8 % phosphoric acid combined with calcium, iron, and aluminium), 19.09 %; potassium carbonate, 55.15 %; sodium carbonate 2.57 %; potassium chloride, 21.89 %; traces of potassium sulphate; water, and other undetermined substances, 20.39 %. When refined this product gives on an average:— potassium carbonate, 68.88 %; sodium carbonate, 3.2 % and potassium chloride 27.27 %, thus resembling, in its potassium content, similar products extracted from molasses and used as fertilisers.

The olive oil residues of Apulia give more than 30 gm. of potassium salts per litre, equivalent to 3 kg. (6.6 lb.) per hectolitre (22 gals.), with 48 % of potassium as carbonate (50-60 %) and chloride (15-20 %). The yield of olive oil residue, although depending largely on the weather, represents almost three times the amount of oil produced, or 30 to 40 % of the weight of the olives. If the oil production of Italy is placed at 44 million gallons or 35 200 000 gallons as in the period 1909-1913, the amount of residue would be about 16 500 000 bushels. If all this were used, about 294 000 cwt. of crude potassium salt containing 141 320 cwt. of potassium would be obtained. If the nitrogen as well as the potassium is to be utilised it may be obtained as ammonium sulphate and potassium cyanide (e. g. by EFFRONT'S method).

In conclusion, the treatment of the 16 500 000 bushels of olive oil residue produced by Italy for the extraction of potash in factories in the districts with the largest production resolves itself essentially into a problem of transport, as for all poor and bulky matter.

(1) See R. April, 1918, No. 394. (Ed.)

849 - **Plant Succession in the South African Thorn Veld.** — BEWS, J. W., in *The South African Journal of Science*, Vol. XIV, No. 4, pp. 153-172 + 10 Figs. Cape Town, November, 1917.

The tree veld is perhaps the most extensive type of vegetation in the Continent of Africa. The species composing it in the various districts depend chiefly on climatic differences, but also on the soil. Practically all the dry valleys in the east of S. Africa are covered with tree veld in which species of acacia predominate. The Protea Veld is more mountainous and extends throughout Rhodesia. There are also other types of veld in this region, such as the Baobab (*Adansonia digitata*) Veld. The Transvaal Bush Veld is a combretaceous-leguminous type with *Terminalia*, *Combretum*, *Burkea*, etc. The mopane (*Copaijera Mopane*) is predominant in a large part of the Tree Veld of Angola and South Central Africa, whereas the Baobab Veld extends up to the Congo. Nearly all South Central Africa is Tree Veld, broken only by forests on the mountain slopes in the east. In the tropics, the great Congo forest and the dense forests which extend throughout the Cameroons and West Africa to Liberia cover a very extensive area, but north of this, and south of the Sahara there is Tree Veld very similar to that of S. Africa. In many parts of the tropics and sub-tropics various palms, such as *Hyphaene ventricosa*, *H. thebaica* or dum palm, *Borassus flabellifer*, etc., predominate. In view of the extent and importance of this type of vegetation in Africa, the study of the natural succession of plants in the veld is of the utmost value.

The species of trees, bushes and lianes which cover the Thorn Veld establish themselves in ravines and on the banks of water courses where the first seeds are carried by birds and other animals. These areas serve as bases for re-stocking the intermediate spaces. The author illustrates this vegetation by that observed at Bisley, where the most common trees, in order of their abundance, are: —

*Acacia arabica* var. *Kraussiana*, *Celastrus buxifolius*, *Hippobromus alata*, *Ehretia hottentotica*, *Jasminum multipartitum*, J. sp. (Gerardi?), *Elaeodendron aethiopicum*, *Zizyphus mucronata*, *Grewia caffra*, *Acacia caffra*, *A. horrida*, *Randia rudis*, *Xanthoxylon capense*, *Combretum Kraussii*, *C. salicifolia*, *Nuxia oppositifolia*, *Royena pallens*, *Pavetta lanceolata*, *P.* sp., (obovata?), *Cussonia spicata*, *Helinus ovata*, *Gymnosporia (Celastrus)* sp., *Brachylaena discolor*, *Dovyalis (Aberia) tristis*, *Azima tetracantha*, *Euclea undulata*, *E. lanceolata*, *Calpurnia* sp., *Rhus* spp. Climbing on these plants are various lianes: — *Dalbergia obovata*, *Vitis cuneifolia*, *V. cirrhosa*, *Clematis brachiata*, *Asparagus* sp., *Dalechampia capensis*, etc. The undergrowth is rich in herbaceous forms: — *Sansevieria thyrsiflora*, *Lippia asperifolia*, *Barleria obtusa*, *Scilla* sp., *Rubus rigidus*, *Vernonia corymbosa*, *Melasma* sp., *Kalanchoe rotundifolia*, *Cyathula* sp. and, near the riverbed, *Selaria imberbis*, *Pennisetum unisetum*, *Cyperus* spp., etc.

Acacias, especially *Acacia horrida* and *A. arabica* var. *Kraussiana* are the chief pioneer species. The author shows that, by their structure, these plants are adapted to unshaded localities where there is no protection against grass fires. These trees prepare the way for other species which follow and establish themselves under their shade, where they find

the soil well-prepared by the activity of earth-worms, termites and ants. There are various stages of vegetation and subsequent species may kill the pioneer. As a rule, however, the thorn-trees predominate in the Thorn Scrub, which at present forms the final stage over most of the areas.

The author gives a list of over 230 species of trees, bushes and lianes of the Thorn Veld, showing their frequency and the undergrowth. He distinguishes three important sub-formations: the Thorn Veld near the coast, that of rocky land, and that of the stream banks; the last two may be considered as distinct formations.

The question of seed distribution is discussed. Wind distribution is of relatively small importance. The chief agents of dispersal are birds, but for species with capsular fruit and small seeds, ants, which abound in the Thorn Veld, are also important.

850 - **The Glandular Pubescence of Several Species of *Medicago*: Observations made in California, U. S. A.** — MCKEE, R. (Office of Forage-Crop Investigations, Bureau of Plant Industry, U. S. Dept. of Agric.), in the *Journal of the American Society of Agronomy*, Vol. X, No. 4, pp. 139-162. Washington, March 20, 1918.

Many varieties of *Medicago* have been classified as sub-species on the basis of the presence or absence of the glandular pubescence, but the author's data show that, in certain varieties, this pubescence varies markedly with the environmental conditions. It can, therefore, not be adopted as a constant character in the determination of sub-species.

Field observations made during many years on several plants of *M. orbicularis* and its sub-species showed that, at the beginning of the season, none had pods with glandular pubescence, whereas later, after several hot, dry days, all the plants and all the pods, young and old, were strongly pubescent.

Some forms of *M. lupulina* are smooth and others hairy all their lifetime; most of them show the same variation, due to environment, as the preceding species (hot and dry weather, dry soil).

*M. falcata*, introduced into the United States, has a marked pubescence in one of its forms only — *M. falcata viscosa*; *M. sativa* is glabrous. Nevertheless, some plants of both these species show glandular pubescence. For this reason the author regards them as hybrids, although they show little variation in their other characters.

*M. hispida*, *M. Echinus*, *M. obscura helix*, *M. intertexta*, *M. tuberculata aculeata*, have a microscopical glandular pubescence on the pods at the beginning of the season, but lose it towards the end of the season.

851 - **Behaviour of Sweet Potatoes in the Ground.** — HASSELBRING, H. (Bureau of Plant Industry, U. S. Dept. of Agric.), in the *Journal of Agricultural Research*, Vol. XII, No. 1, pp. 9-17 + 1 Diagram. Washington, D. C., January 7, 1918.

In the course of previous investigations on the behaviour of sweet potatoes in storage, it was observed that the percentage of starch was always highest and the percentage of sugar lowest in freshly dug potatoes. The constancy of the condition seemed to justify the conclusion that in the growing sweet potato the reserve materials exist essentially in the form

of starch, and that the appearance of sugar in considerable quantities is a phenomenon occurring only in storage or after the destruction of the leaves.

In order to determine whether these quantitative relations between the starch content and the sugar content of the sweet potato remain constant throughout the latter part of the growing season, and to what extent they are changed by the death of the vines, the carbohydrate metabolism in Big Stem sweet potatoes was followed from the time the roots were large enough to furnish the requisite samples (end of August to beginning of September) until they were seriously damaged by frost. From the numerous analytical data given in three tables the following deductions are drawn for September 18 and 25, October 2, 9, 17, 23, and 30, November 6, 13, 20, and 27, respectively:—moisture (per cent):—73.92, 73.24, 73.87, 75.47, 76.30, 77.43, 77.78, 75.99, 78.14, 77.78, 78.93; starch (this percentage as well as the following ones are on a dry matter basis):—71.39, 72.39, 70.90, 69.28, 69.44, 68.51, 64.65, 63.58, 55.27, 50.73, 46.20; saccharose:—7.93, 7.52, 8.81, 8.58, 8.31, 8.86, 11.24, 13.75, 18.40, 23.11, 26.06; reducing sugar as glucose:—1.44, 1.22, 1.72, 2.23, 2.81, 2.80, 3.16, 2.69, 3.29, 3.20, 3.85; total carbohydrates:—80.76, 81.13, 81.43, 80.09, 80.57, 80.18, 79.05, 80.02, 79.96, 77.03, 76.11.

Thus the *moisture content* of the roots was almost uniform from September 18 to October 2, after which it gradually increased till the end of the season. The percentage of *starch* in the dry matter of the roots decreased slightly from September 18 to October 23, and then with increasing rapidity till the end of the season. The rapid disappearance of the starch follows, with a little delay, on the death of the leaves. The *saccharose* content remains practically constant between 7.52 to 8.86 till the rapid decrease of the starch, when it begins to increase correspondingly till it finally represents 26.06 % of the dry matter of the roots. As a rule the changes in cane sugar begin somewhat later than those of the starch. The *reducing sugar* first remains constant, then rises gradually, till the final percentage is slightly more than double the initial one. The increase in reducing sugar somewhat precedes that in cane sugar; this increase is less in sweet potatoes left in the ground than in those in store. The *total carbohydrates* undergo little change till towards the end of autumn, when the roots begin to show injury from frost, which causes evident loss of carbohydrates.

**CONCLUSIONS.**—The changes occurring in the roots of sweet potatoes left in the ground during the end of the growing period proceed regularly. When, on the death of the leaves, transpiration and the flow of material into the epigeal part ceases, the accumulation of water in the roots and the transformation of starch into reducing sugar and from that into saccharose begin. In stored and cured sweet potatoes there is considerable loss of carbohydrates due to respiration, whereas if the roots are left in the ground such loss is insignificant till the roots have been injured by frost. The accumulation of water in roots left in the ground is detrimental to their keeping qualities. It is precisely to reduce this moisture content

that the sweet potatoes are cured, thus giving a product which is generally acknowledged to keep better. It is of the utmost importance that sweet potatoes be not left in the ground after the leaves have been killed by frost.

852 - Comparison of the Hourly Evaporation Rate of Atmometers and Free Water Surfaces with the Transpiration Rate of *Medicago sativa* (1).—BRIGGS, LYMAN J. (Biophysicist in Charge of Biological Investigations) and SHANTZ, H. L. (Physiologist, Alkali and Drought Resistant Plant Investigations, Bureau of Plant Industry, U.S. Dept. of Agric.), in *Journal of Agricultural Research*, Vol. IX, No. 9 pp. 277-292, 4 Fig. + 3 Plates, Bibliography of 11 Publications. Washington, D. C., May 28, 1917.

The rate of evaporation from a free water surface or from a moist porous surface is usually considered the single-valued expression of the intensity of the weather factors influencing transpiration. Such a relationship is, however, subject to the uncertainty arising from the marked differences in the energy-absorbing and energy-dissipating properties of the transpiring and evaporating surfaces. It is evident that the transpiring and evaporating surfaces must be in agreement in this respect if the departure of transpiration from evaporation during the day is to be taken as evidence of a change in the transpiration coefficient, resulting from stomatal control or other reversible changes within the plant body.

Fluctuations in transpiration from day to day appear to be reflected with approximately the same degree of fidelity by a number of widely different forms of evaporating surfaces, provided precautions are taken to maintain the uniformity of these surfaces throughout the period of observation. When the hourly transpiration rate is under consideration, however, the individuality of the evaporating surface to which the transpiration is referred cannot be ignored. It is this phase of the question that forms the subject of the present paper, which deals with a comparison of the hourly transpiration rate of alfalfa with the hourly evaporation rates from various types of porous cup atmometers, a filter-paper evaporimeter, a blackened, shallow tank, and a deep tank.

The comparison between the transpiration rate and the evaporation rate was made by superimposing the hourly transpiration graph on each of the hourly evaporation graphs, choosing the scale of ordinates of the transpiration graph so that the total area under the transpiration graph was equal to the total area under the evaporation graph. The average hourly departure of each of the evaporation graphs from the superimposed transpiration graph expressed in percentage of the mean transpiration for the day was then determined. For the shallow tank the mean hourly departure for the 24 hour period was 17 per cent; for the filter-paper evaporimeter 31 per cent; for the brown cylinder, white sphere, and Bellani plate about 40 per cent; for the white cylinder about 50 per cent; and for the deep tank about 90 per cent of the mean hourly transpiration. The corresponding departures for the daylight hours from 6 a. m. to 6 p. m. were as follows: — For the shallow tank, 12 per cent.; filter-paper evaporimeter, 22 per cent.; brown cylinder,

(1) See also R. February 1917, No. 134. (Ed.).

white sphere, and Bellani plate atmometers, about 30 per cent ; white cylinder atmometer, 38 per cent ; and the deep tank, 93 per cent. Since the hourly evaporation graphs of the various evaporation systems employed differ widely in form, it does not seem justifiable to attribute the discrepancy between the observed hourly transpiration and that calculated from the evaporation rate of any particular system to a change in the transpiration coefficient of the plant during the day, unless it can be shown that under less extreme conditions the transpiration rate is in accord with the evaporation rate. The plant may not be responding freely to its environment, but a departure in its relative transpiration rate from the evaporation rate of an arbitrarily chosen physical system does not necessarily establish this fact. A close correspondence does not appear to exist between the hourly transpiration rate of normal alfalfa plants and the hourly evaporation rate of any of the systems employed in this investigation. The best agreement in this instance was obtained with the shallow, blackened evaporation tank.

The departure of the hourly evaporation rate of the porous-cup atmometer from the hourly transpiration rate of alfalfa is due largely : — 1) to the marked increase in the evaporation over transpiration during the night hours ; 2) to the marked response of the atmometers to changes in wind velocity, which were not accompanied by corresponding changes in the transpiration rate ; and 3) to the lack of a proportionate response on the part of the atmometers to changes in solar radiation.

It should be emphasised in this connection that the failure of an evaporating surface to show a high correlation with the hourly transpiration rate does not necessarily imply a correspondingly low correction on the daily basis. This is strikingly illustrated by the hourly evaporation rate from the deep tank, which, in these experiments, shows practically no correlation with the hourly transpiration rate, but which on a daily basis was found in 1914 to be correlated with the daily transpiration rate to the extent of  $0.63 \pm 0.01$ .

853 - **The Influence of Certain Organic Substances on Plant Growth.** — CIAMICIAN, B. and RAVENNA, C., in the *Atti della Reale Accademia dei Lincei*, Series 5, *Rendiconti*, Vol. XXVI, First Half-Year, Part 1, pp. 3-7. Rome, January, 1917 ; Vol. XXVII, Part 7, pp. 38-42. January, 1918.

The authors describe experiments on the influence of certain organic substances on plant growth, especially with kidney-beans germinated and grown on absorbent cotton.

The substances tested were — mandelic nitrile; benzylic and salicylic alcohols as potassium salts ; vanillin ; eugenol ; tannin ; acid amides, alanin and asparagine ; uric acid and xantilin as potassium salts and compared with caffeine ; pyridine and piperidine compared with nicotine ; quinine, strychnine and morphine.

In the germination tests the seeds were placed on cotton in galvanised-iron germinating trays the bottom of which was covered with filter paper, and moistened with a solution at 1 per 1 000 strength of each of the above mentioned substances. Mandelic nitrile, eugenol, and mustard oil completely prevented the kidney-beans from germinating ; the other substances

were, however, less toxic for germinating seeds, and, on the contrary, even alanin and strychnine, and, to a less degree, cocaine, atropine, quinine and morphine, caused a germination that was premature in comparison with that of the seeds moistened with water. Vanilline, tannin and asparagine neither retarded nor hastened germination. Mandelic nitrile and strychnine had an antithetic action, considering that, when the seed was moistened simultaneously with both the solutions, some germinated, viz. 3 % for the kidney-bean and 26 % for the lupin.

When the young plants had grown sufficiently, they were given the various solutions at 1 per 1000 strength. It was found that the plants in the galvanised-iron germinating trays suffered less from the toxic substances than those in glass trays and that zinc sulphate hinders the toxic action of the aromatic compounds.

Except mandelic nitrile, the other aromatic compounds used had no specific action on the kidney-bean plants so as to modify their external morphology. On the contrary, however, kidney-bean plants fed exclusively on mandelic nitrile alone or with that substance plus a nutritive solution free from nitrogenous compounds, were shorter and more squat, with the roots less developed, rounder leaves and of a deeper green colour, in comparison with control plants in a nutritive solution. Nevertheless these differences became attenuated as growth continued, disappearing at maturity. The eugenol was very noxious; the saligenine, benzylic alcohol, sodium benzoate and salicylate at first caused some harm, which later disappeared; vanilline and tannin had no effect; alanin and asparagine had a favourable action.

Whilst pyridine and piperidine only result in a darker colour of the leaves, all the vegetable alkaloids properly so-called, which were tried by the authors, had a toxic action. Thus, while caffein (trimethylxanthine) kills kidney-bean plants in 2 days, xanthine and uric acid favour their growth; thus proving that methylic radicals can also cause a strong physiological action in plants, which the fundamental compound entirely lacks. These facts are in contradiction with the opinion of those who consider the alkaloids are excretory products, and the methylic radicals, so common in plant products, as a means of protection for weakening the action of too active radicals such as oxyhydrides or imines. Of all the alkalis used in this research, the least toxic was morphine; quinine was more toxic and strychnine still more so.

According to the authors, the known facts point to the hypothesis that alkaloids have, in the plant organism, a function as yet unknown and undetermined, which might be that of plant hormones. The various species of plants, in order to take advantage of the inutilisable waste products as such, might change their composition so as to make them suited to the specific functions which they should fulfil, just as animals, for example, produce the adrenalin of the supra-renal capsules by means of tyrosine.

As regards the faculty of plants to free themselves of useless or harmful substances, the authors record that on inoculating young maize plants

growing in the open soil with the tartrates of nicotine and pyridine, and by keeping the upper part of the plant closed in a flask whose walls were damped with dilute sulphuric acid, they were able to show that the two alkaloïds left the leaves by transpiration. Admitting that plants are not unprovided with elimination systems; if very active substances are found to be present in them, that signifies that the plant has produced the substance with some definite purpose.

PLANT  
BREEDING

854 - **Selected Wheat in India.** — MACKENNA, J., in *Report on the Progress of Agriculture in India for 1916-1917*, pp. 17-20. Calcutta, 1918.

The improvement of wheat by selection and hybridisation has been steadily studied and has already given excellent results. In the various provinces of India the old native forms are gradually being replaced by more productive new varieties, distinguished by the superior quality of their grain.

*Pusa No. 12*, early, resistant to rust and lodging is very popular among farmers and widely grown in the United Provinces, Punjab (Hoshiarpur, Jullundur, Gurdaspur, and Sialkot districts), as well as in South Bihar.

*Pusa No. 4* does well in Bundelkhand, Central India, and especially in the North-West Frontier Province, where it is much superior to the native types in yield and resistance to rust and lodging.

*Pusa No. 12* and *Pusa No. 101* are successfully grown in the Central Provinces, Southern Circle. In the Northern Circle *No. 13* is preferred in the Nerbudda Valley, *No. 88* in Jubbulpore, and *No. 90* where irrigation is used. Hybridisation work (EVANS) is being continued between the local varieties and an Australian variety with the aim of obtaining types yet more resistant to rust.

At the Pusa Experiment Station, where most of the new wheats come from, Mr. HOWARD is continuing his selection and hybridisation work. At present four series of crosses are being studied, two of which, derived from *Pusa No. 6*, have already given promising results. The work aims at combining in one type to the best advantage, good root development, resistance to rust and lodging, good quality grain, and a high yield.

The selected wheat *Punjab 11* is being grown more and more in the irrigated districts of the Punjab. Owing to the good quality of its grain and its high yield, this wheat assures the farmer a good profit. *Pusa No. 12* is grown in this district as well as *Punjab 11*.

In the United Provinces Mr. LEAKE has evolved a new variety, *Cawnpore No. 13*, with very strong straw and grain of good milling qualities.

855 - **Selection of Native Oats and Barley in Norway.** — CHRISTIE, W., in *Aarsberetning angaaende de offentlige foranstaltninger til landbruks fremme i aaret 1916*, pp. 481-525 + 2 Tables. Christiania, 1917.

The varieties of cereals selected in England, Denmark, and Germany cannot be cultivated in Norway because of its different weather and agrogeological conditions; they have been repeatedly tested but have always given negative results on account of their lateness. Good results have, however, been obtained with some of the best types from Svalöf (Sweden), de-

rived from the hybridisation of selected varieties with local ones characterised by their earliness and resistance to cold. Thus, for example, in 200 cultural tests in various districts white Guldregn oats (1) always gave excellent yields of grain and straw. All the Svalöf varieties are, however, very exacting as regards soil, and when sown in the shallow, sand or peat soils so common in Norway they tiller little and yield less than the native Romerike, Trönde, Hedemarken and Vestland varieties. It is, therefore, necessary to select the native types so as to improve them and fix new strains with well marked, stable characters, capable of being crossed with the productive, ultra-selected foreign varieties.

Norwegian oats and barleys include numerous forms differing in yield, strength of straw, earliness, etc. Selection of the best elements is sure to lead to the formation of groups with valuable characters, better developed and superior on the average to the native varieties both in yield and earliness. The paper under review gives the results of pure-line selection of Norwegian oats and barley.

OATS. — In 1905, 127 Hedemarken plants were selected at Vindju, in Ringsake, and, in 1906, 170 plants of the same variety in different parts of the province of Furnes. It should be noted that among the native oats there frequently occur forms of the Propsteier type which was previously largely cultivated in this district. During the years following the first selection a comparative study of the various strains was made and the least promising ones eliminated, thus gradually reducing the number of plants in 1912 to 4 only *i. e.*, 2 from the 1905 selection and 2 from the 1906 selection. The names of the new varieties and the numbers in which they are inscribed in the genealogical register are: — Möistad Grenader, 34, Möistad Odin 0200, Möistad Perle 160, Möistad Thor 0207. During five years they have been subjected to comparative cultural tests with the native Hedemarken variety and the Swedish oats Guldregn and Mesdag. The grain yields (cwt. per acre) are given in Table I.

TABLE I.

	Möistad Grenader 34	Möistad Perle 160	Möistad Odin 0 200	Möistad Thor 0 207	Hede- marken (native)	Guldregn (Swedish)	Mesdag (Swedish)
In soil uncultivated the previous year .	20.47	20.78	24.61	24.61	22.30	21.26	19.67
In soil previously ma- nured and planted with potatoes . .	24.37	20.63	24.29	23.65	21.26	22.78	18.95

In rich soil previously fertilised and planted with potatoes Grenader and Odin did best, but in soil not cultivated the previous year Thor and

(1) See *B.*, 1912, No. 1030. (*Ed.*).

Odin took first place. In all cases Odin yields best. The results obtained are shown in Table II.

TABLE II. — *Results of comparative cultural experiments with different varieties of oats and barley at Hjellum and Møistad.*

	Duration of vegetative period (1) days	Resistance to lodging (2)	Yield in grain per acre cwt.	Relative index of yield in grain	Weight of 1000 grains gm.	Percentage of hulled grain	Yield in straw per acre cwt.
<i>Oats:</i>							
Grenader 34 . . . . .	108	1.2	20.47	83	48.59	77	34.09
Perle 150 . . . . .	97	1.4	20.78	84	34.65	73	31.69
Odin 0200 . . . . .	107	1.9	24.61	100	45.24	74	33.93
Thor 0207 . . . . .	105	2.8	24.61	100	39.22	68	34.52
Hedemarken (native)	104	3.7	22.30	91	35.21	70	34.48
Guldregn (swedish) . .	105	1.6	21.26	86	42.24	76	36.63
Mesdag (swedish) . . .	(98)	3.2	19.67	80	(34.56)	(72)	27.95
<i>Barley:</i>							
Mjøs . . . . .	90	3.00	18.63	100	43.63	—	27.31
Maskin . . . . .	86	1.25	17.92	96	38.23	—	21.90
Bamse . . . . .	88	3.16	17.12	92	37.39	—	25.09
Hedemarken (native)	89	4.00	17.28	93	35.81	—	25.17

(1) Number of days from sowing to harvest. — (2) This resistance is expressed according to an empirical scale ranging from a maximum of 1 to a minimum of 4.

The results are very satisfactory for all the characters considered and the four new varieties are very superior to the original ones. The resistance to lodging (1.2) of the Grenader variety is nearly three times that of the Hedemarken variety (3.7). The vegetative period of the Perle variety does not exceed 87 days. The varieties Odin and Grenader surpass even the Swedish Guldregn variety in the weight of 1000 grains. Finally, in percentage of naked grain Grenader again leads with 77 %, exceeding Guldregn by 1 % (76). The data on the four new varieties may be summarised as follows: —

1) *Grenader 34*. — Comes first for resistance to lodging, percentage of hulled grain and, in rich, fertilised soil, yield in grain. The bright yellow grain is of the Propsteier type, short, compact, and plump. This variety has been put on the market since 1917.

2) *Odin 0200*. — A very productive variety, not only in Hedemarken, but also in the province of Romsdal. Grain of the Propsteier type. On the market since 1917.

3) *Thor 0207*. — In the provinces of Hedemarken, Romsdal and Trøndelag this variety is very productive, even in very poor soils and has at the same time a high resistance to lodging. It is certain to be largely used in Norway owing to its capacity of adapting itself to unfavourable weather

and agro-geological conditions. White grain of the Norwegian type, large and plump. Will be put on the market in the spring of 1919.

4) *Perle 160*. — Remarkable for its earliness which even exceeds that of the Swedish Mesdag oats, famous for this quality. It is equal to Odin and Guldregn in its resistance to lodging. Grain pearl white of the white Norwegian type, very short; a little inferior in dimensions to the common Hedemark oats, but has a higher percentage of hulled grain. This variety cannot be put on the market for 3 or 4 years.

**SIX-ROWED BARLEY**. — Taking as a basis the considerations given above for oats the author made a first selection of 85 barley plants in 1905, and, in 1907, a second selection of 232 plants in the districts of Biörneby, Alu, Trysil, Lom, Hovinsholm, and Helgeöen. A series of comparative tests with the elimination of the more unpromising plants reduced the number of strains to two good new varieties *Miös* and *Maskin* — designated in the genealogical register by the numbers 08 and 077. The results obtained are compared in Table II with those of Bamse barley and unselected common Hedemarken barley. The results were distinctly positive, for the two varieties surpassed the original ones, especially in yield in grain and resistance to lodging. The two varieties may be described as follows: —

*Miös* 08 is distinguished by vigorous growth, high yield in grain and straw and size of grain. In earliness and strength of straw it is, however, equal only to common barley. It was put on the market in the spring of 1917.

*Maskin* 077 is remarkable for earliness (it ripens three days before common barley) and resistance to lodging; it also gives good yields.

**856 — Pure-line Selection of Oats and Barley in Quebec, Canada.** — MURRAY, JAMES, in *The Agricultural Gazette of Canada*, Vol. V, No. 2, pp. 163-165. Ottawa, February, 1918.

By individual selection the author succeeded in isolating strains of Joannette oats differing in many ways from the parent plant; these strains are Nos. 407, 607, 2 007, 2 707, and 3 307. The data given below are the averages of a five-year period.

The *duration of the vegetative period* for Joannette is, on the average, 99.2 days; No. 2 007 is, however, much earlier, 94 days; No. 407 is much later than the original variety, 105.6 days.

The *percentage of hull*, 26.9 for Joannette, is 28.8 for No. 2 007 (an undesirable character), but drops to 24.4 for No. 3 307.

*Yield in grain.* — Joannette yields 59.67 bus. per acre; it is exceeded only by No. 607 which yields 70.09 bus; all the other strains are more or less inferior to the original variety.

Still more satisfactory results were obtained with Mandscheuri barley, as is seen by the five-year averages for the original variety and the selected strains Nos. 6 809, 7 008, 7 408.

Duration of vegetative period

Bushels of grain per acre

86.8 days	52.84
86.8 "	69.95
84.6 "	66.69
86.2 "	67.29

The pure strains give a higher yield than the original variety and one is equally early, whereas the two others are earlier.

**857 - Experiments in the Hybridisation of Maize, in the Philippines.** — MARQUEZ, I. D., in *The Philippine Agriculturist and Forester*, Vol. VI, No. 4, pp. 116-123. Los Baños (Laguna), December, 1917.

Maize hybrids are often more vigorous and more productive than the parent plants, so that hybridisation may be advantageously carried out whenever similar varieties are available so that, when crossed, they give uniform and homogenous progeny. The author made the following crosses: —

- I) First Prize Mestizo (357  $F_2$ ) ♀ × Iowa Ideal (1490  $F_1$ ) ♂
- II) White Flint Moro (2581) ♀ × Pasig White Flint (2298) ♂
- III) Pasig Yellow Flint (2802) ♀ × Old College Yellow Flint (184  $F_4$ ) ♂
- IV) Bay Moro White Flint (3149) ♀ × Native Yellow Flint (3150) ♂
- V) Pure Moro White Flint (3163) ♀ × Bay Moro White Flint (3145) ♂.

The Cross IV, between white and yellow varieties, gave lemon colour hybrids which yielded 21.5 % more than the Native Yellow Flint. The results of Cross V were also very good, the yield of the hybrids exceeding that of the parents by 15.4 %.

**858 - Lint Percentage and Lint Index as Important Factors in the Selection of Cotton Varieties.** — See No. 866 of this *Review*.

**859 - Investigations into the Colour of the Fruit in Hybrids of Tomato, Aubergine and Pepper, in the United States.** — BYRON, HALSTED D., in *The Journal of Heredity*, Vol. IX, No. 1, pp. 18-23. Washington, 1918.

**TOMATO** (*Solanum Lycopersicum*). — The pulp of the fruit may be either lemon colour (y), or red (R); the tegument may be of an orange shade (o), or colourless (o). The characters O and R are dominant, y and o are recessive. There may be four different combinations:—

- 1) yellow pulp and colourless tegument : yellow fruit. yyoo
- 2) " " orange " orange " yyOo
- 3) Red " " colourless " pink " RRoo
- 4) " " orange " red " RROO

The cross 1 × 2 gives, in  $F_1$ , hybrids all of which have orange fruit (yyOo) as a result of the dominance of O, and in  $F_2$   $\frac{3}{4}$  of individuals with orange fruit and  $\frac{1}{4}$  with yellow fruit, in accordance with the ratio 3:1.

Similarly the cross 3 × 1 gives an  $F_1$  composed entirely of pink-fruited hybrids (Ryoo), and an  $F_2$  including three pink-fruited plants. RRoo, Ryoo, yRoo and one yellow-fruited plant yyoo.

The cross 3 × 2 is less simple. In  $F_1$  the two dominant characters combine so that all the fruit is of a different colour from that of the parents. i. e., red, RyOo. These hybrids produce four kinds of gametes — RO, Ro, yO, yo — which combine in  $F_2$  in 16 different ways, as is seen by the appended figure, giving plants with red, pink, orange and yellow fruit respectively in the ratio 9:3:3:1.

		Male gametes of $F_1$			
Females gametes of $F_1$	♂	R0	Ro	y0	yo
	♀				
	R0	RR00 (red fruit)	RR0o (red f)	Ry00 (red. f)	Ry0o (red t.)
	Ro	RR0o (red f.)	RRoo (pink f.)	Ryo0 (red f.)	Ryoo (pink f)
	yo	yRR0 (red f.)	yR0o (red f)	yy00 (orange t.)	yy0o (orange f)
	yo	yR0o (red f.)	yRoo (pink f.)	yyo0 (orange f.)	yyoo (yellow f.)

 $F_1$ 

Crosses between type 4 and the others gave the following results:—

a) Cross 4 × 1 (*red* fruit × *yellow* fruit):— All the  $F_1$  hybrids have red fruit:  $F_2$  behaves as in the cross 3 × 1 (see Figure).

b) Cross 4 × 2 (*red* fruit × *orange* fruit): The  $F_1$  hybrids all have red fruit (Ry00); they produce two sorts of gametes — R0 and y0 — which can combine in  $F_2$  in four different ways, three giving red fruit RR00, Ry00, yR00 — and one giving orange fruit — yy00 — so that  $\frac{3}{4}$  of the  $F_2$  plants have red fruit, and  $\frac{1}{4}$  orange fruit. The hybrids RR00 and yy00 remain constant, whereas Ry00 and yR00 continue to divide into plants with red fruit and those with orange fruit, in the usual ratio.

c) Cross 4 × 3 (*red* fruit × *pink* fruit): this case is similar to the preceding one except that in the cross *red* × *orange* the constant character is that of the tegument (00), whereas here (*red* × *pink*), it is that of the pulp (RR).

AUBERGINE (*Solanum Melongena*). — The most common colour of the fruit is purple, which, however, varies greatly in the different varieties, as may be seen from a comparison between the varieties Black Beauty and Dwarf Purple. In some cases this colour occurs beneath the calyx, in others only in these parts of the fruit exposed to the sun. There are, therefore, two pigments, distinguished by their manner of reacting to light. The fruit of plants which do not contain the factor determining the purple colour have a colourless tegument, and the ripe pulp may be either ivory white or green. There are, then, four cases to be considered:— a) green pulp; b) white pulp; c) purple tegument; d) colourless tegument. The characters "purple" and "green" appear to be dominant. Four combinations are possible;—

- 1) Green pulp and purple tegument: GGPP
- 2) White " " " " : ggPP
- 3) Green " " colourless " : GGpp
- 4) White " " " " : ggpp.

The cross 1 × 2 gives, in all the generations, hybrids with constantly purple tegument. On the other hand, in  $F_1$  the pulp of the fruit is always

green, whereas, in  $F_2$   $\frac{3}{4}$  of the plants have fruit with green pulp (GG; Gg gG) and  $\frac{1}{4}$  fruit with white pulp (gg) in the usual ratio of 3 : 1.

In the cross  $1 \times 4$ , or GGPP  $\times$  ggpp, the hybrids of  $F_1$ , with the formula GgPp produce 4 kinds of gametes — GP, Gp, gP, gp. — which combine in 16 different ways, giving in  $F_2$  9 plants with green pulp and purple tegument (purple fruit), 3 plants with white pulp and purple tegument (pink fruit), 3 plants with green pulp and colourless tegument (green fruit); 1 plant with white pulp and colourless tegument (white fruit). These combinations give a figure similar to that for the tomato. These theoretical results may be obtained by crossing the variety Long White (white fruit) and the variety Dwarf Purple (purple fruit).

Besides the four types already discussed there is another with variegated fruit. When this is crossed with a white-fruited variety hybrids with slightly variegated fruit are obtained in  $F_1$ , but when it is crossed with a purple-fruited variety the hybrids of  $F_1$  have purple fruit, and in  $F_2$  most of the plants have purple fruit and only a few have variegated fruit, showing this second character to be recessive.

PEPPER (*Capsicum* spp.) — Before ripening the fruit may be light or dark green, when ripe, red or orange (red being dominant). In some cases, at the period of ripening, instead of an immediate change from green to red or orange, intermediate colours occur, such as a bright lemon colour, turning first to orange, then to red. In this case the more or less ripe fruit has many shades varying from green in the parts not exposed to the sun, to orange and red. This colour variation is due to a genetic factor which, at the time of ripening, determines the regular and immediate passage from green to red or orange. The most common colour combinations are: — 1) lemon and orange; 2) green and orange; 3) orange and red; 4) green and red.

Some pepper plants have a purple pigment especially in the nodes and stem, but sometimes in the flowers and fruit. Before ripening this appears black. Little is as yet known on the inheritance and genetic value of this character.

To sum up, in all the species considered the colour of the fruit tends to be yellow or red. In the tomato and aubergine the colour of the tegument is the fundamental character in selection and hybridisation tests. In the pepper plant various chromatic factors occur before the ripening phase, some of which are very similar to those of the aubergine. The purple colour occurs particularly in the fruit of aubergine. It is also common in that of pepper, but less marked in tomatoes. In each case it is very sensitive to the action of external agents.

CEREAL  
AND PULSE  
CROPS

860 — **The Cultivation of Cereals in Spain.** — I. QUINTANILLA, G., Cultivation of Cereals in New Castile, in *Boletín de la Asociación de Agricultores de España*, Year X, No. 105, pp. 64-84, Madrid, February, 1918. — II. DANTIN, CERECEDA, J., Experiments in the Dry Farming of Cereals in Spain, in *Boletín de Agricultura técnica y económica*, Year X, No. 112, pp. 316-325, Madrid, April, 1918.

I. — **CULTIVATION OF CEREALS IN NEW CASTILE.** — The great obstacle to an increased cereal production in this district is the climate (1). In

(1) See R July, 1918, No. 725. (Ed.)

the provinces of Guadalajara, Cuenca and Madrid there are frosts every year from November to April or May: in that of Toledo, from November to March. During the last 15 years the minimum and maximum temperatures were  $-6.5^{\circ}$  and  $+40.4^{\circ}$  C respectively in the province of Toledo,  $-12.5^{\circ}$  and  $+38.5^{\circ}$  in that of Cuenca,  $-13^{\circ}$  and  $+39.6^{\circ}$  in that of Guadalajara, and  $-14^{\circ}$  and  $+40.5^{\circ}$  in that of Madrid. The differences are, therefore, considerable, and to these are added another unfavourable factor — snow during 8 or 9 months of the year. This accounts for the low yields. During the 10 years, 1903-1912, the average yields, in cwt. per acre, were: — Toledo, wheat 6.30 (this average, which is very low, includes the yield of irrigated wheat), barley, 13.38; oats, 9.55; rye, 4.38; Cuenca, wheat, 4.93; barley, 9.55; oats, 4.38; Guadalajara, wheat, 6.56; barley, 8.36; oats, 6.66; rye, 7.44; Madrid, wheat, 8.36; barley, 13.14; oats, 7.16; rye, 6.37. For the whole of New Castile the averages were: — wheat, 6.28; barley, 11.53; oats, 6.29; rye, 6.03. It is seen that all these yields are low.

On the other hand, rain is plentiful and well distributed — 361, 477, 410, 417 mm. for the provinces of Toledo, Cuenca, Guadalajara and Madrid respectively.

There are three soil types in New Castile: — 1) that from decomposing rocks, very silicious with only 6 % to 7 % of clay, and containing only 0.5 % to 5 % of lime (the larger amount in the Moucloa district), 0.6 % of phosphoric acid, but up to 6 % of potash; 2) calcareous soil not used for crops; 3) soil derived from feldspathic rocks with more than 1 % of phosphoric acid, containing a fair amount of potash and nitrogen, but heavier than the soil of class 1.

In the experimental plots of the Agricultural Station of Alcalá de Henares the author found 12 to 14 % of moisture at a depth of 23  $\frac{1}{2}$  inches, and 9 to 11 % at the surface. There are also, however, at the Station sandy soils nearly 5 feet deep, which, at 2 feet, have barely 5 % of moisture so that plants can derive little from it. Experiments made at the Station showed that soil 5 feet deep and, if slightly heavy, 3  $\frac{1}{4}$  feet deep, is suitable for cultivation (according to WIDTSØE the requisite depth for sandy soils in the United States is 9.84 feet).

Judging by scientific observations and his own experience as a farmer, the author does not advise for the "Meseta Central" (central table-land) of Spain the dry farming methods usually recommended for dry soils, because he observed that in this district they dry up the soil instead of preserving its moisture. Instead he advises a single preparatory ploughing, as deep as possible, care being taken not to turn the sub-soil onto the surface.

The most satisfactory fertilisers are phosphatic and nitrogenous ones; as a rule little potassic fertiliser is required.

In view of the great climatic variations from one year to another it is impossible to lay down rules for the best time for sowing, but at any rate it should be sufficiently early to avoid injury from late frosts. With regard to the quantity of seed, in many parts of New Castile 187 lb. or more per acre are used. Cultivation consists of one or two hoeings to destroy weeds.

The author studies the different American wheats which, on the whole,

are adapted neither to the particular climatic conditions nor to the soil of New Castile.

II. — EXPERIMENTS ON THE DRY FARMING OF CEREALS IN SPAIN. — The author refers to the work done by Señor José Cascón at the "Granja agrícola" of Palencia and by Señor QUINTANILLA at the Miralcampo farm near Azuqueca, Guadalajara. The former concluded that the factor determining the quantity of seed to be used is not the nature of the soil, but the climate. At Palencia, where the average annual precipitation is 399 mm. the best quantity is 1.4 bushels per acre. With this quantity and good cultural methods the Agricultural Station of Palencia obtained, as a nine-year average, 21.38 cwt. of wheat per acre, or 3.27 times more than the average production (hardly 6.53 cwt.) for the whole of Spain (1). The amount of seed commonly used is excessive and sometimes exaggerated.

For more than a century excellent Spanish agriculturists have tested and recommended sparse sowing. AUGUSTÍN CORDERO tested it near Madrid on behalf of the "Real Sociedad económica Matritense" and, in 1771, obtained for wheat, using 0.92 bushels of seed per acre, 18.88 bushels of grain; in 1772, with 0.74 bushels of seed, he obtained 21.88 bushels of grain. The seed was sown in lines in three rows with a space of one unsown line. In 1773, also with sparse sowing, he obtained 59.27 bushels per acre of barley using 1.96 bushels of seed, and 43.18 bushels of grain with 1.4 bushels of seed. The results of his experiments led him to recommend sowing in pockets, four seeds to each, in squares 1 foot apart leaving 1 line unsown to every 3. He based his calculations for the number of seeds to use on the work of VALCÁRCEL, who had already determined the number of seeds per unit of weight. In 1818 this method was confirmed and recommended by Prof. ARIAS Y COSTA in his text-book entitled *Lecciones de Agricultura explicadas en el Jardín botánico* (Madrid, 1818).

861 — **Yields of Spring Grains in Illinois.** — BURLISON, W. L., and ALLYN, O. M., in *The University of Illinois, Agricultural Experiment Station, Bulletin*, No. 195, pp. 499-508. Urbana, Illinois, January, 1917.

Spring grains form a large proportion of the crops produced in Illinois. Owing to the marked climatic and soil differences in the State, varieties suited to one district are not necessarily desirable in another. The experiments described were carried out to determine the varieties best adapted to northern, central and southern Illinois, as represented by the experiment fields at Dekalb (Dekalb County); Urbana (Champaign County); Fairfield (Wayne County). The methods of culture used were similar to those of the corn belt.

(1) According to Prof. MARRO (*Corso generale di Economia*, Vol. II, p. 152, Rome, 1906) the average wheat yield in Spain is 17.5 bushels per acre. According to Señor GUMERSINDO FERNANDEZ DE LA ROSA during the last 20 years, on an average about 10 of the 40 million acres of the arable land of Spain have been used for wheat, with an average annual yield, according to official statistics (which he considers higher than the actual yields), of over 115 1/2 million bushels, or 13.17 bushels per acre (*Revista de Montes*, Year XLII, No. 992, pp. 338-339. Madrid, May 15, 1918). (Ed.)

**NORTHERN ILLINOIS.** — (Soil : brown silt loam ; rainfall : 33.64 inches per year) : — The rotation was chiefly maize, maize, oats, and clover, but tests were also made with oats, spring wheat and barley in the rotation maize, oats, spring wheat and clover.

*Oats.* — Of the varieties tested for 6 years Silvermine, Schoenen and American Banner gave the highest yields with an average of 64.0, 63.3, 61.1 bushels per acre respectively. Great American, Scottish Chief and White Kherson (Iowa 103), tested for 2 years only, gave very satisfactory yields (70.8, 70.2 and 68.6 bushels per acre respectively). Tests made over 6 years with northern oats and home-grown oats showed that the first produced an average of 3.0 bushels per acre more than the second ; this difference is not sufficiently great to justify the extra expense incurred by shipping northern seed oats.

*Spring wheat, barley, rye and emmer.* — The tests with these cereals have been too limited to justify any conclusions as to the relative value of the varieties.

**CENTRAL ILLINOIS.** — (Soil : brown silt loam ; rainfall : 35.76 inches per year). — The crops were grown in two rotations, 1) maize, maize, oats or other spring grain, and clover ; 2) wheat, maize, oats and clover.

*Oats.* — The best varieties tested over a number of years were :—

Variety	Average yield (bushels per acre)	Variety	Average yield (bushels per acre)
Sixty Day (11 yrs.). . . . .	58.1	Irish Victor (11 yrs.) . . .	49.9
Swedish Select (6 yrs.) . . .	54.6	Silvermine (8 yrs.). . . . .	49.2
Schoenen (9 yrs.). . . . .	51.1	Siberian (13 yrs.) . . . . .	49.0
White Bonanza (12 yrs.). . .	49.9	American Banner (13 yrs.).	47.0

The most promising of the varieties grown over 2 years only were : — Great American (72.1 bushels per acre), Yellow Kherson (Iowa 105) (68.9 bushels per acre), Big Four (68.8 bushels per acre), and Wisconsin Pedigree No. 1 (67.9 bushels per acre).

*Spring wheat.* — This crop is not ever likely to become important in Central Illinois, though it offers possibilities, especially where there is a danger of winterkilling. The results obtained in 1916 were : — Spring (a home-grown variety), 27.9 bushels per acre ; Durum, 24.6 bushels per acre ; Marquis, 21.8 bushels per acre ; Red Fife, 18.3 bushels per acre.

*Barley.* — Common barley, with a 5 year average of 40.1 bushels per acre, seems the most promising of the varieties tested. It is very similar to Oderbrucker, which gave a 4 year average of 38.1 bushels per acre. The trials carried out so far are, however, insufficient to give any definite results.

**SOUTHERN ILLINOIS.** — (Soil : grey silt loam on tight clay ; rainfall : 40.25 inches per year). — Climatically southern Illinois is not well adapted to spring cereals, though, in favourable seasons, fair yields may be obtained. Texas Red and the early varieties of oats give better results than the late varieties.

The bulletin concludes with a table setting out the characteristics of the varieties of oats tested.

862 - **Researches on the Gases of Swamp Rice Soils, in India.** — See No. 843 of this *Review*.

863 - **The Recurving of Milo and Some Factors Influencing It.** — CONNER, A. B. and KARPEN, R. E., in *Texas Agricultural Experiment Station, Bulletin* No. 204, 30 pp. + 10 Tables + 13 Figs. Austin, Texas, February, 1917.

Recurving or "goosenecking" in milo and certain other sorghums is undesirable on account of impracticability of harvesting the crop with machinery, and the probable reduction in yields by loss of heads during the early stage of development.

Climatic conditions at the Lubbock station, where experiments were conducted, were very favourable to the study of the fundamental cause, or causes, of recurving and the factors influencing it.

Tallness or dwarfness in the same strain is the result of lengthening or shortening of the internode. No apparent difference was observed in the tenderness of the peduncle of different grain sorghums at similar stages of development. In every case noted the normal inclination of the peduncle was toward the side of the leaf sheath opening. The removal of a vertical section of the back of the upper leaf sheath, however, always resulted in complete recurving of the peduncle in the direction of the opening, this fact indicating that the support from the leaf sheath alone controlled the direction in which the head inclined. Dwarfness in stature is associated with a high percentage of erect heads, while tallness is attended by a high percentage of pendant heads. Rapid growth of the plant is conducive to tallness, while slow growth is conducive to dwarfness. Root-pruning and consequent limitation of food supply increased the number of erect heads and decreased the number of pendant heads. Limitation of moisture and food of individual plants, by reducing the feeding area per plant, resulted in an increase in the number of erect heads and a decrease in the number of pendant heads. Measurements of internode and sheath lengths in both milo and kafir have shown that while the internode varies widely under different environmental conditions, the sheath length remains quite stable. A shortening or a lengthening of the internode without a corresponding change in the length of the sheath results in the sheath's overlapping the internode in varying degrees when the same plant is grown under different conditions. Long overlapping of the sheath undoubtedly lends support to the stem, including the peduncle, while a short overlapping of the sheath lends correspondingly little support. The removal of the inrolled sheath tip before any part of the head appeared resulted in increasing the percentage of erect heads. It seems conclusive that in milo a tightly inrolled upper leaf sheath tip influences the position of the head. Plants of tall stature showed a long inroll, as compared with dwarf plants, and long inroll of the upper sheath seems to be associated with a large number of pendant heads.

864 - Important Root Crops of the Philippines. — KINGMAN, F. C. and DORYLAND, E. D., in *The Philippine Agricultural Review*, Vol. X, No. 4, pp. 410-433. Manila, 1917.

The following plants are largely cultivated throughout the Archipelago, usually as secondary crops. Their produce is on the market all the year round, and though the total production is unknown, they play an important part in the food supply of the population.

GINGER. — It is of good quality and consumed entirely locally. Besides *Zingiber officinale* 4 other varieties are cultivated. The yield per acre is from 4.77 to 7.16 metric tons of roots which lose 70 % of their weight when dried. It is sold coated or uncoated and scraped (decorticated when fresh and dried; this is "white ginger"). Ginger ale is made from a water extract of dried ginger root mixed with sugar, lemon juices, and yeast.

ARROWROOT. — Although all the different species used in the manufacture of arrowroot (*Maranta arundinacea*, *M. nobilis*, *Manihot utilissima* [cassava], *Canna Achiras*, *C. edulis*, *C. flaccida*), except *Maranta nobilis* and *Canna Achiras*, are grown in the Philippines, only *Maranta arundinacea* and *Tacca pinnatifida* are used largely. The former occurs wild in some localities. Under favourable conditions it yields 4.98 metric tons of roots per acre, which, with the local, crude processes of manufacture, yield 15 % of starch. The latter plant grows wild, especially near the coast.

CASSAVA. — There are many varieties in the Philippines, both bitter (*Manihot utilissima*) and sweet (*M. Aipi* = *M. palmata*), but they are not named. The average yield per acre is at least 9.95 tons of fresh roots containing 25 to 30 % of starch, 80 % of which is extracted by modern methods. Cassava does best in sandy soil, alone, at intervals of one year, in squares, or with a leguminous crop (cowpeas or mungos, etc.) between the lines, which should then be 5 feet apart. All the roots (sweet and bitter) contain hydrocyanic acid, which is removed by washing, drying, roasting or prolonged boiling. The roots are best for human food between 6 and 9 months after harvest.

SINCAMAS (*Pachyrrhizus erosus* = *P. angulatus*). — A Leguminous vine, which has become acclimatised and grows wild in the Philippines. It is propagated from seed sown sparsely in rows about 23 inches apart, allowing from 15 to 20 seeds to the metre (3.28 feet). The plant matures completely in about 2 years, but is harvested 5 or 6 months after sowing, i. e., when the root, which is the edible part, is still tender and not yet fibrous. The yield is about 6 tons per acre.

ELEPHANT EAR PLANT (*Colocasia esculentum* = *C. antiquorum*), known locally as "gabi". The edible part is the starchy, acrid stalk, or corm, the acrid constituent of which is removed by boiling. The average yield is about 23 *cavans* (46.86 bushels) per acre.

Some years ago the Bureau of Agriculture of the Philippines made a collection of 21 species and varieties of gabi, most of which had to be discarded because of their liability to fungoid diseases.

SWEET POTATO (*Ipomoea Batatas*). — The sweet potato is known in the Philippines by the Mexican name of "Camote" under which it was

introduced centuries ago. There are several good-producing native varieties, but none of them are equal to the best varieties imported from North America, the best of which are New Jersey Yellow, known locally as Momingan, New Jersey Red, and California Large White. The second variety holds the record for productivity, having yielded 256.78 cwt. per acre. In the Philippines the sweet potato is propagated by cuttings from young vines or, in sandy soil, by planting whole or half potatoes. When transplanting the plants are placed in the centre of the ridges (flat-ground planting gives low yields and bad-shaped roots, as was shown at the Singalong Agricultural Station). The best time for planting is towards the end of the rainy season, but if irrigation water is available the potatoes may also be planted during the dry season. Cultivation consists in working with a cultivator, followed by hoeing; it is rarely necessary to repeat the process. The most common diseases are mosaic disease, due to physiological causes, and rots of the tuber during storing. The most injurious insect is *Cylas formicarius*, which lays its eggs near the collar. The larvae bore holes in the root, where they pupate. Control measures consist in early harvesting, rotation, and the burning of all root refuse.

**YAM.** — In 1912 the Philippine Bureau of Agriculture collected 116 species and varieties of the genus *Dioscorea* from all parts of the Tropics, and cultivated them for several years. The 96 which became acclimatised were subjected to a complete chemical analysis, and to growing and feeding tests. Only 34 (10 varieties of *D. fasciculata*, 18 *D. sp.*, 1 *D. Daemona*, 4 *D. alata*, 1 *D. aculeata*) were considered adapted to Philippine conditions. These are being propagated for distribution purposes at the Agricultural Station of Lamao, Bataan.

*D. fasciculata* grows wild in some parts of the Philippines. Propagation is by tubers or crowns of tubers in lines 2.36 to 3.28 feet apart at distances of 3.28 feet; trellises are erected later. The roots are harvested 7 to 9 months after planting. The production is equal to or better than that of the best varieties of sweet potato; some of the larger varieties yield nearly 23 metric tons per acre, but as they are difficult to harvest they are rarely grown.

A table is given showing the results of analyses made by the Bureau of Science of Manila of the roots of 96 species and varieties of *Dioscorea* grown in the Philippines. In most cases the tubers weigh about 500 gm. and contain about 70 % of water, 0.2 % of ether extract, 0.3 % of saccharose, 0.4 % of reducing sugar, 2 % of protein, less than 1 % of ash, about 20 % of starch, less than 1 % of fibre, and about 5 % of undetermined substances.

Owing to the difficulties of the present times cotton growing in Algeria is still localised in the Orleansville and Oranie districts. Nevertheless, very good results have been obtained. The only varieties cultivated

are derived from Egyptian cotton and the product, which is very good, commands high prices.

Two varieties selected by the Botanical Department from seed from the Yuma Station, California, have given good results.

The "Yuma" variety, selected from Mit-Affi, yielded at Orleansville 16.9 cwt. of raw cotton per acre. Under the same conditions Mit Affi yielded 13.5 cwt. per acre. At present prices a yield of 13.5 cwt. gives fibre worth £56 per acre. No other crop can give such good results in the Chélif plain.

At the Ferme-blanche Experiment Station the best results were obtained with a variety called temporarily "California", which proved there superior to Yuma, especially in earliness. This variety seems well suited to the soil and climate of North Africa.

For some years Egyptian planters have suffered much loss through injury done by the larvae of *Gelechia gossypiella*, which attacks the pods. The larvae hibernate in the seed and may be carried in it. As disinfection experiments with the seed gave unsatisfactory results, it is most important that no more seed should be imported from Egypt. At present sufficient selected seed is produced in Algeria to meet the local requirements. The Co-operative Society of Orleansville, the Cotton Association of Oran and the Ferme-blanche Experiment Station at Habra, are in a position to supply all the demands for seed in Algeria, Tunis and Morocco.

**866 - Lint Percentage and Lint Index of Cotton and Methods of Determination; Investigations in the United States.** — MELOV, G. S., in the *U. S. Department of Agriculture, Bulletin* No. 644, pp. 1-12 + 2 Figs. + 4 Plates. Washington, January 18, 1918.

The danger of diminishing the vitality and earliness of varieties of cotton by breeding those with undesirable characters by over-emphasising the percentage of lint as a measure of their comparative values was pointed out in 1908 by Mr. O. F. COOK (1). It has been suggested that instead of the percentage of lint only, the weight of lint ginned from 100 seeds should be used as an additional standard for judging varieties. This standard of comparison was called the lint index. Subsequent experience has shown not only the desirability of using this standard, but has also led to improved methods and apparatus for determining the lint index and the lint percentage in samples of seed cotton used by selectors.

The lint percentage is the ratio between the weight of the fibre and the weight of the seeds from which the fibre is ginned expressed as a percentage of the unginned seed cotton. The buyers of seed cotton were the first to use this lint percentage. It should be very carefully used if adopted by breeders and growers as a measure of the comparative value of varieties as it is misleading unless used in connection with the lint index.

An increase in the lint percentage may be due entirely to a reduction in the size of the seed without any corresponding reduction in the amount of fibre, and vice-versa.

(1) COOK, O. F., *Danger in Judging Cotton Varieties by Lint Percentages*. *U. S. Dept. Agr., Bur. Plant Industry, Circ. No 11*, pp. 16. 1908. (Author).

The lint index is a measure of the abundance of the fibre rather than the measure of the ratio between the weight of the fibre and the weight of the seed, as for the percentage of lint.

The lint index shows the number of seeds and consequently the number of bolls, producing 1 lb. of fibre. The number of seeds and bolls required to produce 1 lb. of fibre is constant for all varieties of cotton having the same lint index regardless of the percentage of lint.

An increased lint index corresponds to an increase in the weight of the seeds and reduces the number of bolls required to produce 1 lb. of fibre.

The lint index is an important factor in the cost of production of cotton. An increase of a single gram in the weight of fibre per 100 seeds, without any change in the lint percentage, reduces the labour of picking cotton, thus increasing the amount picked by each worker. It is essential that a planter should know the lint index of a variety as well as the lint percentage when choosing a variety to be planted.

#### METHODS FOR DETERMINING THE LINT INDEX AND THE SEED WEIGHTS.

— After having weighed a standard sample of 100 gm. of seed cotton and determined the percentage of lint, which is the actual weight of the lint, the lint index and the weight of 100 seeds are obtained by the following formulae: —

$$\frac{\text{Percentage of lint}}{\text{Number of seeds in sample}} \times 100 = \text{lint index.}$$

$$\frac{\text{Percentage of seed}}{\text{Number of seeds in sample}} \times 100 = \text{weight of 100 seeds.}$$

The lint index may be determined as follows: — 100 average seeds fairly ginned are weighed on a sensitive balance, or still better, the average weight of two lots of 100 seeds is determined. The following formula may then be used: —

$$\frac{\text{Weight of 100 seeds}}{\text{Percentage of seed}} \times \text{lint percentage} = \text{lint index.}$$

A method is described by which the lint index and the size of seeds of a variety of cotton may be determined without a balance by means of tables given in the bulletin. A description is also given of a balance for the direct reading of the lint percentage. This balance is on the market.

867 - **The Cultivation of Gombo as a Textile Plant; Experiments in Mexico.** — *La Revista agrícola, Órgano oficial de la Dirección de Agricultura, Secretaría de Agricultura y Fomento*, Vol. 1, No. 10, pp. 398-400 + 2 Figs. Mexico, January 15, 1918.

This paper contains the results of experiments carried out a few years ago by Señor L. E. MARTÍNEZ at the Agricultural Station of Villa Hermosa, Tabasco, of which he was the director.

Gombo or "chimbombó", as it is called in Mexico, includes two species, the dwarf *Hibiscus abelmoschum* and the giant *H. esculentum*, which, in hot climates, reaches a height of nearly 10 feet.

This Malvaceae is very strong and adapts itself to the most varied climates (it only suffers from hard frosts) and to all soils. It does best, however, in sandy humus soils which have not long been cleared

of trees and in alluvial soils. In warm countries it can be sown throughout the year, in temperate countries in spring and summer. As the tegument of the seed is hard it is well, if possible, to irrigate before sowing, otherwise it is best to wait for the period following the first rains. If gombo is cultivated especially as a vegetable, i. e., for its green fruit, it should be sown in lines 6  $\frac{1}{2}$  feet apart with 3  $\frac{1}{4}$  feet between the plants; if grown for its fibre these distances should be reduced by half. The only cultivation needed is hoeing. The plant begins to bear fruit 2 months after sowing. If the fruit, especially the first, is cut as soon as it forms, the plant develops better and in 6 months grows to a height of 10 feet or more; it should then be cut and not left till it loses its fine texture and sheen. The stalks, cut and put up in bundles, are macerated for 8 days; if possible the water should be renewed and the bundles washed frequently; finally they are rinsed in clean or soapy water and laid out in the sun to dry and bleach.

An ordinary sized gombo plant yields from 50 to 100 gm. or more of clean fibre, corresponding to 11 to 16 cwt. per acre. Before macerating the stalks the capsules are collected; the seeds obtained (4 to 8 cwt. per acre) yield an edible oil and a cake which may be used either as a concentrated food or as a fertiliser. Roasted they are used as a substitute for coffee. The tender fruit is prepared in various ways; cut in slices and dried in the sun it keeps till winter. The wood of the stalk and the fibrous covering of the capsule are excellent material for paper-making. The leaves and tender parts of the plant, if ensilaged, form excellent fodder for cattle; dried naturally they may serve as a substitute for tobacco, for they resemble it in appearance and when burning have almost the same smell.

868 - Results of Growing Sweet Sorghum in Piedmont, Italy. — JACOMETTI, G., in *Cronaca agricola, Organo Ufficiale dell'Associazione Agraria Piemontese*, Year XXIII, No. 9, p. 44 + 3 Figs. Turin, May 16, 1918.

SUGAR CROPS

The author grew sweet sorghum at Villafranca Piemonte (province of Turin). On a plot 45  $\frac{1}{2}$  sq. yds. in size he obtained, as an average of several years, 220 lb. of stalks and 22 lb. of seed. The 220 lb. of stalks yielded from 90 to 120 lb. of juice, and from 99 lb. of juice were obtained from 15  $\frac{1}{2}$  to 17  $\frac{1}{2}$  lb. of sweet syrup. The author recommends the cultivation of this sorghum in Italy, especially for the preparation of the syrup for home use (simply by concentrating and removing the scum).

869 - Plants Suitable for Paper-Making in South Africa. — LEIGHTON J., in *The South African Journal of Science*, Vol. XIV, No. 6, pp. 287-289. Cape Town, January, 1918.

VARIOUS CROPS

South Africa can furnish large quantities of Tambookie grasses (*Andropogon* spp.) suitable for making paper pulp. Samples of such paper, prepared by BERTRAMS, Limited, of Edinburgh, were quite satisfactory. The commonest Tambookie grasses are *A. hirtus*, growing to a height of from 2 to 3 ft., and *A. Nardus*, growing to a height of 5 or 6 ft. The former species is common throughout South Africa, while the latter occurs in patches adjoining forests and in moist places.

*Cyperus textilis* and *C. hexangulare*, common near rivers and wet localities in South Africa, produce a very strong paper; 5 to 10 % of their pulp mixed with Tambookie grass pulp produces an extra strong paper.

Among other plants suitable for paper-making are : *Sansevieria thyrsiflora*, an underbush plant common in the eastern regions ; *Fleurya peduncularis*, a nettle common in moist places ; *Agave americana*, introduced all over the country ; maize cob husks and plantain fibre.

FRUIT  
GROWING

870 - **Investigations into the Autumn Growth of Fruit, in Italy.** — MANARES, ANGIO, in *Il Coltivatore*, Year LXIV, No. 9, pp. 180-183, and No. 12, pp. 246-248 + 1 Diagram. Casale Monferrato, 1918.

The experiments described were carried out by the author in an orchard at Imola planted in 1903 with pears (*Curato* and *Bergamotta Esperen* varieties) grafted on quince, with apples (*Reinette*, *Belle fleur jaune*, *Rosa romana*, *Garofana*, *Rosmarina* varieties), grafted on doucine and quinces (*Van Demon* and *Géante de Vranja* varieties) grafted on stock sprung from seed.

The author summarises the results of his investigations carried out to verify the studies of RIVIÈRE and BAILHACHE in France (1) and of WHITEHOUSE in the United States (2), according to whom winter pears, like apples, grow most during the period immediately preceding harvest.

1) The volume (and, naturally, the circumference as well) increases till a little after mid-October for winter pears, till after mid-November for late apples. Quinces are intermediate between the two, but resemble pears rather than apples. Consequently it would be well to bear these facts in mind when gathering these fruits unless other circumstances make an earlier harvest preferable.

2) The development curve of these fruits shows clearly that, contrary to the results obtained by the above mentioned workers in France and America, growth decreases as the season advances.

3) The specific weight of these fruits continually decreases during the last weeks before they fall.

4) The growth of the fruit depends on their more or less favourable situation and the number of fruits on the branch or on the plant.

871 - **The Common Honey Bee as an Agent in Plum Pollination.** — HENDRICKSON, A. H., in the *College of Agriculture, Agricultural Experiment Station, Berkeley, California*, *Bulletin* No. 291, pp. 215-236 + 13 Figs. Berkeley, January, 1918.

The results of these experiments, which are a continuation of those of the preceding year (3), may be summarised as follows : —

The average yield per tree of French (Agen) plums was increased by the use of bees in the orchard, but there was no increase in the yield of the Imperial variety. The percentage of setting was greatly reduced for both varieties when all pollen-carrying insects were kept away from the trees. The percentage of setting in a French plum tree enclosed in a tent of mosquito netting with wooden supports alone or with an Imperial tree and a colony of bees was higher than the orchard average for the variety. An Imperial

(1) G. RIVIÈRE and G. BAILHACHE, Etude sur l'accroissement du volume des fruits (*Journal de la Société nat. d'Horticulture de France*, December, 1917). — (2) W. E. WHITEHOUSE, A Study of Variation in Apples During the Growing Season (*Oregon Station Bull.* 134, 1916, 3-13) (*Auithor*). — (3) See R. JUNE, 1918, No. 649. (*Ed.*)

tree gave a good crop when alone in a tent with bees, but a slightly higher yield than the orchard average when enclosed with a French plum tree and bees. The French plum tree which had given a heavy crop in 1916 when enclosed in netting with bees, gave a very light crop in 1917 when left free. A plum tree which had given a small crop in 1916 when under a tent alone, gave, in 1917, a percentage of setting which was satisfactory although below the general orchard percentage. Both the Imperial trees which had given a small yield in 1916, gave heavy crops in 1917 under open orchard conditions. The percentage of setting of the French varieties was in inverse proportion to their distance from the Imperials.

The results of the two year's work led to the following conclusions: —

1) Both French and Imperial plum trees set better if hives are placed in the orchard during the flowering period, provided the trees are in normal healthy condition.

2) If there are no bees in the orchard the percentage of setting of these varieties may be low.

3) The French plum does not absolutely require to be interplanted with the Imperial, though such interplanting may prove beneficial to both varieties.

872 — **The Mulehng of Orange Groves in California and its Effects.** — See No. 840 of this *Review*.

873 — **The Chasselas × Berlandieri 41 B. Vine in Sicily.** — PAULSEN, F., in *Le Progrès agricole et viticole*, Year XXXV, No. 16, pp. 367-369. Montpellier, April 21, 1918.

VINE GROWING

For some years Sicilian vine-growers have re-constructed their vineyards with two stock only: — Aramon × Rupestris Ganzin No. 1 and, by preference, Rupestris du Lot. They should realise that other hybrids may be used many of which, especially those of Berlandieri, are superior to Rupestris du Lot under certain soil conditions.

One of these, little known and little used in Sicily, is Chasselas × Berlandieri 41 B, a hybrid created by MILLARDER which was successfully used in reconstituting the Charentes vineyard in France, in a district where there is a predominance of tertiary limestones, which are most apt to cause chlorosis. Under these very difficult conditions of growth the most reliable and satisfactory reconstitution of these vineyards, planted with Folleblanche, which give the best cognac of world-wide fame, was obtained with 41 B.

Chasselas × Berlandieri was not readily used in the foremost Sicilian experimental yards because there were numerous phylloxera growths on its roots and its resistance in the Sicilian climate was doubted. Time, however, has shown that in spite of its susceptibility to phylloxera it is sufficiently resistant. The author has never seen it die either in stock plantations or even in the oldest experiment fields. He considers it a stock which might be advantageously used for reconstituting Sicilian vineyards if it is judiciously employed and adapted particularly to the conditions it prefers. It is especially suited to very calcareous soils with marly sub-soil. In the Sicilian climate it resists well in soils containing 80 to 90 %

of lime. The author has also observed it in very good condition in calcareous loam and even in sandy loams where clay predominates without any trace of lime. It should not be used in arid, poor soils and those retaining an excess of water which are cold and wet in spring. The soils which suit it best are those which warm rapidly but have a cool sub-soil.

It did well in the Marsala experiment vineyards in ground with rich calcareous marly sub-soil, but failed in dry soil the sub-soil of which consisted of arid calcareous tufa. Excellent results were obtained with it in the experiment field of S. Giuseppe Lata, on the estate of Prince CAMPOREALE in calcareous loam, and it also does well in the stock yard of the Royal Nursery of American Vines in the Luparello district, in rather heavy sandy loam.

‡ Chasselas × Berlandieri 41 B is very satisfactory for budding and has a good affinity for most of the local vines. It is one of the plants most resistant to bramble-leaf disease.

874 - **The Influence of the Stock and Other Factors on the Quality of the Wine: Experiments Carried Out in Sicily.** — PAULSEN, F. and MAGGIONI, N., pp. 47 + 3 Tables + 4 Diagrams. Palermo, 1915. Abstract in *Le Progrès agricole et viticole*, Year XXXIV, Nos. 42 and 43 Montpellier, 1917.

The results of comparative experiments carried out at Marsala from 1907 to 1912 are given: —

1) The quality of the wine depends in part only on the scion and the stock and much more on other conditions which are quite independent of the grafted vine — good or bad seasons, soil conditions, date of harvest, condition and quantity of produce, etc. It is a character, therefore, due partly to internal (intrinsic) and partly to external (extrinsic) conditions or due to the environment in and conditions under which the vine is cultivated.

2) A high yield is not always proof of an inferior quality produce; on the contrary there is sometimes no connection between quality and quantity in the case of very productive stock planted in fresh and fertile soil.

3) The differences in the alcohol degree of wines due to variations in weather condition from one year to another, are very marked and range from a minimum of 1.3° to a maximum of 3.4°, according to the quality of the stock, but are much less in dry years (1.5°) than in wet years (2.6°).

4) The differences in the alcohol degree, due to variations in soil are less marked than the preceding ones, and range from a minimum of 0.3° to a maximum of 1.3°, according to the stock. The limits within which these variations occur are the same in dry as in moist soils.

5) Differences due to the nature of the stock are still less marked and do not exceed an average of  $\frac{8}{10}$  of a degree.

6) Such variations in the alcohol degree of one stock or another may be obscured by other components of the wine, so that they are hard to detect by the taste.

7) An average of four years of experiment shows that the various stock may be classed in the following decreasing order with regard to the

quality of the produce :— 420 A, Aramon  $\times$  Rupestris 1202 and 17-37 (both of the same degree) and Rupestris du Lot.

8) The stocks which gave produce of the most constant quality and quantity were 17-37 and 420 A. As a rule these are vines of average yield and vigour, earlier or less sensitive to seasonal influences and various other factors. Aramon  $\times$  Rupestris, Rupestris du Lot, and 1202 gave irregular produce, though with a high alcohol degree, especially the first two.

9) The differences from one year to another, and even in the same year, between the yield of Grillo and that of the native vines grown in the Marsala district, are very marked, even when the plants are grafted on the same stock.

10) The quality of the produce, within certain limits at least, is in inverse ratio to the drought-resistance of the stock, their vigour and the delay in the ripening of the grapes in moist soils or wet years, and vice versa. It improves in proportion to the lateness of the harvest, and is in accordance with the facility with which the vines adapt themselves to very calcareous soil.

What is the practical importance of the variations produced by the scion on the different stocks, and how can they be combined with those produced by environment and other known causes so as to produce the best results? First of all it is possible to obtain with grafted vines wine of excellent quality even surpassing that of the wines obtained in the past; the same applies to yield.

There are many causes accounting for differences in the quality of the produce — larger productive capacity of native vines grafted on American ones, earlier development and riper grapes, more careful selection of the graft cuttings and the native varieties, simultaneous and concordant action of the variations caused by the scion with that of the other factors, or of the compensation between the effects of the scion and those of other causes acting in the opposite sense.

Grafting on American vines is an efficient method of regulating the vegetation and yield of the vines. All depends on a choice of a scion which, without prejudice to the yield and life of the plant, develops best the desired qualities.

On the other hand, however, experience has shown that the yield of no stock is positive, but only relative, according to the year, nature of the soil, etc. Therefore, whereas on one hand preference should be given to certain stock which give a high yield of the best quality fruit, it would on the other hand be well to be able to dispose of several stock to take advantage of the character of each, according to the year. The system of plantations of mixed stock and that of cultivating too many different varieties of native vines which, though they produce well are not to be recommended for quality, is to be condemned. At Marsala such varieties should be limited to Grillo and Cataratto; only in special cases should Catanese and Damaschino be used.

Many Sicilian vine-growers have been too easily led to favour Aramon  $\times$  Rupestris, a stock which certainly has undeniable advantages, amongst

which is the very important one of giving very high yields, but which for various reasons should not form the sole base of reconstitution or the risk of making a serious mistake is incurred. In reconstitution more importance should be given to the Berlandieri hybrids, hitherto little used as compared with Aramon  $\times$  Rupestris, but for which a great future is in store by reason of their characteristic qualities, and, above all, the excellent and regular yield obtained from native vines with them. Of these may be specially recommended 420 A, 17-37, 34 E. M and also 41 B, to which may perhaps be added in time other good hybrids obtained in Sicily by PAULSEN, RUGGERI, and GRIMALDI.

Another stock which has given excellent results in the Marsala district is Mourvèdre  $\times$  Rupestris 1 202, especially when grafted with Grillo, not only by reason of its luxuriant vegetation, but also because of the high alcohol degree and fineness of the wines made from it.

The system of using a single stock, even in the case of the quality, has been, and always will be, a great mistake, as great, or even greater, than that of mixing many different vines.

From a point of view of wine-making, the authors found that at Marsala, beside the typical liqueur, it would be possible to produce an excellent, almost colourless white wine, alcoholic, but of an acid and slightly tart flavour. This is obtained especially from Grillo grafted on Aramon  $\times$  Rupestris or other late-ripening stock. Such wine would be valuable in the export trade. To make it, apart from the use of the varieties mentioned above, it is only necessary to subject the wine as little as possible to the action of air and heat, which are the two essential factors in the manufacture of Marsala. These conditions may easily be obtained by bottling the new wine when a few months old, after decanting it with a pump to avoid contact with the air, closing the bottles hermetically and keeping them in a coldish cellar. If this is not done, in time the wine changes colour and flavour, acquiring the characters of Marsala without any special process.

## LIVE STOCK AND BREEDING.

### HYGIENE

875 - Observations on Abortion Disease, in the United States. — SCHROEDER, E. C. and CORRON, W. E. (Bethesda, Md., Experiment Station, Bureau of Animal Industry, U. S. Department of Agriculture), in *The Journal of Agricultural Research*, Vol. XI, No. 1, pp. 9-16. Washington, April 2, 1917.

As far as the writers have been able to learn in their wide experience with the disease, the abortion bacillus is an obligatory parasite. It may live and retain its virulence for a long time in infected material expelled from the uteri of infected cows, but no data are available to support the belief that it can maintain itself or multiply under natural conditions as a saprophyte. Hence, the chronic persistence of the microparasite in the bodies of infected cows is probably the most important among the causes responsible for the propagation, the perpetuation, and wide prevalence of the disease.

The favourite habitat of the abortion bacillus in the bodies of cows is the udder, and the udder is seemingly its only habitat in the bodies of non-pregnant cows. One cow under test for 7 years gave abortion bacilli continuously in her milk. The bacillus was never found in the milk from a cow unless both her milk and her blood serum possessed agglutinating properties for it, but repeatedly cows were found which reacted, but the bacilli were not found in the milk. By experimental inoculation of a cow, the authors were able to demonstrate that the bacilli passed from the udder to the uterus. They believe that the abortion bacilli in ingested milk do not penetrate deeply or abundantly into a calf's body.

**876 - Contribution to the Study of the Mortality of Calves: Coli-bacillary Broncho-pneumonia.** — **COMINOTTI, L.** (Stazione sperimentale per le Malattie infettive del bestiame in Milano), in *La Clinica veterinaria*, Year LXI, No. 7, pp. 167-173. Milan, April 15, 1918.

Under the general term of mortality ("moria") of calves various morbid forms are included that are classified differently by various authors. The predominating form is, however, coli-bacillosis, though it appears under different clinical, anatomical and pathological aspects. The appended observations were made by the author during protracted researches.

Coli-bacillosis of calves may develop under the clinical, anatomical and pathological form of an acute broncho-pneumonia.

The articular form of coli-bacillosis may, in certain cases, represent a complication of the septicæmic form of uncertain course, owing to a secondary infection by common organisms.

*Bacterium coli* may cause nodular formations in the liver of calves, as was observed by LANGER for a bacillus of the sub-group *Enteritidis Paratifo* B., and by VALLÉE in pseudo-tuberculosis of calves.

**877 - Method for Freeing Pigs from Lice.** — *Chacaras e Quintaes*, Vol. XVII, No. 1, pp. 13-15 + 2 Figs. São Paulo, January 15, 1918.

The following mixture is recommended for destroying lice and all ectoparasites of pigs: oil (any quality) 1.75 pints; paraffin 0.88 pints; essence of turpentine 0.44 pints; about 2 gallons of hot water. This preparation should be applied twice at an interval of ten days. When breeding on a large scale baths should be constructed, or it may be applied by the pigs themselves by means of special apparatus (one is sufficient for 250 animals) consisting of a support firmly fixed into the ground against which the animals rub themselves, surmounted by a vessel containing the mixture and fitted with valves which open when the support is slightly raised by the pigs rubbing themselves. The sties must also be disinfected.

**878 - On the Hereditary Transmission of Rabies (1)** — **I. LANFRANCHI, A.** and **LENZI, F.**, Transmission of the Virus of Rabies from Mother to Fœtus, *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXI, No. 8, pp. 396-398. Paris, April 28, 1918. — **II. REMLINGER, P.**, On the Possibility of Conceptional Rabies. *Ibid.*, pp. 418-419.

**I.** — The authors record a new case of the transmission of the virus of rabies from mother to fœtus, observed in a bitch which had lived for some

(1) *Sec R*, April 1916, No. 413. (Ed.)

time in contact with a mad dog, 6 months before conception. At the post-mortem, NEGRI corpuscles were found in the region of the cornu of the brain; the biological test (injection of dilute marrow in rabbits) gave positive results. This proves that the virus of rabies in the blood-stream can pass the placental filter and infect the fœtus.

II. — The possibility of conceptional rabies presupposes the presence of the virus of rabies in both the sperm and ovule. For this reason the author sought for it in the contents of the seminal vesicles, in the testicles, and in the ovaries of rabid guinea-pigs. The results were always negative. The author concludes that conceptional rabies does not exist and that all the cases of inherited rabies are to be traced back to placental infection.

879 — **Studies on Sarcoma in Chickens.** — JABLONS, B., in *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXI, No. 7, pp. 327-328 Paris, April 13, 1918.

The author first studies the spread of sarcoma virus through the chicken's organism. The virus enters the blood. The serum of an infected chicken (prepared either by coagulation or by centrifugalisation of freshly drawn blood) injected into a new chicken in amounts of 1 cc. reproduces sarcoma with the characteristic fusiform cells. If the chicken shows general sarcomatosis of the peritoneum the virus passes into the ascitic liquid.

The increase in the virulence of the serum of infected chickens kept 10 days in the incubator at 37° C. was then studied. Under these conditions the serum was four times as virulent and reproduced lesions in a fresh chicken when injected in quantities of 0.25 cc. The author does not believe this to be a case of true increase in virulence, but rather of an increased number of micro-organisms which have multiplied at the temperature of the incubation. The passage of the virus through the chicken increases its virulence and shortens the incubation period of the disease (after the 7th. passage of the virus the lesions developed in 13 days instead of 27 to 42).

The fleshy tumour dried and kept in the ice-chest, retained its virulence for twelve months, but lost it at the end of the thirteenth.

880 — **Mallophaga Ectoparasitic on Birds, in Formosa.** — UCHIDA, SEINOSUKE, in the *Journal of the College of Agriculture, Imperial University of Tokyo*, Vol. III, N° 4, pp. 171-188 + 1 Plate. Tokio, June 15, 1917.

The author describes 21 species (17 being new to science) belonging to 8 genera of Mallophaga ectoparasitic on birds, killed in Formosa. These are: — *Laemobothrium loomisii* on *Nannocnus cinnamomca*; *Lipeurus variabilis* and *Nirmus vittatus* on *Accipiter virgatus*; *Colpocephalum osborni* on *Milvus ater govinda*; *Colpocephalum pachyaster* on *Pandion haliaetus*; *Nirmus ovatus* n. sp., *Lipeurus variabilis*, *L. intermedius* var. *major* n. var., *Goniodes intermedius*, *Menopon productum*, *M. mikadokiji* n. sp., on *Calophasis mikado*; *Lipeurus formosanus* n. sp., *L. rubrifasciatus*, *Gonicotes microcephalus* n. sp., *Menopon pallescens*, *M. longipectum* n. sp., on *Arboricola crudigularis*; *Colpocephalum umbrinum* var. *trilobatum* on *Tringa subminuta*; *Nirmus incanis* on *Tringa ruficollis*; *Lipeurus baculus* on

*Turtur chinensis*; *Lipeurus baculus* and *Goniocotes kurodai* n. sp. on *Spenocercus sororius*; *Docophorus communis* on *Pericrocotus griseigularis*; *Lipeurus baculus* and *Goniocotes kurodai* on *Grancalus rex-pineti*; *Menopon urocissae* n. sp. on *Urocissa cerula*.

FEEDS  
AND FEEDING

881 - **A Study of the Dietary Essential, Water-Soluble B, in Relation to its Solubility and Stability towards Reagents.** — MCCOLLUM, E. V. and SIMMONDS, N. (Laboratory of Agricultural Chemistry of the University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXXIII, No. 1, pp. 55-89, 11 Diagr., Bibliography of 13 Publications. Baltimore, Md., January, 1918.

In conducting the work reported in this paper the authors fed rats on a diet of purified food substances together with 5 per cent of butter fat to supply an abundance of the fat-soluble A. This diet was complete except that it was free from the water-soluble B. The rats were confined to this food mixture until they either had become stationary in weight or were declining. By the 5th week nearly all were either stationary in weight or were failing and they almost invariably showed signs of paralysis at about this time. When the rats were thus prepared, the material to be tested for the water-soluble B was put into the diet. The animals then either continued to decline or responded with growth. This method served to show within 2 weeks whether the substance B was contained in significant amount in the preparation under investigation.

In the experimental part of this paper it is shown that the water-soluble B is not extracted directly from beans, wheat germ, or pig kidney by ether, benzene, or acetone, but it is readily extracted in great part by alcohol. After being removed by alcohol it is shown to be soluble in benzene, but very slightly soluble in acetone. The probability that there should be two or more physiologically indispensable substances in what is termed water-soluble B, both or all of which should show the same solubility relations with three solvents, is relatively small and lends support to the authors' view that the substance which protects animals against polyneuritis is the only essential complex in the extract described. In other words, the data support the view that there are no specific substances present in these extracts which protect against such diseases as scurvy, rickets, pellagra, sprue, etc., and tend to confirm the contention that the latter are not due to specific starvation as in the case with beri-beri and xerophthalmia (1).

882 - **A Comparative Study of the Behaviour of Purified Proteins towards Proteolytic Enzymes.** — FRANKEL, E. M. (Sheffield Laboratory of Physiological Chemistry, Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XXVI, No. 1, pp. 31-59 + 9 Tables + 4 Diagrams. + Bibliography of 33 Publications. Baltimore, Md., August, 1916.

After having rapidly considered the methods — physico-chemical, optical, colorimetric, purely chemical — used up to the present for studying the processes of digestion, the author describes his experiments for the pur-

(1) See R. January 1918, No. 2 (Ed.)

pose of studying the digestibility of the white of egg by means of pepsin, trypsin and erepsin; the results obtained by the author are given below.

It has been demonstrated that pepsin is the effective agent in pepsin-hydrochloric acid digestion, since hydrochloric acid alone in the concentrations ordinarily employed has very little proteolytic effect. As a result of a series of experiments the conclusion seems justified that comparable results in proteolysis studies are to be obtained only when the substrates are in solution; otherwise deviations of 10 to 15 per cent may be encountered in duplicate experiments. An examination of the digestion of thirteen proteins shows that there is a parallelism in the cleavage curves of all the proteins, if the cleavage is calculated as the ratio of the amino-nitrogen liberated at any one time to that obtained on total hydrolysis of the protein with strong acid.

Pepsin-hydrochloric acid can liberate about 20 per cent. of the total amino-nitrogen of a protein in less than 100 hours. Trypsin acting upon proteins partially digested with pepsin effects a cleavage of about 70 per cent. The action of trypsin upon native proteins can cause a cleavage of about 50 per cent of the peptide linkages. Further addition of trypsin may cause further disintegration of the protein.

Erepsin following the action of pepsin is a very effective agent in causing the disruption of the protein molecule. In two series of experiments cleavage of about 85 per cent of the protein could be demonstrated. The successive action of pepsin, trypsin, and erepsin liberates about 85 to 90 per cent of the total amino-nitrogen of the protein studied.

**883 - Study of the Proteins of Certain Insects with Reference to their Value as Food for Poultry.** — MCHARGUE, J. S. (Laboratory of Chemical Research, Kentucky Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. X, No. 12, pp. 633-637 + Bibliography of 9 Publications. Washington, September 17, 1917.

THOMAS was the first to demonstrate experimentally that animal proteins are much superior to vegetable proteins in maintaining the nitrogen equilibrium of the animal body. He showed that the minimum daily quantities necessary to protect body protein from loss were: — meat protein 30 gm., milk protein 31 gm., rice protein 34 gm., potato protein 38 gm., bean protein 54 gm., bread protein 76 gm., maize protein 102 gm.

The author determined the percentage of growth-promoting acids in the proteins of two common insects — the June bug (*Lachnosterna* sp.) and the grasshopper (*Melanoplus* spp.) as compared with the percentage of proteins in roast beef and turkey white meat. He found the following values for each of the two insects respectively: — Ammoniacal nitrogen, 8.96, 9.14; melanin, 6.78, 3.42; arginin, 11.53, 14.98; histidin, 6.57, 5.62; cystin, 0.35, 0.23; lysin, 8.02, 8.04; amino nitrogen (in filtrate from bases), 50.80, 52.87; non-amino nitrogen (in filtrate from bases), 5.84, 4.32. There is, on the whole, a great similarity in the proteins from such different sources. There is a close agreement in the lysin and arginin contents of the two insects studied and beef and turkey meat. In the beef and turkey the percentage of cystin is almost double and that of histidin two to three times that of the insects.

The protein content of grasshoppers, killed by potassium cyanide, dried at 100° C., ground in a mortar, and kept in a closed bottle for seven months, underwent no alteration, thus showing that the dried material can be kept indefinitely. An analysis of the dried matter gave the following percentages: — Protein, 75.28; ether extract, 7.21; crude ash, 5.61. Dried grasshoppers contain more protein than commercial meat meal and would probably be an excellent substitute for it in poultry feeding.

884 — **Utilization of Farm Wastes in Feeding Live Stock in U. S. A.** — RAY, S. H., <sup>111</sup>  
*U. S. Department of Agriculture, Farmers' Bulletin 873*, pp 1-12. Washington, D. C., April, 1917.

More than  $\frac{1}{3}$  of the total production of cereal straw in the United States is not used to advantage, and  $\frac{1}{2}$  of this amount is a total loss, the value of which is estimated at more than \$ 100 000 000. In a three years' study of corn-belt cattle the Office of Farm Management found that the breeding herds maintained most largely on oat or wheat straw, maize stover, etc. (with a very small quantity of concentrated feed such as cottonseed meal, maize, etc.), returned the largest profits.

Of all the uses to which straw and maize stover may be put, the only really economical ones are as food or bedding, and, of these two, their use as food is by far the most satisfactory.

To prepare stover for feeding purposes it should be cut and shocked; it may be chopped or shredded if cheap power and labour are available, but otherwise the cost is disproportionate to the advantages gained. Waste is greatly decreased by shredding or cutting dry corn stover and putting it in the silo with water. Of all the methods, ensiling is the most economical. Straw and stover should be used in the fattening rations of all animals except hogs, and should compose the larger part of all winter or maintenance rations for cattle, sheep and horses. Breeding herds of beef cattle, and dairy cows do well on rations composed largely of these products; the same applies to ewes if some grain is added. Horses doing very light work or none at all need little grain if they have a liberal allowance of clean straw or stover. Rye straw should not be fed to dairy cattle, because of its toughness and the danger from ergot, and buckwheat straw, on account of its low food value, should only be given when other roughages are not available. When barley straw is used the mouths of the cattle should be examined occasionally as the dry, stiff beards are apt to set up irritation.

The following rations are proposed for various classes of animals: —

**BEEF CATTLE. Winter rations. —**

- 1) Straw, 10 lb.; silage, 20 lb.; cottonseed or linseed meal, 1 lb.
- 2) Straw, 20 lb.; cottonseed or oil cake, 2 lb.
- 3) Straw, 10 lb.; maize fodder, 10 lb.; cottonseed or linseed meal, 1 lb.
- 4) Stover, 35 lb.; cottonseed or linseed oil meal, 1 lb.

**Fattening rations (for 1 000 lb. steers). —**

- 1) Straw, 5 lb.; silage, 18 lb.; maize, 12 lb.
- 2) Straw, 8 lb.; leguminous hay, 6 lb.; cottonseed or linseed cake, 5 lb.
- 3) Stover, 10 lb.; silage, 15 lb.; maize, 12 lb.
- 4) Straw, 5 lb.; stover, 15 lb.; maize, 6 lb.; cottonseed meal, 3 lbs.

DAIRY CATTLE. *Ration for dry cows, bulls and heifers.* —

Maize stover and straw, unlimited; clover hay, 10 lb.; maize silage, 20 lb.; cottonseed meal, 1 lb.; maize- and-cob meal, 2 lb.

*Ration for cows about to calve.* —

Maize stover, 5 lb.; clover hay, 12 lb.; maize silage, 25 lb.; wheat bran, 3 lb.

*Ration for cow giving 16 lb. of 4 % milk.* —

Maize stover and straw, unlimited; clover hay, 12 lb.; maize silage, 20 lb.; cottonseed meal, 2 lb.; maize-and-cob meal, 3 lb.

*Ration for cow giving from 20 to 25 lb. of 4 % milk.* —

Maize stover and straw, unlimited; clover hay; 12 lb.; maize silage, 25 lb.; cottonseed meal, 2 lb.; maize and cob meal, 3 lb.; gluten feed, 3 lb.

SHEEP. (Supplementary rations with a little grain). —

1) Maize stover, 2 lb. (amount eaten, not amount fed); leguminous hay, 2 lb.

2) Oat straw, 2 lb.; leguminous hay, 2 lb.;

3) Oat straw or maize stover, 1 lb.; silage, 1 1/2 lb.; leguminous hay, 2 lb.

HORSES. *Maintenance rations for 1000 lb. idle horse.* —

1) Maize stover, 9 lb.; alfalfa hay, 3 lb.; maize on cob, 5 lb.

2) Oat straw, 8 lb.; alfalfa, 8 lb.; cane molasses, 3 lb.

*Daily ration for 1000 lb. horse at light work* —

Maize stover, 5 lb.; Bermuda hay, 5 lb.; cottonseed meal, 1/2 lb.; cowpeas, 2 lb.; shelled maize, 5 lb.

*Daily ration for 1000 lb. horse at heavy work.* —

Maize fodder, 4 lb.; alfalfa, 12 lb.; ground soy beans, 1 lb.; shelled maize, 12 lb.

*Daily rations for 1250 lb. idle horse.* —

1) Maize stover, 11 lb.; alfalfa, 5 lb.; ear maize, 4 lb.

2) Oat straw, 10 lb.; pea hay, 4 lb.; common beets (or other roots or silage), 4 lb.; oats, 4 lb.

*Daily ration for 1250 lb. horse at light work.* —

Barley straw, 5 lb.; alfalfa hay, 6 lb.; rolled barley, 8 lb.

*Daily ration for 1500 lb. idle horse.* —

Maize fodder (with ears), 18 lb.; alfalfa, 5 lb.

## BREEDING

885 — **Observations on the Inheritance of Colour and Distribution of Sex in Certain Animals at the Government Cattle Farm, Hissar, Punjab, India.** — BRANFORD, R. (Superintendent, Government Cattle Farm, Hissar), in *The Agricultural Journal of India*, Vol. XII, Pt. IV, pp. 573-578. Calcutta, October, 1917.

**INHERITANCE OF COLOUR IN MULES.** — Several years of breeding gave the following results:

Number and colour of mares	Colour of donkey	Number and colour of males
12 } bay or brown	black or dark brown	111 bay or brown
12 } bay or brown	mouse-colour	6 bay or brown
13 chestnut	black or dark brown	41 bay or brown
1 chestnut	mouse-colour	1 bay
13 roans	black or dark brown	18 bay or brown; 2 dun
14 grey	black or dark brown	18 bay or brown; 6 grey; 2 dun; 1 mouse-colour.
6 grey	mouse-colour	6 bay or brown.
4 dun	black or dark brown	4 bay or brown.
1 dun	mouse-colour	1 bay
2 sk. white	black or dark brown	3 bay or brown.

It is seen, therefore, that by crossing brown or mouse-coloured donkeys with brown or chestnut mares bay or brown mules, are sure to be obtained. The army prefers dark mules. Chestnut colour, which is recessive in mares and does not exist in donkeys, is rarely found in mules though it does occur. Of 1200 mules entered in the register of the Government Cattle Farm, Hissar, 8 were chestnut. Similarly, by crossing dun, roan or skewbald mares with dark donkeys, bay or brown mules are nearly always obtained. Uniform colour in donkeys seems dominant to white spots on the head and legs in mares, as mules practically never have these spots.

From two chestnut mares and one skewbald mare served by a zebra were obtained three hybrids with coats having a light bay, rather yellow ground, and the distinctive black markings of the zebra.

#### INHERITANCE OF COLOUR AND DISTRIBUTION OF SEX IN DONKEYS.

— The following data are compiled from the Government Cattle Farm, Hissar register. It is pointed out that mistakes may easily be made in describing a donkey as grey; this largely discounts the value of the figures:—

Number and colour of mares	Colour of stallion	Number and colour of foals
16 brown	black or dark brown	82 brown; 8 grey; 3 mouse-colour.
4 brown	mouse-colour	2 mouse-colour; 1 grey; 1 brown.
9 mouse-colour	black or dark brown	14 mouse-colour; 17 brown; 6 grey;
1 mouse-colour	mouse-colour	1 mouse-colour.
4 white	black or dark brown	12 grey; 1 brown; 6 mouse-colour
13 grey	black or dark brown	26 brown; 5 mouse-colour, 27 grey.

It seems that, as a rule, black or dark brown donkeys transmit this colour to their progeny. The striking tendency of the coats of grey horses and mules to turn lighter with age is not observed in donkeys, whose coats tend to become darker. During the last 10 years 530 donkeys, of which 272 were colts and 258 fillies, were born at the Government Cattle Farm, Hissar.

**INHERITANCE OF COLOUR IN SHEEP.** — Seven lambs of five black ewes served by an Australian white Merino ram were all black.

**INHERITANCE OF COLOUR AND DISTRIBUTION OF SEX IN CATTLE.** — Red Sihwal cows bred to a red bull of the same race gave 48 red calves and 2 grey ones. Sihwal cattle may be of various colours, but red is usually preferred. During the last 10 years there were born on the Hissar Government Farm 7642 calves, of which 3927 were male and 3715 female.

886 — **Oatless Rations for Draught Horses.** — DECHAMBRE, M. P., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 15, pp. 480-497. Paris, May 1, 1918.

HORSES

This is a paper presented to the "Académie d'Agriculture", indicating the substitutes which may be advantageously used at the present time in the feeding of draught horses, and giving formulae for mixing them so as to obtain a food value equal to that of oats, as well as complementary rations containing rough and concentrated foodstuffs.

The food value of a substitute is based on the amount required to replace 1 lb. of oats. The proportion, however, is not constantly exact; to

obtain a good ration of substitutes the foodstuffs must be judiciously mixed in order to obtain the essential result; *i. e.*, to give the animal amounts of food equal to its original ration without modifying perceptibly the volume and bulk of the ration or the equilibrium established by determining its nutritive ratios.

*Equivalency in oats of the principal substitutes* (weight in lbs. equal to 1 lb. of oats):

Groundnut cake . . . . .	0.745	Molasses straw (25 % saccharose) . .	1
Locust bean . . . . .	1	Palm kernel cake . . . . .	0.850
Copra cake . . . . .	0.800	Paddy . . . . .	1
Dried brewer's grains . . . . .	1.100	Sesame cake . . . . .	0.760
Barley germ . . . . .	0.900	Soya cake . . . . .	0.725
Cottonseed cake . . . . .	0.800	Soya meal . . . . .	0.750
Nut cake . . . . .	0.750		

*Formulae for mixing concentrated foods capable of replacing oats* (in lbs.).

1) Groundnut cake 1, cottonseed cake 0.500, barley germ 1, molasses straw 1.500.

2) Palm kernel cake 1, soya cake 0.500, bran 1.

3) Dried brewer's grains 1.500, rice residue 0.750, groundnut cake 0.500, copra cake 0.500.

4) Groundnut cake 2, bran 2, molasses straw 2.

5) Rice residue 2, groundnut cake 0.400, meat meal 0.150.

One pound of each of these mixtures will replace 1 lb. of oats; the final ration should be completed with hay and straw.

The following simpler mixtures are intended for partial substitution by available materials; each has the same food and energy value as 1 lb. of oats:

1) Equal weights of dried brewer's grains, rice residue, wheat bran, cottonseed or copra cake.

2) Equal weights of wheat bran, dried brewer's grain, groundnut meal.

3) Equal weights of sorghum or barley bran, dried brewer's grains, soya meal.

4) Wheat bran 0.900 lb., rice residue 0.600 lb.,

5) Rice bran 0.750, groundnut cake 0.150,

6) Barley roots 0.700, bran 0.400; mixture recommended for the preparation of mash.

These formulae may be varied in numerous ways. Chopping hay and straw makes possible other combinations of which the following two are samples: —

1) Groundnut cake 15 lb., cottonseed cake 5, bran 20, molasses 20, chopped straw 25, chopped hay 20; 1.1 lb. of this mixture equal 1 lb. of oats.

2) Cake (groundnut, sesame) 1 lb., soya meal 5, cottonseed cake 2, bran 18, molasses 20, chopped straw 25, hay 20; 0.98 lb. equal 1 lb. of oats.

Other foodstuffs — sorghum and buckwheat brans (which contain four times more cellulose than ordinary bran), sainfoin seed unsuitable for germination (food value similar to that of oats; should be used in small

quantities, in the natural state and mixed with oats or after soaking), beet seed also unsuitable for sowing (value = about  $\frac{2}{3}$  that of wheat bran.)

*Aqueous foodstuffs.* — Tubers and roots may be used in feeding horses to a larger extent than is customary, thus allowing a reduction in the quantity of oats. The amount to be substituted cannot be calculated with as much precision as for the preceding foods because of the difference in chemical composition and especially in the volume and water content of this produce.

*Carrots.* — 1 lb. of oats, 1 lb. of hay, 1 lb. of straw may be replaced by 6 lb., 3 lb., and 2 lb. of carrots respectively. The usual carrot ration is 12 lb. for a horse of the average weight of 1 000 lb.

*Parsnip.* — Preferred to carrot in Brittany; same proportion for substitution.

*Beet.* — As much as 22 to 26 lb. may safely be given to horses used for field work

*Jerusalem artichoke.* — A ration of 22 to 26 lb. may be safely fed; 3.5 to 4 lb. equal 6 lb. of carrots. A heavy draught horse (to which this foodstuff is better suited than to a carriage horse) can consume 13.2 lb. of Jerusalem artichoke, thereby replacing 3.3 lb. of oats or similar produce.

*Boiled potatoes.* — An amount equal to 0.9 lb. of dry matter is equal to 1 lb. of oats; thus, 3.60 lb. of average quality potatoes containing 25 % of dry matter can replace 1 lb. of oats. The ordinary ration is 11 lb. as a substitute for 2.97 lb. of oats.

All these substitutes should be worked on to gradually, beginning with small quantities; this is essential to avoid refusal to eat them and consequent waste.

Horses may be profitably put to grass and fed on alfalfa and green clover to economise maintenance expenses, but they must be put on oats again as soon as they re-start heavy work. The amount of green fodder which can be fed daily to a horse of 1 000 to 1 300 lb. without danger of digestive trouble, varies from 88 to 110 lb. according to the nature of the soil and the forage.

887— **Winter Steer Feeding Experiments in Indiana, U. S. A.** (1). — SKINNER, J. H. and KING, F. G., in *Purdue University Agricultural Experiment Station Bulletin* No. 206, Vol. XX, pp. 1-28. Lafayette, Indiana, September, 1917.

CATTLE

The ration feeding trials reported in this bulletin were conducted under exceptional economic conditions. The object of the trial was to obtain additional information on the comparative value of leguminous hay alone and in combination with maize silage as roughage for fattening cattle, to test the comparative value of clover hay and alfalfa hay as roughage for full-fed cattle, and to test the value of different rations with a limited feed of maize with maize silage as compared with a full feed of maize for finishing steers.

*Plan of experiments.* — Seventy medium feeding cattle were secured

(1) For similar experiments conducted under normal conditions see also R. June 1918, No. 668. (Ed.)

and divided into seven lots of ten steers each, as nearly alike as possible in size, condition, quality, thrift and breeding.

Each lot of cattle was placed in similar surroundings and fed for 140 days. The only differences between lots were in the rations fed which were as follows:—

*Lot 1.* No maize during the first month and a gradually increasing amount of shelled maize for the remainder of the period, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, maize silage, clover hay throughout entire period.

*Lot 2.* Shelled maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, clover hay.

*Lot 3.* Shelled maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, alfalfa hay.

*Lot 4.* Shelled maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, maize silage, clover hay.

*Lot 5.* No maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, maize silage, clover hay.

*Lot 6.* One-half feed maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, maize silage, clover hay.

*Lot 7.* Shelled maize, cottonseed meal 2.5 lb. daily per 1 000 lb. live weight, maize silage, alfalfa hay.

The prices of feeds used in presenting financial results are based on the actual market prices at the time the experiment was in progress. The average price of maize in La Fayette was as follows:—first month 88.3 *cents*, second month 93.9 *cents*, third month \$ 1.007, fourth month \$ 1.138, fifth month \$ 1.431 per bushel, cottonseed meal \$ 45.00 per ton, clover hay and alfalfa hay \$ 12.00 per ton, maize silage \$ 6.00 per ton. All financial statements are based on the above mentioned prices of feeds.

Each lot of cattle also contained ten hogs. They were of good quality and averaged approximately 105 lb. per head at the time the experiment started. All lots of hogs received maize in addition to droppings from the cattle. Table I shows a summary of the feeding operations and their results as relating to the 7 lots, comparing:—in lots 2, 4, 3, 7 (Part I) maize silage and leguminous hay vs. leguminous hay as roughage; in lots 4, 1, 6, 5 (Part II), a limited feed of maize with a full feed of maize; in lots 2, 3, 4, 7 (Part III); clover vs. alfalfa hay as roughage.

In the determination of costs no charge was made for straw used for bedding nor for labour of feeding; neither is any credit given for any manure produced by the cattle, it being considered that this by-product will pay for the labour of feeding and the straw used for bedding.

The principal results of these experiments may be summarized, as follows:—

*Part I.* (Maize silage and leguminous hay vs. leguminous hay as roughage for fattening steers; Lots 2, 4, 3 and 7).

The addition of 33.88 lb. of maize silage to a ration of shelled maize, cottonseed meal and clover hay, decreased the daily maize consumption 2.79 lb. per head and the daily hay consumption 11.46 lb. per steer.

## Summary of Experiments.

Part I, II, III.

Ration	Lot 1 Shelled maize (1), cottonseed meal, maize silage, clover hay	Lot 2 Shelled maize, cottonseed meal, clover hay	Lot 3 (2) Shelled maize, cottonseed meal, alfalfa hay	Lot 4 Shelled maize, cottonseed meal, maize silage, clover hay	Lot 5 No maize, cottonseed meal, maize silage, clover hay	Lot 6 One-half feed maize, cottonseed meal, maize silage, clover hay	Lot 7 Shelled maize, cottonseed meal, maize silage, alfalfa hay

(1) Fed limited grain ration.

(2) Nine steers in Lot 3.

The addition of 34.21 lb. of maize silage to a ration of shelled maize, cottonseed meal and alfalfa hay, decreased the daily maize consumption 3.06 lb. per head and the daily hay consumption 13.00 lb. per steer.

The addition of maize silage to a ration of shelled maize, cottonseed

meal and clover hay, increased the rate of gain 0.19 lb. daily per steer. The addition of maize silage to a ration of shelled maize, cottonseed meal and alfalfa hay, decreased the rate of gain 0.15 lb. daily per head.

The addition of maize silage to the ration, decreased the cost of gain \$ 2.48 per hundred pounds when clover hay was fed and 41 cents per hundred pounds when alfalfa hay comprised a part of the ration.

Maize silage in the ration increased the selling value of the cattle 25 cents per 100 lb.

The profit per steer not including pork was increased \$ 10.08 per steer by adding maize silage to a ration of shelled maize, cottonseed meal and clover hay; the profit per steer not including pork was increased \$ 6.10 by the addition of maize silage to a ration of shelled maize, cottonseed meal and alfalfa hay.

*Part II.* (A limited feed of maize as compared with a full feed of maize for fattening steers. Lots 4, 1, 6 and 5).

The elimination of maize from the ration of shelled maize, cottonseed meal, maize silage and clover hay induced the cattle to increase the roughage consumption 19.33 lb. of maize silage and 0.87 lb. of hay daily per head.

The elimination of one-half the maize in the ration of shelled maize, cottonseed meal, maize silage and clover hay induced the cattle to increase the roughage consumption 8.77 lb. of maize silage and 0.7 lb. of hay daily per head. Feeding no maize during the first month and afterwards a gradually increasing amount until the fifth month, when it amounted to 11 lb. daily per head, induced the cattle to increase the consumption of roughage 10.15 lb. of maize silage and 1.97 lb. of hay daily per head. Cattle receiving a full feed of shelled maize in addition to cottonseed meal, maize silage and clover hay, gained 2.50 lb. daily per head at a cost of \$ 17.51 per 100 lb. gain. Cattle receiving no maize in addition to cottonseed meal, maize silage and clover hay, gained 1.63 lb. daily per head at a cost of \$ 14.87 per 100 lb. gain. Cattle receiving one-half feed of shelled maize in addition to cottonseed meal, maize silage and clover hay, gained 1.62 lb. daily per head at a cost of \$ 20.97 per 100 lb. Cattle receiving a gradually increasing amount of maize in addition to cottonseed meal, maize silage and clover hay gained 1.91 lb. daily per head at a cost of \$ 18.12 per 100 lb.

*Part III* (Clover hay vs. alfalfa hay as roughage for fattening steers; Lots 2, 3, 4 and 7).

Cattle fed a ration of shelled maize, cottonseed meal and clover hay consumed slightly less maize and considerably less hay than cattle fed alfalfa hay instead of clover hay.

Cattle fed a ration of shelled maize, cottonseed meal, maize silage and clover hay consumed slightly more grain and hay but less silage than cattle receiving a similar ration with alfalfa hay replacing the clover hay.

Cattle fed hay in addition to shelled maize and cottonseed meal, gained 2.31 lb. daily per head when clover hay was fed and 2.16 lb. daily per head when alfalfa hay was fed.

Cattle fed clover and alfalfa hay in addition to shelled maize, cotton-

seed meal and maize silage gained 2.5 lb. daily per head when the hay was clover and 2.01 lb. daily per head when it was alfalfa.

Gains on cattle were made at a cost of \$ 19.99 per 100 lb. when the roughage was clover hay and \$ 21.77 per 100 lb. when it was alfalfa hay ; at a cost of \$ 17.51 per 100 lb. when the roughage fed consisted of maize silage and clover hay as compared to a cost of \$ 21.36 per 100 lb. when the roughage consisted of maize silage and alfalfa hay.

Cattle fed a ration of shelled maize, cottonseed meal and clover hay, were valued at \$ 11.75 per 100 lb. and returned a profit not including pork of \$ 10.85 per head, as compared to a value of \$ 11.75 per 100 lb. and a profit of \$ 7.74 per head when clover hay was replaced by alfalfa hay.

With maize silage added to the same ration, cattle were valued \$ 12.00 per 100 lb. and returned a profit not including pork of \$ 20.93 as compared with \$ 13.84 per head when clover hay was replaced by alfalfa hay.

**888 - The Relation of the Quality of Proteins to Milk Production.** — HART, E. B. and HUMPHREY, G. C. : I. with the cooperation of SCHAAL, A. A. II. with the cooperation of SURE, BARNETT (Department of Agricultural Chemistry and Animal Husbandry of the University of Wisconsin, Madison), in *The Journal of Biological Chemistry*, Vol. XXVI. No. 2, p. 457-471 + 4 Diagr. September, 1916; Vol. XXXI, No. 2, pp. 445-460 + 7 Diagr. August, 1917, Baltimore, Md.

I. — In 1915 the authors presented data showing marked inequality in the efficiency of the protein mixture of rations for milk production (1). These further studies furnish additional evidence that the nutritive ratio or plane of protein intake for milk production may vary according to the nature of the concentrates and basal ration used.

Data are presented on the comparative value for milk production of the proteins of gluten feed, oil meal, distiller's grains, casein, and skim milk powder. These concentrates furnished 50 per cent of the total digestible protein of the ration and were used to supplement a basal ration of maize stover, maize silage, and maize meal. The total protein intake constituted about 10 per cent of the dry matter of the ration and the nutritive ratio was approximately 1 : 8.

With a daily production of 40 to 45 lb. of milk carrying 10 to 12 per cent of total solids, negative nitrogen balance persisted throughout the experiment of 16 weeks' duration. Only during the period of skim milk powder feeding was one of the animals storing nitrogen. In spite of this long negative balance milk secretion continued at the expense of catabolizing tissue. The total yields and total solids of the milk declined slightly after 2 months of continuous negative nitrogen balance.

There was a marked difference in the utilisation of the concentrates ; gluten feed showed a percentage efficiency of 45, oil meal 61, distiller's grains 60, casein 59, and skim milk powder 60. These data represent the efficiency in the mixture used.

(1) See B. August, 1915, No. 834. (Ed.)

II. — In the preceding article the writers pointed out that the comparison would probably hold only for the mixture studied and that a different behaviour might be expected should the basal ration be varied. These expectations were entirely confirmed by the results given in this paper, which are summarised as follows:—

The concentrates involving gluten feed, oil meal, distiller's grains and cottonseed meal, furnished approximately 40 per cent of the digestible protein of the ration and were used to supplement a basal ration of maize meal, maize silage, and clover hay. The total protein intake constituted about 12 per cent of the dry matter of the ration and the nutritive ratio was approximately 1:8.5. On this low protein intake positive nitrogen balances were maintained during most of the period of observation (16 weeks) with a slow shrinkage in milk volume, but a maintenance of the percentage composition of the milk.

Earlier records showed the inferiority of the proteins of gluten feed as a supplement to the proteins of maize meal and maize stover for milk production to those of oil meal, distiller's grains, or milk. These records show an equality in efficiency between the proteins of gluten feed, oil meal, distiller's grains, and cottonseed meal as supplements to the proteins of maize meal and clover hay for milk production.

These facts must emphasize in a very striking manner the limitations of any classification of natural foods in respect to the efficiency of their proteins, based on the determination of such nutritive worth in a single food material or a single food mixture.

#### SHEEP AND GOATS

889 — **A Cross Between a Goat and a Ram, in Brazil.** — SEIXAS, DANTON DE, in *A. Estancia*, Year VI, No. 3, pp. 57-60 + 4 Figs. Porto Alegre, March, 1918.

An common 3-year black-marked goat, served by a common white ram bore two healthy kids having the characters of both the parents. A photo accompanying the article shows one of them with white wool (belonging to the author at Porto Alegre, Brazil).

#### VARIOUS ANIMALS

890 — **Study on the Land and Fresh-water Snails of Indo-China.** — DEMANGE, V., in the *Bulletin économique de l'Indochine*, Year XXI, New Series, No. 128, pp. 88-100 + 6 Plates of 27 col. Figs. Hanoi-Haiphong, January-February, 1918.

The poorer classes in Indo-China use land, and especially fresh-water, snails very largely as food, enormous quantities being consumed. The mother of pearl has only recently been exploited and will probably be of importance in the future.

A description of 20 fresh-water and 3 land species is given, together with the Latin and Annamite names.

### FARM ENGINEERING.

#### AGRICULTURAL MACHINERY AND IMPLEMENTS

891 — **Electricity in Agriculture: Consumption, Distribution and Ploughing.** — TARCHETTI, A., in *Il Giornale dell'Agricoltura*, Year VIII, N° 2, pp. 25-30, No. 3, pp. 41-46. Vercelli, February 28 and March 31, 1918.

**CONSUMPTION.** — From the standpoint of Piedmontese conditions, where the soil is mostly average, with a resistance of 40 to 60 kg. per sq. metre of soil ploughed, the author calculated that, for a normal ploughing.

at 15 to 25 cm. deep, the theoretical work per hectare would be an average of  $1,000,000 \times 50 \times 0.20 = 10$  million kilogrammetres, corresponding to a consumption of 27.2 kw.-hour, but as electric ploughs do not yield more than 50 %, the average energy consumed would not be less than 50 kilowatt-hours per hectare (1). The societies for the application of electricity to agriculture in Piedmont, where a million hectares could be cultivated in this way, ought to study the outline of the chief lines, the quality and tension of the current, and the conditions of sale of electrical energy to farmers.

**DISTRIBUTION.** — As the plough has to be moved from one field to another, the electric motor has to be supplied with current no matter where it moves. Thus a short, movable, low-tension line is needed, joined to a fixed or movable transformer cabin, which is connected to the main supply by a second, high-tension line, either fixed or loose. The author is convinced that to assure safe and easy electric ploughing, it is absolutely necessary to fix permanent secondary lines and establish transformer stations. The supply companies should be paid to fix the secondary lines and run the transformer stations themselves, without which the author is certain that there will never be any great development of electric ploughing.

The author thinks that economic and practical difficulties could be solved by using motors of as high tension as possible, always providing for the safety of the workmen, so that the low-tension line would allow of the cabin being moved without any notable fall of potential, while making it lighter and easier to handle.

Taking the case of a cable machine that can plough 100 hectares per station, there is a maximum radius of 550 metres; if the low-tension wire can be prolonged up to 500 metres from the transformer, a single station could serve about 350 hectares, which would correspond to the annual working capacity not of 1, but of 2 ploughing machines. But if a continuous current was available (or if the alternating current was transformed in the same cabin by means of a converter or a static mercury rectifier), at the same time raising the tension up to 500 volts even and eliminating anxiety for losses in yield from the 3-phase motors on account of the decrease of the power factors, the effective radius of the cabin might be increased to more than 1,300 metres, or over an area of more than 500 hectares.

It is obvious that, under such conditions, the installation cost of a short, permanent, secondary line and a fixed transformer station is slightly compensated for by the surplus energy that the station can supply without including:—

- 1) the small cost of upkeep and greater working safety;
- 2) the possibility, even the desirability, of using fixed, secondary lines of steel, iron or even copper;
- 3) the possibility of using oil-cooled transformers, surer and better

(1) In the ricefields in the Vercelli region (Sig. SEMENZA and A. TARCHETTI, "Le prove di aratura elettrica in risaia", Ed. Società An. d'Elettricità Alta Italia, 1915), on light soils (37 kg. per sq. dm.) at 23 cm. deep, a consumption of 48.3 kw.-hour, measured at the transformer, was found for a cable machine.

yielding and of such a power that several machines could be working simultaneously.

**PLOUGHING.** — The author reviews the FOWLER, HOWARD, and ZIMMERMANN (1) systems as regards their use in Italy. He notes that the last system (cable haulage) has been recently applied to a PATUZZO machine by the engineer G. GOLA. In the GOLA apparatus, the insulated and live conductor consists of a movable aerial wire parallel to the furrows, easily transportable, mounted on terminal stretchers and intermediate posts; an ingenious counterpoise arrangement assures the constant contact of the tackle, which, sliding on the line, transmits the current to the motor, through a trolley. However, the author states that it is awkward to move the line in practice, two such lines being required for continuous working, and they have to be moved every 8 or 10 yards of breadth of ploughing.

As regards direct electric traction, the author thinks that the difficulty of supplying current when turning necessitates the disuse of one-way motor ploughs, and that the system should only be applied to balance ploughs.

**892 — The Transformation of Motorcars and Motor-lorries into Agricultural Tractors and Windlasses (Landrin System).** — FREMIER, V., in *Le Génie Rural*, Year X, No. 81, pp. 9-10 + 2 Figs. Paris, 1918.

M. MARCEL LANDRIN, of Soissons (Aisne, France), has devised two arrangements for transforming existing motorcar frames and motor-lorries into agricultural tractors and windlasses.

In the first device, between the ordinary driving and steering wheels are fitted 2 large diameter driving wheels with narrow tyres, which, provided with projections on each side, give a good grip on any soil without causing any damage. These wheels are chain-driven from chain-wheels keyed onto the hub of the ordinary driving wheels. Under direct drive, the reduction gives a speed of about 3 miles per hour. The special wheels are connected to the frame by springs that allow of sufficient suppleness to avoid strain. When the vehicle runs on the road the springs of the ordinary driving wheels are free, whilst the springs of the special wheels are kept compressed, so that the latter wheels are raised some 8 inches above the ground. For work in the fields, however, the compression on the springs is reversed, by means of an easy lever-movement, and the special wheels are used for driving while the ordinary driving wheels are lifted above the ground and only serve to convey the power. The axle of the special wheels is such that it carries nearly all the weight of the frame, using it to obtain grip.

The wheel base being thus much reduced, turning is carried out in a very short radius. Turning is facilitated by independent brakes for each wheel and by detachable hoops, mounted by the side of the steering wheels and which penetrate an inch or so in the soil. The draw bar hook for at-

(1) See R., 1917, No 1202. (Ed)

taching the implements is fixed as low as possible in front of the axle of the special wheels. Traction thus helps steering while adding to the grip of the driving wheels. This device allows of a vehicle being used equally well as a tractor or for transport. The device for transforming a motor lorry into an agricultural windlass is recommended for high-powered machines. It consists of a shaft placed on the frame above the back axle. The shaft carries 2 large windlass drums with internal teeth which engage with 2 wheels fixed on the interior of the driving wheels. The reduction is such that the cable speed is 3 miles per hour, in direct drive, the engine running at its normal rate.

The cables unroll in a direction parallel to the longitudinal axis of the frame, passing through two guides; because of the large diameter of the drums and the reduced breadth of the groove, the cables unroll quite easily. The equal tension of the two cables is provided for by the differential, which is an excellent compensator.

For moving sideways the front of the frame is carried on a small truck with 4 steering wheels and the back part on 2 detachable wheels. The movement is obtained by a capstan fixed on the drums or by a small windlass hauling on a fixed point. The back axle is held by grips that keep it in the required position. To move from the field, the drums are freed from the gears, the detachable wheels are removed and the back axle freed, and the small cart removed that supported the front frame. Thus small cart, which carries the accessories, is hooked behind the frame together with the plough, so that the whole machine moves under its own power. The machine can be removed and set up again very quickly. It would be particularly useful to sugar manufacturers, as by means of it they could haul their stores with 5 to 6 ton lorries towing trailers and then plough the land of the farmers that grow sugar-beets for them.

**893 - A Study of the Plough Bottom and its Action upon the Furrow Slice.** — WHITE, E. A. (Assistant Prof. of Farm Mechanics, College of Agric. of the University of Illinois), in the *Journal of Agricultural Research*, Vol. XII, No. 4, pp. 149-182 + 26 Figs. + 4 Plates. Washington, January 28, 1918.

Geometrically exact mouldboards (plough bottoms) have often provided the basis for more perfect developments, but the results obtained by empirical plough designers were so far superior to the results obtained in the laboratory that the theories were abandoned, the makers basing their work on practical experience only.

This paper is an attempt to begin a fundamental analysis of the plough bottom and its work, in the hope that some light may be thrown on the work, and other attempts stimulated to study the theory of this important implement. The writer's work can be divided into 3 parts: — 1) a study of the forms of plough bottoms; 2) an attempt to analyse the motion of the soil particles as they pass over the surface, and 3) a mathematical analysis of the surfaces of the most important historical plough bottoms which were designed to be geometrically exact.

For this work the author developed the equation for determining the surface of a plough bottom.

In studying the motion of the soil particles in ploughing, observations were carried out in grass-land with a sod plough in order to determine the compression or stretching of the furrow slice and the movement (speed and acceleration) of the soil particles composing the furrow slice. The observations obtained are discussed in detail, and some are supported by the mathematical results obtained.

The mathematical analysis of the mould board surfaces includes a study of the mould boards of JEFFERSON, LAMBRUSCHINI, SMALL, STEPHEN, RHAM, KNOX, MEAD, and HOLBROOK.

The author also discusses mould boards by DAVIS (1818), WITHEROW & PIERCE (1839), for which he had not sufficient data to enable him to develop the equations for calculating the surface.

894 - **The Russell Turnip Thinner.** — *The Implement and Machinery Review*, Vol. XXXIV, No. 517, p. 72 + 1 Fig. London, May 1, 1918.

There exists no turnip thinner that leaves only a single plant, but with a good machine, it is possible to leave a very small bunch of plants at regular intervals. A satisfactory machine which has proved its worth has been constructed by the MALDEN IRON WORKS Co., Ltd., Maldon, Essex. It may be used for thinning roots in general.

The RUSSELL thinner shown in the appended figure is provided with a serrated cutter, which can be quickly adjusted to leave very small or large bunches of plants. The thinning apparatus is nicely balanced, and is entirely under the control of the man working the machine. If the crop is patchy, the attendant can lift the cutters so that plants required to be left in are not taken out. The machine is fitted with 5 speeds, for gapping 8, 10, 12, 14 or 16 inches, whilst the cutting apparatus and road wheels are arranged to slide along the axle to suit varying widths of row.

The RUSSELL turnip thinner.

895 - The "Universal" Electric-drive Thresher. — *Schweizerische Landwirtschaftl. Zeitschrift*, Year XLVI, No. 22, pp. 462-465 + 2 Figs. Zurich, May 31, 1918.

This thresher, built by H. WOLF & Co., of Zurich (Switzerland), includes a wagon frame mounted on 4 wheels, at the back of which is placed the closed box containing the motor. The box contains the motor, the cut-out, and a drum with 325 to 650 feet of cable. On the front of the frame a thresher is mounted with a straw shaker, caving screen, elevator and bagging device. The machine is driven directly by the motor. The belts can be tightened as required, a spring friction-roller being provided. The feeding table and the straw delivery should not be removed for transport, so that the machine can start working in a few minutes. When the threshing season is over, the thresher can be removed by unscrewing 4 screws; a circular saw or other machine can then be mounted on the frame so that the motor can be used all the year round, which is a distinct advantage.

896 - Safety Devices for Chaff-cutters. — I. MASSARELLI, F., in *La sicurezza e l'Igiene nell'Industria*, Year III, No. 6, pp. 131-147 + 19 Figs. Milan, December 31, 1916. — II. BERTONI, C., in *Il Coltivatore*, Year LXIV, No. 1, pp. 6-10, + 3 Figs. Casale, January 10, 1918.

The author considers fly-wheel chaff cutters, which are the most used, and the means of preventing the accidents that are so common with these machines. These accidents can be classified as: — a) accidents due to the fly-wheel; b) accidents due to the feed rollers; c) accidents due to the gearing and drive in general. The safety devices applied to chaff-cutters are based on two different principles: —

1) Devices stopping or changing the movement of the feed rollers and platform by quickly moving suitable mechanisms by the hand or foot. The devices, though improving the working qualities of the machine, are only relatively efficacious, as they are rather *attenuating* than *preventive* devices and should be supplemented by others.

2) Devices, automatic or not, that make it impossible to pass the arm or hand beyond a certain limit into the mouth where the forage enters. For hand-driven fly-wheel chaff-cutters, the author describes guards, made of wood, cast iron, sheet iron, or grating. As regards protection against accidents that might happen when feeding the machine, a board, fixed on the edge of the hopper, and of sufficient length, will prevent the arm passing beyond a safe limit.

One of the essential conditions for the safety of machine-driven chaff-cutters is that there should be both a fixed and free pulley together with the disengaging gear that is so often lacking in the older machines. It should be so made that the belt cannot suddenly slip from the free on to the fixed pulley and thus start the machine. A lever disengaging gear mounted on a bracket is very suitable for belt-driven chaff-cutters, which should have a guard for the fly-wheel and a lattice protecting the knives.

This lattice, even when lowered on the feed-trough, allows the workman to see the position of his hands and watch the work more closely, and as it is connected by a lever to the side mechanism controlling the cylin-

ders and feed platform, if the workman's hands happen to pass into a dangerous position, the lattice lifts, thus stopping or reversing the movement

**897 — Balance for the Direct Reading of the Lint Percentage of Cotton.** — See No. 866 of this *Review*.

**898 — The Gibaudan Alcohol-meter.** — FOURNIER, L., in *Le Génie Civil*, Year XXXVIII, Vol. LXXII, No. 19, pp. 338-340 + 7 Figs. Paris, May 11, 1918.

The Company for the manufacture of meters and supplies for gas-works, France, makes an alcohol-meter for use in agricultural and commercial distilleries, to measure separately the production of pure alcohol and distillation waters. The meter consists of a rectangular box rounded on its upper part. The front face bears the thermometric and alcohol-metric graduations on an arc of a circle placed high up, between the dials of the clockwork registering the distillation waters and pure alcohol. Two air-bubble levels enable the apparatus to be levelled. Behind are the connections by which the liquid arrives and flows away, together with a by-pass so that the apparatus can be cut out without stopping distillation.

The measurement and recording of the pure alcohol are done automatically in the new meter, which discharges in quantities equal to the capacity of an interior measuring fly-wheel (constant volume), recorded by the distillation-water clockwork, then estimates the alcohol for each of them, the pure alcohol at 15° C being shown on a second dial.

The meter includes : — 1) a measuring fly-wheel consisting of a metal cylinder with thin walls, divided internally into 5 compartments by oblique partitions and worked by the weight of the liquid, which enters by an axial pentrough and then passes from the first compartment into the second, and so on ; 2) an alcohol-meter ; 3) a thermometer ; 4) a registering device.

A detailed description, illustrated by the necessary drawings, is given of the construction of the meter ; the mechanical connection of the various parts is also described in order to show the relation between them and the device recording the volumes of distillation water and pure alcohol.

900 — **Rapid House Construction with Concrete Studs.** — *Engineering News-Record*, Vol. LXXX, No. 13, pp 604-606 + 3 Figs + 2 Plans. New York, March 28, 1918.

The description of a new method of house construction with fire-resistant walls made of cement stucco on metal laths.

The system proposed by Mr. E. G. PERROT, of BALLINGER and FERROT, engineers and architects, Philadelphia, allows of building 10-unit rows, each house costing, at present prices of labour and materials, about \$ 2 500, including the cost of hot-air heating apparatus. The price is as low as that of similar houses of wood frame construction and is \$ 100 lower per house than where 8-in. brick walls are used for exterior and party walls.

The concreting is carried out in one operation, in which both the frame members and stucco are placed. After the cellar is excavated a stone or concrete foundation wall is built, and the first-floor wood joists are set in place on the foundation walls. On these joists a wood frame consisting of studs, joists and rafters is erected in the usual manner of building a frame house. Every fourth stud is doubled, allowing a 3 × 4-in. space between, which is later filled with concrete to form a concrete stud. At the second-floor and roof levels a ledger board with bottom attached is placed over the studs and so arranged that the concrete when completed will be continuous from foundation to roof. On top of the ledger board the second-floor joists are set, then the second-story studs and forms. When this frame is completed, heavy waterproof paper is nailed to the outside of the exterior wall studs, leaving the space between the doubled studs open to receive the concrete. Over the waterproofed paper the metal lath or concrete reinforcement is stretched. The concrete studs are reinforced with steel rods fastened to the metal lath.

The wood studs not only support the cement stucco while it is being applied, but also serve as furring strips in the finished building. A 2-in. concrete coating is next applied on the outside, and at the same time the spaces between the doubled studs and in the ledger boards are filled to form the concrete studs and caps. The work is preferably done with the cement gun, otherwise it is done by hand. The rapidity of the work depends only upon the number of cement guns used, or the number of workmen employed.

A concrete roof may be used on such a house, but Mr. PERROT prefers wood roof framing and a fire-resisting covering (asbestos and asphalted-felt shingles, slate, and built-up roofings of felt, tar and gravel).

According to the designers this method of construction eliminates shrinkage and settlement cracks. A ten-house unit can be built in 3 weeks from the time the cellar is dug. The method is considered to be well adapted for building barracks, hospitals and one-story factories.

## RURAL ECONOMICS.

901 - Study of some Egyptian Farms. — BAROIS, C., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 13, pp. 417-427 Paris, April 10, 1918.

At the Meeting of April 10, 1918 of the French "Académie d'Agriculture", the author described some capitalist farms in Egypt with the intention of pointing out to the French public the advantages capitalist colonial agricultural enterprise, if well managed, may offer to French investment. Five farms, those of *Kom-Ombo*, *Cheikh Fadl*, *Ouady Toumilat*, *Sakha*, and *Santa* were studied.

**KOM-OMBO FARM.** — In 1903 a company bought from the Egyptian government 32 124 acres on the banks of the Nile in a plain 1760 miles south of Cairo by 24.5° northern latitude. It was absolutely desert land, never reached by the waters of the river, with a minimum height of 37.16 to 49.20 feet above low water level. The soil was not composed of Nile alluvion, but of deposit from the neighbouring valleys. The climate was tropical. These 32 124 acres cost £ 11 597, or about 7s. 2d. per acre.

The problem to be solved was to raise mechanically and distribute the water of the Nile in all seasons to the highest point of the estate, and to render fit for cultivation land which had not only never been cultivated, but had never borne any kind of plant. Four powerful pumps of 1 400 HP., each with sheet steel delivery pipes 6 ½ feet in diameter and 1640 feet long were installed, 110 miles of road, 121 miles of railway, and about 220 miles of canal were built, numerous buildings for the pumps, staff, peasants (school, mosque, hotel, etc.) erected, and the land levelled and prepared.

The total cost of the original installation was nearly £981 310, or £4. per acre for the 22 980 acres now under cultivation. The estate, uninhabited before the work began, now counts a population of 20 000 inhabitants.

After five years of not always successful experiments in the growing of cotton besides cereals, beans and fodder (winter crops), and maize (alternate summer crop), cotton is at last being replaced by sugar cane. In 1916, the cultivation of sugar cane which covered only 27 % of the area cultivated, brought in a gross profit of £150 666, as compared with £79 298 from all the other crops together.

The annual farming expenses are £194 280, corresponding to £8.10.0 per acre, including 14s. in taxes. These figures include £1.18.6 per acre for raising the water, and, in 1913, represented a profit of 5 ½ %.

The land is cultivated either by the tenants for the ordinary crops, or in conjunction with the fellahs and the company for these crops and for cotton, or directly for sugar cane. In all cases the pumping expenses are met by the company. For direct cultivation the estate is divided into farms of 1 977 to 2 471 acres, each with its directing staff, workmen and material. The utilisation of motive power from the Assouan dam and the adaptation of cotton to the land improved by irrigation are expected to make the enterprise very prosperous.

**CHEIKH RADL FARM.** — This farm is situated in central Egypt, a district suited to the production of cotton and sugar cane. It is an example

of an estate, previously fairly badly managed, taken over by a company, improved by it, and cultivated exclusively by farmers. The land is on the right bank of the Nile, between the river and the Arabian plain. It does not receive the river water directly, and can only be irrigated by pumping; it is of average quality.

The estate contains 9 204 acres. The company with a capital of £594 700 bought it from the Egyptian Government in 1900. The cost of the original installation was:—land (cost and preparation), £566 000; buildings, £24 680; machines and steam-ploughs, £33 750; dredging machines, £11 410; miscellaneous expenses, £7 070, or a total of £632 910, and represents an outlay of about £70 per acre.

All the land is let out to farmers. The irrigation water is supplied by the company.

Besides cereals, beans, maize and clover, which are included in the rotations, the principal crop is sugar cane. The chief tenant is a large sugar company which cultivates 6 857 of the 9 204 acres of the estate. The receipts for 1915-1916 were:—rents, £46 620; miscellaneous receipts, £660; interest, £1 380, or a total of £46 660. The expenditure was:—farming expenses, £11 280, general expenses £3 140, a total of £14 420. There was, therefore, a profit of £32 240. The average rent is £5 per acre, and the company's annual outlay about £11.11.0 per acre. Each year the company pays its shareholders 5 ½ % and in 1916, after 15 years' existence, its reserve fund exceeded £39 650.

**OUADY TOUMILAT FARM.**—This farm is of a totally different character. It is an estate of 21 250 acres, most of which has deteriorated owing to the infiltration from a large public canal. In 1891 only 7 412 acres were still cultivated, 3 460 acres were occupied by canals or were fallow, and 10 378 acres were considered suitable for cultivation if drained.

The estate is in a hollow in the desert between the Delta and the Suez Canal. It was exploited by the administration of the Wakfs (religious mortmain) and the profits devoted to the maintenance of the Government schools. From 1892 to 1895, £29 130 were spent on 'building':—1) a water-raising plant with four large centrifugal pumps to raise the drainage water to a height of 8.85 feet in the neighbouring Lake Mahsamah; 2) a feeding canal over 48 miles long; 3) a drainage canal over 13 miles long.

Owing to the neglect of the Wakfs these works did not improve the condition of the estate, and, in 1899, the area suitable for cultivation had not increased. The Ministry of Public Works then undertook the management of the estate with the intention of completing the drainage works as well as of clearing the 10 378 acres capable of being reclaimed for cultivation.

The necessity of increasing the power of the water-raising plant and to empty the overflow from Lake Mahsamah into the Suez Canal by means of a canal nearly 55 miles long was first recognised. By the end of 1906 7 265 acres had been reclaimed for cultivation and only 3 113 acres remained to be cleared. The advance money for the works, amounting to £46 400 had been entirely repaid to the Wakfs from the profits from the farm; the taxes of £5 947 had been paid regularly and, in addition, an annual income of

£8 250 had been paid to the Government schools. The work of clearing was then continued using the annual profits, which increased progressively. In 1916, when the work of clearing had been finished, the net income of the estate was £31 323, or about £11.15.0 per acre cultivated.

In the Ouady Toumilat district the soil is light and of inferior quality. As throughout all Lower Egypt the principal crops are cereals, clover, maize, and cotton.

The agricultural population which in 1891 was reduced to 4 500 inhabitants, is now 17 000, about 5 000 of whom are workmen. Thanks to the reclamation work undertaken since 1891, the cost of which has exceeded £99 120, or £9.10.0 per acre reclaimed, this estate is once more prosperous.

**SAKKA AND SANTA FARMS.** — These are two estates with abundant yields situated in the best part of the Delta. The SAKKA estate with 6 412 acres of good, average quality land, is managed by a State Administration called "Egyptian State Properties", that is to say, it is methodically, but expensively managed, as is the case with all State administration.

The land is partly cultivated directly by the Administration, partly leased yearly, let to workmen for a quit-rent, or leased for special crops. In 1912, 4 146 acres were being directly cultivated with the following rotations and yields: —

Wheat, 410 acres, 19.08 bushels; barley, 175 acres, 33.28 bushels; beans, 640 acres, 22.65 bushels; clover, 783 acres; cotton, 1 907 acres, 2.93 cwt.; gardens, 10 acres.

The Administration reserves the cultivation of cotton exclusively to itself, leaving that of maize to the tenants. The receipts for the whole estate, including the crops grown directly, rents and quit-rents were £44 682, the expenditure £25.144; the balance, therefore, is £19 538. The receipts amount to £7 per acre, the expenditure £4, and the profits £3. The taxes are 16s. per acre.

The SANTA farm, in Lower Egypt, is also demesial, and has land of the best quality. It contains 11 794 acres, 6 635 of which are cultivated directly and the remainder by annual leases and quit-rents, like the Sakka estate.

The results are superior to the preceding ones. The rotations and yields for the crops grown directly were, in 1912: — Wheat, 1 243 acres, 29.90 bushels; barley, 655 acres, 49.54 bushels; beans, 329 acres, 20.02 bushels; clover, 1 517, 20.65 bushels; cotton, 2 874 acres, 4.13 cwt; gardens, 15 acres.

For the whole estate including crops cultivated directly, leases and quit-rents, the receipts were £139 043, the expenditure £63 220, and the profits £75 823. This represents receipts equal to £11.16.0 per acre, expenditure of £5.7.0 per acre, and profits of £6.9.0 per acre. The taxes are £1.9.10 per acre.

These examples show the profits which might be derived from similar districts in the French colonies, so long as individual initiative is supported by sufficiently large capital aided by competent management. Above all such large enterprises should not be entered upon before the subject has been thoroughly studied and numerous extensive experiments made.

902 - **Studies in the Cost of Market Milk Production in the United States.**—ANDERSON, A. C. and RIDDELL, F. T. (Michigan Agric. Exp. Station), in *The Journal of Dairy Science*, Vol. I, No. 2, pp. 181-184. Baltimore, July, 1917.

The data presented in these studies cover a period of two years, from 1914 to 1916, and include figures from 25 farms near Grand Rapids, Michigan. Most of the other figures secured on this point in the United States were collected in New England or Atlantic Coast States. The data were secured by a one day visit to each farm monthly. All the farms visited produced market milk, some of them being dairy farms solely, although most of them were coupled with grain, vegetables, live stock or fruit production, and each farm was conducted according to the ideas of the owner or operator. The average expenditures of the farms visited were as shown in Table I.

TABLE I. — *Average expenditures.*

Items of expenditure	1914	1915
Total number of farms . . . . .	25	25
Average number of cows per year . . . . .	459.4	428.57
Man labour . . . . .	\$ 28.68	27.19
Hauling milk and other horse labour . . . . .	15.54	14.77
Feeds:		
Roughage . . . . .	31.02	30.38
Concentrates . . . . .	28.61	26.68
Pastures . . . . .	8.36	7.60
Cash sundries . . . . .	1.96	1.77
Veterinary services and drugs . . . . .	0.86	0.99
Taxes, interest and depreciation on herd . . . . .	9.88	9.49
Taxes, interest, insurance and depreciation on buildings . . . . .	8.72	10.33
Depreciation on barn tools and dairy utensils . . . . .	0.50	0.48
Actual losses on live stock . . . . .	1.95	6.25
Added earning power of owner due to knowledge, experience, and interest in excess of that possessed and used by ordinary labour . . . . .	6.00	6.00
Added risk due to instability of market for product as whole milk, which in single years amounts to 30 per cent, and in one year out of every five would be 6 per cent . . . . .	8.47	8.30
Total . . . . .	150.57	150.29

The average receipts of the farms visited, for the dairy, were as shown in Table II.

The authors bring in a new point, that of "instability of market for product as whole milk" which in a single year may amount to 30 per cent and occurs, as they estimate, one year in five, which would be 6 % of the total cost of production, in this case \$ 8.47 for 1914 and \$ 8.30 for 1915.

TABLE II. — *Average receipts.*

Items of receipts	1914	1915
Average pounds of milk produced . . . . .	6 928 lb	7 156.8 lb.
Gallons of milk produced . . . . .	834.70 gal.	862.3 gal.
Average price per gallon delivered into Grand Rapids.	16.90 cents	16.35 cents
Value of milk produced . . . . .	\$ 141.35	\$ 139.01
Credit by manure . . . . .	17.45	17.59
Total value of products per cow . . . . .	158.80	156.60
Net profit per cow . . . . .	8.23	6.31
Cost of production per gallon . . . . .	15.90 cents	15.39 cents
Net profit per gallon . . . . .	1.0 cents	0.7 cents
Cost of production and delivery per hundred pounds .	\$ 1.916	\$ 1.854
Cost of production per quart . . . . .	3.475 cents	3.848 cents

The investment on the farms studied, expressed in percentage is as follows: —

Investment in cattle . . . . .	45 %
Investment in buildings . . . . .	54 "
Investment in equipment . . . . .	1 "

For 1915 the distribution of cost factors was as follows, expressed in percentage: —

Grain . . . . .	17.8 %	Taxes, interest and depreciation	
Roughage . . . . .	20.2	on buildings . . . . .	6.9%
Pasture . . . . .	5.1	Same on cows . . . . .	6.3
Hauling milk . . . . .	9.8	Losses on cows (tuberculosis, etc.)	4.1
Man labour . . . . .	18.1	Management . . . . .	4.0
Market losses . . . . .	5.5	Depreciation on tools, etc . .	0.3
		Veterinary services . . . . .	0.7
		Cash items . . . . .	1.2

The authors point out that during the last two years the cost of labour has increased 25 %, concentrated feeds 30 to 35 %, roughage 10 %, and minor supplies and milk room equipment 25 to 60 per cent.

## AGRICULTURAL INDUSTRIES.

### INDUSTRIES DEPENDENT ON PLANT PRODUCTS

903 — *The Intrinsic Values of Grain, Cottonseed, Flour and Similar Products, Based on the Dry-Matter Content.* — BOERNER, E. G., *U. S. Department of Agriculture, Bulletin* No. 374, pp. 1-32 + 12 Tables + 3 Figs. Washington, D. C., October 17, 1916.

The moisture content of grains or cottonseed varies with the season, the part of the country in which they are grown, and the way they are handled and stored after being harvested. The minimum and maximum moisture content of grains, cottonseed, or their manufactured products generally varies between 10 to 30 %; new maize, however, frequently exceeds this maximum; whereas thoroughly dry small grain and cottonseed may contain less than 10 % of water.

All else being equal the value of grain, cottonseed, flour, meal, etc., to the consumer is in proportion to their content in dry matter. Moreover moisture is a serious hindrance to good keeping; enormous quantities of grain and cottonseed are seriously damaged each year by moulds and fermentation because their moisture content is too high for safe storage or transportation, and the danger of such damage increases with each additional percentage of moisture.

The value of a low moisture content has long been recognised in the trade, where the rules governing the grading of grain lay down that grain, to be classed in the higher grades must be "dry", in the intermediate grade "reasonably dry", and in the lowest grades "damp" or "wet". This classification is very indefinite, but it was only in 1916 that rules giving definite maximum limits of moisture for the various grades of corn were drawn up by the Grain Dealers' National Association, and adopted by the State grain inspection departments and grain exchanges. In 1914 the Department of Agriculture drew up grades for commercial maize and fixed definite limits of moisture for each of the six numerical grades. These grades are now in force in most of the maize markets in the United States. In certain States the pure-food laws also deal with the amount of moisture grain and flour may contain in order to enter the State.

When a unit of weight of grain, cottonseed, etc., containing excess moisture is dried naturally or artificially to a lower moisture content, the weight is reduced by the loss of water, but all the dry matter is retained. As only the dry matter is considered as having any value the total value before and after drying will be the same. The comparative value of the dry matter is, therefore, of great importance. The author gives a series of tables by which the comparative value, on a dry-matter basis, of grain, cottonseed, flour, etc., containing various percentages of moisture and quoted at various prices per unit of weight, may be easily and rapidly calculated. These tables show that the difference in value for each 1 % of dry matter increases in direct proportion to the increase in price, so that, as the price of the product increases, the difference in value for each 1 % of dry matter or moisture becomes of greater importance to the producer and consumer. Moreover, it is clear that if a dry product commands a better price than one with a high moisture content the farmer will be encouraged to improve his methods of farming and storing.

Grain, especially maize, is frequently put on the market with a moisture content too high to remain sound during storage or transportation, and has to be dried by machine. Whether dried naturally or artificially the shrinkage in weight of such grain is always greater than the difference in the percentage of moisture content before and after drying, as shown by the moisture tester, unless all the moisture is dried out, when the shrinkage and the reduction in moisture are equal. In order to facilitate the estimation of this percentage, the author gives a table by which the shrinkage may be determined when the original moisture content and the moisture content after drying are known. He also gives formulae for finding the percentage of shrinkage corresponding to any reduction in moisture content and for finding the weight of the dried

material when the original weight and the moisture content before and after drying are known.

In drawing up the tables only the fundamental factors of moisture and dry matter were considered; there are, however, other factors of equal importance in the buying and selling of cottonseed flour and other products, among which may be mentioned: — 1) the relative quantity of damp grain in the grain-producing States that have a surplus, or in the district bordering on any given grain market, and the relative quantity of the market receipts; 2) the tendency of damp grain to deteriorate during storage or transit, and the increased danger of such deterioration as the moisture content increases; 3) the conditions of supply and demand at the time of marketing, and the relative capacity of the markets to absorb or dispose of damp grain at a profit; 4) weather conditions at the time of marketing and future weather conditions which may affect the condition and carrying capacity of the grain; 5) the extra cost incurred by the artificial drying of the grain and by the freight on the water handled; 6) the slight "invisible loss" in weight during the drying process.

904 - **The Utilisation of Sisal Waste for the Production of Alcohol.** — *Tropical Life*, Vol. XIII, No. 10, p. 155. London, Oct., 1917; Abstract in the *Bulletin économique de l'Indochine*, Year XXI, No. 128, New Series, Hanoi-Haiphong, January-February, 1918.

After the fibre has been extracted from sisal there remains much waste, which has a very disagreeable smell and, when possible, is used as a fertiliser. Investigations have been made to see whether this waste can be put to a more profitable use. The experiments dealt partly with its utilisation for paper-making and partly on the extraction of alcohol from the leaves and stems.

The experiments, made in British East Africa, show it is possible to extract alcohol from sisal. An analysis of the juice of the leaves showed the plants from the coast as well as those from the Highland to contain 3 % of sugar. At Yucatan, whence sisal was first exported and where alcohol has been made from the waste and put on the market, the sugar content was never below 9.4 %, and sometimes, after a long dry season, reached 14.1 %. Most of the alcohol was made from leaves containing 12 % of sugar.

A yeast was isolated from sisal plants which fermented a glucose solution but was quickly killed in the sisal extract. This was no doubt due to the large quantities of organic acids present. After neutralisation with sodium carbonate and the addition of a small quantity of glucose it was found possible for the yeast to live in the sisal extract, but no fermentation took place.

905 - **The Beet Sugar Industry in the Netherlands.** — GOOSSENS, G., in *In en Uitvoer*, Year III, Nos. 7 and 9, pp. 151-152 and 200-202. Antwerp, February 13 and 27, 1918.

After giving an historical survey of the beet sugar industry in the Netherlands the author gives the figures for the production of sugar in that country from 1864 to 1916. In 1864 there were only 6 refineries with a production of 3 700 metric tons of sugar, an average of 617 tons per factory.

In the period 1899 to 1900, 31 refineries were working and producing 71 092 metric tons of sugar, an average of 4 940 per factory. The 28 refineries working during 1912 to 1913 produced 279 000 metric tons, an average of 9 980 each. In 1916 the 28 refineries only produced 247 209 tons. A table giving the average yield of sugar beets per acre from 1908 to 1914 shows that, in 1908-1909, the yield was 260 cwt. of roots with a 16.80 % sugar content, yielding 43.75 cwt. of sugar. After dropping, in 1909, to 217 cwt. of roots containing 15.5 % of sugar, and yielding 33.58 cwt. of sugar per acre, the average yield of sugar beets rose in 1911-1912 to 286 cwt. of roots, containing 16.57 % sugar and yielding 47.61 cwt. of sugar per acre, and in 1913-1914, again dropped to 219 cwt. of 16.55 % roots giving 36.25 cwt. of sugar.

Besides the beets produced in the country the refineries also deal with beets imported from Germany. On the other hand the Netherlands also export beets into Belgium to be used by the factories there. The author considers the sugar position in the Netherlands during the last three years, and concludes that the production for 1917-1918, estimated at about 200 000 metric tons, will be sufficient to meet the demand for beet sugar there in 1918, which is estimated at about 170 000 metric tons.

906 - **The Fat of the Residue of the Decortication of Rice.** — GARELLI, FELICE, in *Annali della R. Accademia d'Agricoltura di Torino*, Vol. LX, pp. 132-139. Turin, 1917.

The annual production of rice in Italy exceeds 11 760 000 cwt.; the residue from decortication ("pula di riso") represents 980 000 cwt. and contains about 147 000 cwt. of oil. This residue is composed of the perisperm, embryo and part of the outermost starch layers of the caryopsis, to which, in the trade, are added varying quantities of husks. Without the husks it represents 7 to 8 % of the weight of the rough rice, but the commercial type represents about 10 % of this weight. Up to the present it has only been utilised in part as a food for cattle (1), and before the war, the greater part of it was exported (chiefly to Switzerland and Germany) and sold on a basis of its total fat + protein content, which varied from 15 or 16 % to 24 or 26 %.

By removing the fat from this product its keeping quality is improved, it is made more healthy (the fat is slightly irritating and relaxing) and easy to transport. The extract is of great value, especially at this moment when all the war industries require so much fat. Experiments on the extraction of this fat were, therefore, made.

Repeated pressure under 300 atmospheres each of nearly 2 cwt of meal, previously moistened and heated, gave an average yield of 6.5 % of crude oil. The properties and characters of the fat vary greatly, especially according to the state of preservation of the residue, and also according to the method of preparation (by compression or volatile solvents). That prepared by compression is liquid at ordinary temperatures; it is a true oil with a density of 0.912, of a greenish-grey colour. The cake obtained by this method is similar in appearance to that of sesame seed.

(1) See R. 1917, Jan., No. 56; Aug., No. 739; Oct., No. 933. (*Fd.*)

The crude residue of decortication contains 2.38 % of nitrogen, corresponding to 14.87 % of crude protein which, together with 15.23 % of fat, gives a total value of 30.1 %. In the dried cake this value is 33.8 % (16.7 % of crude protein and 17.1 % of fat).

The extraction of this fat is of great value, and should be started immediately, leaving till later a detailed study of the possibility of complete extraction by volatile solvents. By the compression method it would be possible to obtain 39 200 to 58 800 cwt. of excellent oil for the manufacture of soap, fatty acids and glycerine.

907 — South African Paper-making Plants. — See No. 869 of this Review.

INDUSTRIES  
DEPENDENT  
ON ANIMAL  
PRODUCTS

908 — A Substitute for Litmus for Use in Milk Cultures. — CLARK, W. M. and LUBS, H. A. (Research Laboratories, Dairy Division, Bureau of Animal Industry, U. S. Dept. of Agriculture), in the *Journal of Agricultural Research*, Vol. X, No. 3, pp. 105-111. Washington, D. C., July 16, 1917.

The colour changes which occur in litmus-milk cultures may be due to changes in the hydrogen-ion concentration of the medium or to reduction or even destruction of the dye. If it is the degree of acid or alkali fermentation which is sought, it is advisable to use an indicator which will not be affected except by a change in the hydrogen-ion concentration. Dibromooorthocresolsulfonphthalein, for which the short name bromcresol purple is suggested, fulfills this condition.

Litmus undergoes a temporary reduction during sterilisation in the presence of milk. Bromcresol purple does not. The colouring power of litmus is relatively weak; bromcresol purple in very high dilution is useful. Litmus and azolitmin are indicators of uncertain composition; bromcresol purple is a definite individual compound obtainable in crystalline form and therefore reproducible. The impurities of litmus preparations vary in their effect upon the hydrogen-ion concentration of milk and often necessitate elaborate adjustment either of the litmus solution, of the milk, or of the mixture if reproducible colour is to be obtained. Bromcresol purple, on the other hand, may be used with the assurance that, if other conditions are constant, it will always produce the same colouration.

Some of the difficulty experienced in reproducing a particular initial colour with either indicator is shown to be due to the changes in hydrogen-ion concentration which occur when milk is sterilised by heat.

The comparative value of litmus and bromcresol purple in milk cultures was tested with a variety of organisms. It was found that no change in reaction could be observed with litmus which could not be followed equally well with bromcresol purple. In many instances litmus was rendered useless by reduction or destruction while bromcresol purple continued to act a true indicator of the hydrogen-ion concentration.

909 — Preliminary Note on Certain Changes in Some of the Nitrogenous Constituents of Milk Caused by Bacteria. — SUPPLEE, G. C., in *The Journal of Dairy Science*, Vol. I, No. 4, pp. 313-319. Baltimore & London, November, 1917.

The data presented in this preliminary note are the result of a preliminary investigation on certain quantitative changes in the nitrogenous

constituents of milk caused by bacteria before any change in the physical appearance of the milk is evident.

The following species of bacteria were used: *Bact. lactis acidi*, *Mic. albidus*, *Ps. liquefaciens*, *B. lactis viscosus*, *B. mycondes*, Acid peptoniser (species unknown), *Bact. bulgaricum*, *B. coli communior*, *Bact. aerogenes*, *B. prodigiosus*, *Ps. pyocyaneus*, *B. subtilis*.

The plan of the analyses was one of fractional precipitation by various precipitating reagents and the subsequent determination of the nitrogen in each of the fractions.

In many instances the changes in the nitrogen content of the various fractions were very slight. Many of the results, however, were beyond the realm of experimental error. A study of the tables presented reveals the following general results:—

All organisms tested except two caused a decrease in the casein fraction and in most cases this decrease was more marked with those organisms known to possess extreme proteolytic properties. With some organisms there was an increase in the albumin fraction, with others a decrease in the albumin fraction and little or no decrease in the casein fraction. The changes in the nitrogen content produced under these conditions will serve as a preliminary basis for further work.

**910 - Experiments on Determination of Cow Manure in Milk; Moisture Content and Solubility of Cow Manure.**—TAYLOR, G. B., in the *Journal of Dairy Science*, Vol. I, No. 4, pp. 303-312. Baltimore & London, November, 1917.

A series of experiments was conducted on cow manure from the experimental farm at Beltsville to determine primarily whether the manure in unstrained milk can be measured quantitatively by chemical methods. A method was found which gave good results provided the original quantity of manure present was fairly large. For average milks, however, this chemical method is impractical on account of the fact that, while manure is always present, it is as a rule in such small amounts that it cannot be measured chemically.

The experiments lead to the conclusions given below.

**Conclusions:**—The moisture in the cow manure examined averaged nearly 83 per cent. Air dry manure contains about 6 per cent of moisture; 5 per cent of the remaining solid matter is soluble in milk. This would indicate that only 11 per cent of dry manure dissolved in milk, 6 per cent of this being water. Nearly 85 per cent of fresh cows' manure will dissolve in milk, 83 per cent. of this being moisture. Manure in whatever condition is less soluble in milk than in water. Of the manure present in bottled milk, 91 per cent will be visible on the bottom, leaving 9 per cent of foreign matter in suspension.

**911 - Methods Adopted in the Production of "Clotted Cream" in Devonshire and Cornwall, England.**—SADLER, W., in the *Journal of Dairy Science*, Vol. I, No. 4, pp. 291-302. Baltimore & London, November, 1917.

Enquiries have been conducted on behalf of the Board of Agriculture as to the methods adopted by the producers of "clotted cream" in the counties of Devonshire and Cornwall in England. Experiments have subse-

quently been undertaken at the Midland Agricultural and Dairy College, Kingston, Derby.

The results of these experiments so far tend to show:—

1) That provided a suitable system be adopted and reasonable care be taken in management and manipulation, clotted cream having the typical and characteristic properties can be produced in any district.

2) That, while a rich milk is preferable, it is not at all essential for the production of characteristic clotted cream to have only the breeds of cattle favoured by the producers in Devonshire and Cornwall.

3) That the flavour and keeping properties of the cream are problems of a bacteriological nature.

4) "Scalding" for 20 to 30 minutes with a final temperature of 187° F proved to be a satisfactory procedure.

5) One pound of clotted cream was produced from 23 pounds of milk.

6) The average percentage of butterfat in the clotted cream was 62 to 64 per cent.

7) The average butterfat content of the scald milk was 0.75 per cent.

912 - **Studies in Butter Shrinkage.** — GUTHRIE, E. S., in the *Journal of Dairy Science*, Vol. 1, No. 2, pp. 136-138. Baltimore, July, 1917.

The Dairy Division of the Cornell University has completed the storage studies of 100 tubs of butter. This butter was made in eight different churnings from sweet pasteurised cream. The body was good and the moisture was nicely incorporated. All the butter was overworked somewhat, which has a tendency to complete the incorporation of the water. The tubs were paraffined, and were weighed just before the butter was packed in them. The butter was weighed on November 20 after being in cold storage for 134 days at 0° to 10° F. The shrinkage or increase in weight was determined for each tub.

Seventeen packages showed an increase in weight ranging from 0.5 ounce to 27.5 ounces. Eighty three tubs showed shrinkage which varied from 0.5 ounce to 15.5 ounces. The total shrinkage was 377.5 ounces. The total increase of weight was 85 ounces. The net shrinkage was 292.5 ounces, or 18.28 pounds, which is 0.1828 pound for tub or 0.29 per cent.

913 - **The Relation of *Oidium lactis* and *Penicillium* to the Keeping Qualities of Butter.** — COMBS, W. B. and ECKLES, C. H., in the *Journal of Dairy Science*, Vol. 1, No. 4, pp. 347-355. Baltimore and London, November, 1917.

The primary object of the experiments reported in this paper was to determine the relation of *Oidium lactis* and a mould of the *Penicillium* group to the keeping qualities of butter, especially when these organisms had developed in the cream before churning. Only a portion of the data taken during the experiments is given, but the results were consistent and conclusive.

It was found that moulds do not grow readily upon butter, but their growth is influenced by the amount of protein, salt and moisture the butter contains and the moisture of the surrounding atmosphere.

The quality of cream as usually judged by taste is influenced to a marked degree by the growth of *Oidium lactis* and *P. Chrysogenum* when the cream is sweet, but no objectionable flavour can be detected in the cream as a result of mould growth when the cream is sour.

The growth of *Oidium lactis* or *Penicillium* upon cream exerts a decidedly detrimental effect upon the keeping qualities of the butter.

Mould spores do not germinate or make growth in butter. The growth of mould on butter is the result of a contamination from the outside.

Pasteurisation at ordinary temperatures greatly improves the keeping qualities of butter made from cream upon which moulds have made growth, but it does not entirely check the action of the enzymes which they produce. This action may be checked entirely by heating to a sufficiently high temperature but this point is beyond the limit of practicability for commercial use.

The abnormal flavours which develop in butter due to mould growth on the cream, are caused by enzymes which are secreted by the mould in the cream.

914 - **Varieties of Cheese: Descriptions and Analyses.** — DOANE, C. F. and LAWSON, H. W., in *U. S. Department of Agriculture, Bulletin No. 608*, pp. 80 + Bibliography of 103 publications. Washington, March 6, 1918.

This bulletin gives descriptions of 287 different cheeses and analyses of 129 varieties extracted from the books and technical periodicals of the producing countries. The varieties are arranged in alphabetical order. It is pointed out that one type of cheese is frequently known under different names, thus making classification difficult.

915 - **Study on the Normal Production of Gas in Cheese: Investigations at the Agricultural Experiment Station of Hoorn, Netherlands.** — BOEKHOUT, F. W. and VRIES, J. J. OTTIE, in *Verslagen van Landbouwkundige Onderzoekingen de Rykslandbouwproefstations No. XXI*, pp. 14-28 + 1 Plate. The Hague, 1917.

The authors undertook an investigation into the gas-producing organisms of cheese. As culture medium they employed that used by VON FREUDENREICH and JENSEN for the study of propionic fermentation in Emmenthal cheese. The constituents of this medium, which contains peptone and calcium lactate, are very similar to the nutritive matter of cheese which may be attacked by the organisms.

Samples of 4 to 5 weeks old Gouda and Edam cheese with many holes, were crushed with a physiological salt solution and put with VON FREUDENREICH'S nutritive liquid into glass tubes, which were evacuated, sealed, and kept at 21° C. The tubes were opened and the contents used as inoculation material wherewith to repeat the operation. The final product was grown on gelatine.

1) **CHARACTERISTICS OF THE BACTERIUM.** — The authors succeeded several times in isolating the bacterium responsible for the production of gas in cheese. It is rod-shaped, 1.75 to 3  $\mu$  long and 1.2  $\mu$  broad. Milk is not a good culture medium. As a source of nitrogen the bacterium requires peptone, and calcium lactate as a source of carbon. The gas produced is a mixture of carbonic acid, hydrogen and nitrogen. Cultures

of this bacterium have very great vitality and contain living bacteria after 10 months. The optimum temperature is about  $21^{\circ}$  C.; a lower temperature, 10 to  $12^{\circ}$  C., greatly reduces development, and that of  $55^{\circ}$  C is fatal.

2) INFLUENCE OF SALT AND LACTIC ACID. — The influence on the bacterium of varying quantities of salt and lactic acid added to the peptone and calcium lactate solution was then studied. The experiment was continued with the sealed tubes to which were added increasing quantities of salt and lactic acid. Including the salt already contained in the nutritive solution; the maximum quantity tolerated is 4.5 %; the maximum concentration of lactic acid is 0.3 %. When the lactic acid concentration is only 0.1 % a salt concentration of 4.5 % allows fermentation at the end of 21 days, and a concentration of 5.5 % at the end of 1 month.

3) REDUCING PROPERTIES. — The presence of hydrogen in the gas produced shows reducing properties. In the culture medium containing 0.03 to 0.05 % of nitrates there is reduction and transformation of the nitrates into nitrites, the final reduction of the latter being rather slow. If, however, the culture medium contains only nitrites they are completely reduced. (The same reduction phenomenon occurs with sodium nitrites and potassium chloride). Fermentation occurs only when the nitrates have been reduced, and this influence on the bacterium is the same in cheese as in culture media. Edam cheeses made with pasteurised milk were inoculated with the bacterium and 0.05 % of potassium nitrate; cheeses without nitrates were used as controls. In some of the cheeses there was no fermentation even after 10 or 20 days and the nitrates were still present. In those in which fermentation had taken place the nitrates had disappeared. Fermentation occurred in all the control cheeses (without nitrates).

As a rule, as soon as the bacterium has no more free nitrogen at its disposal it attacks the calcium lactate (formed in the cheese by the lactic fermentation). Carbonic acid and hydrogen are thus formed, causing cracks and holes in the cheese. The composition of the gases in the cheese is similar to that of the gases given off in the culture medium.

The authors were unable to isolate butyric ferments in the cheeses by this method and concluded that these ferments take no part in normal gas production and the formation of cracks.

916 - The Growth of Green Mould (*Penicillium glaucum*) for the Manufacture, of Blue Cheeses. — CHAVASTELON, K., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 18, pp. 564-566. Paris, May 22, 1916.

The author (Professor of general and agricultural Chemistry in the Faculty of Science at Clermont-Ferrand) describes a simple and practical method of growing *Penicillium glaucum*.

Bread is cut into slices 1 to 1.5 cm. thick, and soaked for about 10 minutes in a solution containing 35 to 37 gm. of tartaric acid per litre. The slices are then laid flat on frames made of reeds, about 5 to 6 mm. thick with a distance of 1 to 2 cm. between each, or, if need be, on straw mats; both must be previously scalded. The slices are sprinkled on both sides with green mould spores and the frames, which may be placed one

on the other, left in a damp place in which the air is always near its saturation point or, if speed is necessary, at a constant temperature of about 25° C.

If the damp condition is maintained fine cultures are obtained at the end of 16 days for temperatures of 14 to 18°, and at the end of 31 days if the temperature is about 8°. The production is maximum if the slices are turned over on the frames or mats once or twice during the period of culture so that all the parts are regularly aired.

To maintain the desired degree of moisture, in a simple installation, coarse sacking or matting, the ends of which are constantly in water, may be hung in the room.

The cultures are collected when the slices, which have become very thin, are uniformly green on both sides; this does not always occur. They are then dried in the air before being pulverised or passed through a mill. The fine powder, which only contains a very small proportion of the original bread, and, in the multitude of its spores, represents a very concentrated and almost pure culture, is kept in boxes.

If the operation is well carried out 20 lbs. of bread will suffice to sprinkle many thousand pounds of cheese.

917 - **Researches on the Physical and Chemical Constants of the Oily Matter of the Egg ("Eieröl").** — SCHAFER, F. and MEYER, L. (Laboratorium des Schweizer Gesundheitsamtes), in *Mitteilungen aus dem Gebiete der Lebensmitteluntersuchung und Hygiene*, Vol. IX, Part 2 and 3, pp. 135-136 + 1 Table, Berne, 1918.

There is little available data regarding the physical and chemical constants of the oily matter of the egg, *i. e.*, the oils extracted from the yellow of the fowl's egg by means of solvents. Recent determinations carried out by L. MEYER in the laboratory of the "Service Suisse de l'hygiène publique" were made with fresh eggs and eggs that had been stored a long time, using chloroform and petroleum ether as solvents. The results are summarised in table form, from which it appears that:—

1) The nature of the solvent has a marked influence on the value of these constants, as was observed by JEAN (*Ann. Chim. analyt.*, 53, 1903); while petroleum ether only extracts the oily matter, chloroform extracts the cholesterin and a part of the lecithins as well.

2) The differences found for the refractive and iodine indexes vary, even for products that have been stored a long time, between the limits stated in publications on the subject. The results obtained for the iodine value, to which LAVES gives the value 64 as the minimum, show a considerable variation, however, being 74 to 75 on an average.

3) The phosphorus pentoxide content of the lecithins diminishes gradually during storage, being 1.27 % for the fresh egg and 0.8 % after storage for 2 years.

918 - **The Relative Influence of Microorganisms and Plant Enzymes on the Fermentation of Maize Silage.** — LAMB, A. R. (Iowa Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. VIII, No. 10, pp. 361-380, 9 Tables, + 13 Diagrams + Bibliography of 27 Publications. Washington, D. C., March 6, 1917.

The question of the respective causal relationship of micro-organisms and plant cell enzymes to the fermentation of maize silage has long been in

AGRICULTURAL  
PRODUCTS:  
PRESERVING,  
PACKING,  
TRANSPORT,  
TRADE.

controversy. It is difficult to differentiate between the activities of these two kinds of agents. Work with antiseptics both by earlier investigators and by the writer is not conclusive. Experimental silage, other than antiseptic silage, has been made, with results of some value; but the most conclusive evidence was obtained by the determination of the rate of change in various phenomena of the fermentation under normal conditions. Curves plotted from these data show that bacteria are mainly responsible for acid production and the concomitant disappearance of sugars. Alcohol is formed first by plant enzymes and later by yeasts. Protein is hydrolysed first by enzymes and later by micro-organisms. Carbon dioxide evolution seems to be very largely due to respiratory or enzymic activities, but yeasts probably have a share in its production after the first day or two. Micro-organisms are probably largely responsible for the heating of the silage. Both kinds of factors are always present during silage fermentation and the process is due to the activities of both in the absence of air.

**919 - Changes in Composition of Sweet Potatoes left in the Ground when Mature.**

— See No. 851 of this *Review*.

**920 - The Influence of Salt on the Changes Taking Place in Storage Butter.** — WASHBURN, R. M. and DAHLBERG, A. C., in the *Journal of Dairy Science*. Vol. I, No. 2, pp. 114-126. Baltimore, July, 1917.

It is generally believed, and most experimental evidence supports this belief, that salt improves the keeping quality of butter. It has been observed; on the other hand, that unsalted butter in commercial cold storage keeps as well as or better than salted butter.

The experiment reported in this paper deals with this point and considers only salted versus unsalted butter. The butter was first held for the usual cold storage period in a commercial cold storage butter room and was then held for a short time at the usual ice box temperature. This latter treatment is comparable to that which commercially stored butter would receive before being consumed. At each scoring the usual bacteriological and chemical analyses were made so that probable causes of a possible difference would not be overlooked.

*Making, Storing, and Scoring the Butter.* — The cream used was sweet, clean cream of good flavour. It was ripened without pasteurisation on the addition of a starter to an average acidity of 0.58 per cent lactic acid. It churned in 20 to 30 minutes; the churning was stopped at the wheat kernel stage; the butter was washed twice, salted or not, and worked from 23 to 27 revolutions in a Victor double roller churn. Half the butter of each churning was salted and worked and the other half worked unsalted so that each sample of unsalted butter had an exact duplicate in the salted butter. It was then packed into 5 pound paraffined wooden butter drums lined with parchment paper. Enough of these containers were packed so that one from each lot could be taken out at every scoring. Initial data as to score, chemical and bacteriological analysis were obtained. The butter was stored in a commercial butter storage room in St. Paul, at a temperature of  $-15^{\circ}$  F. After 284 days in cold storage it was held for twenty days in a butter-cutting room at  $58^{\circ}$  to  $60^{\circ}$  F.

The following points were studied:—Influence of salt on score; influence of salt on bacterial activity; influence of salt on acidity; influence of salt on moisture, protein content; relation of score, acidity and bacteria in salted and unsalted butter. The following facts were brought out:—

Salt, exclusive of its antiseptic property, hastened the deterioration of the butter.

When stored at  $-15^{\circ}$  F. unsalted butter kept as well as salted butter.

The bacteria in the unsalted butter decreased more rapidly at  $-15^{\circ}$  F. than they did in the salted butter and increased more rapidly at  $58^{\circ}$  F.

The acidity of the unsalted and the salted butter increased uniformly at  $-15^{\circ}$  F, but at  $58^{\circ}$  F the increase was greater in the unsalted butter.

Moisture was lost from the salted butter, but not from the unsalted kept at  $-15^{\circ}$  F.

Little if any relationship existed between the bacteria, the acidity, and the score in this butter.

## PLANT DISEASES

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

#### GENERAL

921 - "Fucha" of the Cotton Plant, in the Department of Boyacá, Republic of Colombia. — PESTICO, J. F., in the *Revista Agrícola*, Year IV, No. 2, pp. 113-116 + 1 Fig. Bogotá, 1918. \*

Towards the middle of 1917 in the comarca of Miraflores, an eastern province of the department of Boyacá, the cotton plantations were attacked by a disease commonly known as "fucha", which, by stopping growth, destroys the greater part of the produce.

The disease is characterised by numerous small swellings on the leaves and young branches and also, more rarely, on the flowers. It usually becomes visible after prolonged rain and the diseased plant fades and dies one or two weeks later. Occasionally the plant survives but gives no crop.

Growers in the comarca of Miraflores consider cotton as an almost wild plant requiring no attention. Without any previous preparation of the soil they sow and await the harvest.

According to the author it is the lack of cultural methods which causes the appearance of the disease in question, which can only be overcome by radically reforming the present methods and replacing the variety of cotton now grown by others from strong and healthy plantations.

The lack of weeding allows a multitude of bushes to grow up round the cotton plants. These receive the abundant rain and the sun, and cause the formation of a hot, damp atmosphere, favourable to the development of swellings. On the other hand, cotton under such conditions is weak and incapable of assimilating the elements supplied by the soil. Chlorosis of the young branches increases and growth in general is weak.

To avoid the decadence of cotton-growing in the above-mentioned district there is a crying need for deep and repeated ploughing several weeks before sowing, for a careful selection of seed, continuous weeding, etc. It is also necessary to regulate the date of sowing so that the wet season will coincide with the growth of the plants and the dry season with the ripening of the bolls.

## DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

- 925 - Bacteria and Fungi Recorded as Parasitic on Cultivated Plants in the Province of Turin and Adjacent Regions in 1916 (1). — VOGLINO, P, in the *Annali della R. Accademia d'Agricoltura di Torino*, Vol. LX (1917), pp. 205-229. Turin, 1918.

In this phytopathological review 110 bacteria and fungi are recorded as being the most harmful to cultivated plants in the province of Turin and the adjacent regions during 1916. The most important are given below.

1) A bacteriosis of the dwarf bean observed in market gardens at S. Bernardino (Trana); on many of the plants with pods nearly 2 in. long, the terminal leaves and consequently all the young buds, withered in a few days, while the leaves that were well developed turned yellow or mottled red; in the tissues of both buds and leaves there were colonies of bacteria identical with those observed previously in market gardens at Trana; it is recommended that infected plants should be at once burnt.

2) Peach bacteriosis, observed in the orchards at Vezza d'Alba near Canale and characterized by yellowing of the leaves, drying-up of the branches and the death of the plant; according to the author these phenomena are due to the formation of woody tumours of various sizes on the root system; a bacterium corresponding to *Bacterium tumefaciens* has been isolated from the tubers; this disease, which the author thinks is identical with "crown gall", appears to be spreading alarmingly.

In order to help in the defence against vine mildew the Phytopathological Observatory of Turin founded, in 1916, a service of "preventive detection" by means of a number of observatory Stations. Although 1916 was, on the whole, unfavourable for the disease, the first year's results of this Service are very satisfactory and show its absolute necessity as regards the indication of the exact period when the first treatments must be carried out against the parasite.

- 926 - Uredinales of the Andes, South America. — ARTHUR, J. C., in *The Botanical Gazette*, Vol. LXV, No. 5, pp. 460-474. Chicago, May, 1918.

This paper enumerates 25 species all, with the exception of four, collected by Dr. and Mrs. Rose on a journey taken in 1914 through the west of South America, particularly Peru and Chile. The list includes some species new to science, and some rare ones. Special mention should be made of:—

1) *Coleosporium Senecionis* (Pers.) Fries, collected on various species of *Senecio* in different parts of Chile and La Paz, Bolivia. It is remarkable that this rust, which is very common in Europe, is also abundant in Chile and, apparently, also in Argentina, whereas it is practically unknown in

(1) See R., July, 1917, No. 680. (Ed.)

North America. The aecidia occur on the leaves of pine. The fungus was collected at Providence, Rhode Island, in 1883 on *Senecio vulgaris*, but seems to have disappeared rapidly and was not reported again from any station in North America. No telia were found in any of the material examined. This shows that the aecidia on pine are rare or absent in that district, and that the rust is chiefly or wholly reproduced by uredospores.

2) *Puccinia Malvacearum* Mont., on *Malva sylvestris* and '*Malvas-trum capitatum*', in different parts of Chile. It is one of the commonest and best known rusts which, from its native country, the Andes, has spread to all parts of the world where *Malvaceae* grow.

3) *P. Nicotianae* n. sp. on *Nicotiana tomentosa* at Santa Clara, Peru.

4) *Uredo Erythroxylonis* Graz., on '*Erythroxylon Coca*', at La Paz; it is a common rust wherever this plant grows.

927 — ***Nezara viridula* and Kernel Spot of Pecan.** — TURNER, W. F., in *Science*, New Series, Vol. XLVII, No. 1220, pp. 490-492. Lancaster, Pa., May 17, 1918.

In 1914 RAND described *Coniothyrium caryogenum* as a cause of the infectious disease known as kernel spot of pecan (*Carya olivaeformis*). It attacks the seed, causing the formation of irregular dark brown or black spots, which are usually rather sunken. The discolouration sometimes extends to the interior of the kernel, which becomes bitter.

The disease seems to exist wherever pecan is grown, although, as a rule only a few of the kernels are attacked. Occasionally, however, as in 1916, it becomes of considerable economic importance, causing the loss of thousands of dollars to the growers.

*Nezara viridula* L. (1), commonly known as the green soldier bug, is found throughout middle and southern Georgia, where it occurs every year, occasionally, as in 1916, becoming very abundant. This insect appears to attack cow peas in preference to all wild or cultivated plants. In autumn, when the cow pea begins to dry up, the bugs leave them for any other plants or trees near.

Pecan growers commonly sow cow peas in the plantation in early summer to use it later as green manure. When, in September or early October, the plant begins to dry up the insects pass from it to the pecans.

In 1916 a serious invasion of *N. viridula* was reported, coinciding with a severe outbreak of kernel spot. Although it is possible that it was a mere coincidence, many growers observed that the disease only appeared to be serious in the plantations where cow pea had been grown. Moreover, in at least one case, the insects were observed feeding on the pecan nuts.

Preliminary experiments were, therefore, made, in which specimens of *N. viridula* taken from cow pea were placed on green pecan nuts, on which they fed, living on them for a month in three cases. An examination of the ripe nuts showed all those in the cages used during the experiment to be seriously attacked by kernel spot, as many as five distinct spots being found on one kernel. Of several hundred nuts from the same tree not confined in cages only two or three had spots.

(1) See R. March, 1917, No. 298. (Ed.).

It has not yet been possible to determine whether *Coniothyrium caryo-*  
*genum* is present in the spotted areas. In any case the data obtained point  
strongly to the fact that *N. viridula* is an important factor in producing or  
spreading the disease. This is of special interest because it is another of  
those observations, more and more frequent of recent years, of the economic  
importance of a large group of insects (several families of the Heteroptera,  
and, among the Homoptera, those of the *Cicadellidae* and *Aphididae*) as  
specific agents in various plant diseases, and as carriers and intermediaries  
in other diseases of bacterial or fungoid origin.

931 - Experiments on the Action of Polysulphide Against Oidium of the Vine. —  
CAPUS, J., in *Revue de Viticulture*, Vol. XLVIII, No. 1251, pp. 393-394. Paris, 1918.

DISEASES  
OF VARIOUS  
CROPS

In 1917 the author made several experiments on the treatment of  
oidium with alkaline polysulphide, known commercially as "liver of sul-  
phur", applied in quantities of 500 gm. per hectolitre of water with 500 gm.  
of soft soap. Oidium attacks were not serious in Gironde in 1917, and in  
only two of the six vineyards in which the experiments were made was it  
possible to obtain clear and interesting results.

At the Chateau of Issan, at Cantenac in Médoc, the first application of  
polysulphide was made on June 30. The adjacent rows of both sides were  
treated with sulphur on the same day. The second application was on  
July 21. The adjacent rows were treated twice more with sulphur. The  
two polysulphide applications gave a protection as efficient as that of the  
three sulphur ones.

At Saint-Emilion, at Lamarzelle Chateau, two polysulphide treatments  
gave the same results as two sulphur treatments. This vineyard was in-  
fested with *Polychrosis botrana* which did much damage there in 1917.  
Polysulphide was applied for the second time during the first fortnight of  
July, at the time of the flight of the moths. On the clusters treated with  
polysulphide there were only half as many larvae as on those sprayed with  
sulphur.

In another experiment carried out at Saint-Sornin (Charente-Infé-  
rieure) lime-sulphur spray mixed with Bordeaux mixture was tried instead  
of polysulphide against oidium and mildew. The first results were satis-  
factory and the author intends continuing the experiment in 1918.

From a theoretical point of view alkaline polysulphide controls oidium.  
From a practical point of view, however, sulphur will always be preferred  
because:— 1) sulphur is always ready for use, whereas polysulphide must be  
dissolved; 2) sulphur is a fine powder and scatters more easily, penetrating  
better to the organ to be protected, *i. e.*, the fruit, than a liquid, especially  
in summer when the clusters are hidden by the leaves; 3) polysulphide may

injure the spraying machines, which are usually of copper, and must be carefully washed with fresh water after use.

Should the vine-grower have only an insufficient amount of sulphur he may use polysulphide only for the first treatments, to made before flowering. During this period it would have the following advantages:— 1) as the young bunches are not yet hidden by the leaves the liquid reaches them more easily; 2) at this time of year the temperature is not always sufficiently high to make the sulphur active; 3) as attacks of oidium have not yet begun the treatment is preventative; the sulphur being a powder, does not remain long on the leaves and is active only for a short time; 4) polysulphide may be applied at the same time as sulphur. More complete experiments will show whether, under these conditions, copper mixture is equally efficacious against mildew.

### WEEDS AND PARASITIC FLOWERING PLANTS.

932 - **Mexican Marigold (*Tagetes minuta*), a Weed in Rhodesia.** — EYLES, F., in *The Rhodesia Agricultural Journal*, Vol. XV, No. 2, pp. 153-154 + 2 Plates. Salisbury, Rhodesia, April, 1918.

In recent years Rhodesia has been invaded by a troublesome weed, *Tagetes minuta* L. (Compositae). It is generally known as Mexican Marigold, but is locally called Mexican Poppy, and, in Australia, Stinking Roger. It is a native of South America and believed to have been introduced into South Africa during the Boer War.

At the present time it is spreading with great rapidity in Rhodesia, both in waste and cultivated land and shows a marked preference for ant hills. Its root system is shallow and not very extensive, and it should be possible to destroy the plant or prevent its spreading. It succumbs to the usual methods of cultivation, but if its spread is to be checked it must be uprooted and killed while young, *i.e.*, before flowering, so that seed may not be formed.

The author has recently heard some farmers call this plant "Khaki Weed", which is an entirely different plant, *Alternanthera echinata* (fam. *Amarantaceae*), known in Rhodesia long before the Mexican Marigold first appeared. The confusion is probably caused by the fact that the Dutch call the Compositae "Khakibos".

### INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

#### GENERAL

933 - ***Aleyrodidae* Injurious to Various Plants in Different Countries (1).** — QUAIN-TANCE, A. L. and BAKER, A. C., in *Proceedings of the U. S. National Museum*, Vol. LI, No. 2156, pp. 335-445 + 10 Figs. + 46 Plats. Washington, 1917.

This paper is a continuation of the author's work on the classification of the *Aleyrodidae* based on material in the collections of the United States National Museum and the Bureau of Entomology, Washington.

(1) See R. Nov., 1916, No. 1241 (Ed.).

The following insects are described morphologically :—

- 1) *Aleurocanthus bambusae* (Peal), abundant on various species of *Bambusa* near Calcutta. Generally only a few leaves of a group of plants are attacked by the insect, but nevertheless it has been found in very large numbers in some bamboo clumps; in such cases it is a rather serious pest and often kills most of the leaves. The insect is controlled by a parasite, probably a chalcidid. When the insect is removed from the leaf the part beneath it is found to be yellow and discoloured.
- 2) *A. banksiae* (Maskell), living on *Banksia integrifolia* and *Callistemon linearis*, in Australia;
- 3) *A. calophylli* (Kotinsky), on *Calophyllum neophyllum*, at Levuka. (Fiji);
- 4) *A. citricolus* (Newstead), on *Citrus* sp., at Dares Salaam, German West Africa;
- 5) *A. citriperdus* Quaintance and Baker, on orange and an unknown tree in Java. Ceylon and India; apparently an abundant species;
- 6) *A. dissimilis* n. sp., on unknown vine, at Mirdon, Lower Burma;
- 7) *A. hirsutus* (Maskell), on *Acacia longifolia*, in Australia;
- 8) *A. longispinus* n. sp., on *Bambusa*, at Calcutta and Moulmein, Burma;
- 9) *A. mangiferae* n. sp., on mango, at Bombay, Saharanpur and Dehra Dun, India;
- 10) *A. nubilans* (Buckton), on leaves of *Piper Belle*, at Backergunge, India, where it did considerable damage;
- 11) *A. piperis* (Maskell), on *Piper nigrum* (?), in Ceylon;
- 12) *A. serratus* n. sp., on an unknown tree in the Botanical Gardens of Buitenzorg, Java;
- 13) *A. spiniferus* (Quaintance), on *Citrus* sp. and rose, at Garch, Java;
- 14) *A. spinosus* (Kuwana), on unknown host; found by KUWANA among Coccidae from Formosa;
- 15) *A. T-signatus* (Maskell), on *Acacia longifolia* near Sydney, Australia;
- 16) *A. woglumi* Ashby, a very common species in the east, recently introduced into the West Indies and Bahama Islands;
- 17) *A. voeltzkowii* (Newstead), on un-named plant, the leaves of which were almost entirely covered with the black puparia, larvae and eggs of the insect, at Sainte-Marie, Madagascar;
- 18) *Aleurocybotus graminicolus* (Quaintance);
- 19) *A. setiferus* n. sp., on *Imperata*, at Java, and on grass, at Peradeniya, Ceylon;
- 20) *Aleurolobus barodensis* (Maskell), on *Saccharum officinale*, at Baroda, India; reported as injurious;
- 21) *A. flavus* n. sp., on unknown tree in the Royal Botanic Gardens, Ceylon and on *Loranthus*, at Peradeniya;
- 22) *A. marlati* (Quaintance), on orange, at Hokato and Kumamoto, Japan;
- 23) *A. olivinus* (Silvestri), on olive in central and southern Italy;
- 24) *A. philippinensis* n. sp., on unknown tree and on *Murraya exotica*, at Manila, Philippines;
- 25) *A. setigerus* n. sp., on *Harpullia pendula* and on unknown host, at Peradeniya;
- 26) *A. simulus* (Peal), very abundant on *Bombax malabaricum* (Simul tree), in Calcutta; the leaves are thickly covered with the insect, become yellow or spotted where attacked and finally die;
- 27) *A. solitarius* n. sp., on *Cercis canadensis*, at Champaign, Illinois;
- 28) *A. taonabae* (Kuwana), on grapes at Okoga and on grapes and *Taonabo japonica* at Tokio;
- 29) *Aleuroparadoxus iridescens* (Bemis), on *Arctostaphylos* sp., near Camp Rincon, San Gabriel Mountains, California;
- 30) *A. punctatus* n. sp., on *Lithraea caustica* and *Quillaja Saponaria*, at Santiago, Chile;
- 31) *Aleuroplatus* (subgen. *Aleuroplatus*) *berbericulus* n. sp., on *Berberis Aquifolium*,

at Kaslo, British Columbia; the insect was also collected at Mexico City and on *Ilex*, at Toluca, Mexico;

32) *A. (Aleuroplatus) cockerelli* (Jhering);

33) *A. (Aleuroplatus) coccolus* n. sp., on coconut at Santiago de las Vegas, Cuba, and in Trinidad; on *Eugenia Michellii*, at Ceara, Brazil; has also been found in Panama;

34) *A. (Aleuroplatus) coronatus* (Quaintance), on *Quercus agrifoliae*, in Los Angeles, Pomona and Whittier, California, on unknown plant in San Bernardino, Calif., and on chestnut in Pasadena, California;

35) *A. euryae* (Kuwana);

36) *A. (Aleuroplatus) ficus-rugosae* n. sp., on *Ficus rugosa*, in the Royal Botanic Gardens of Calcutta;

37) *A. (Aleuroplatus) gelatinosus* (Cockerell);

38) *A. (Aleuroplatus) incisus* n. sp., on *Ostodes zeylanica*, *Garcinia spectabilis* and on an unknown tree in the Royal Botanical Gardens, Peradeniya;

39) *A. (Aleuroplatus) myricae* n. sp., on *Myrica* sp. (?), at Griffin, Georgia;

40) *A. (Aleuroplatus) oculiminutus* n. sp., on *Ficus* sp., in Trinidad;

41) *A. (Aleuroplatus) oculireniformis* n. sp., on *Passiflora*, at Ceara, Brazil;

42) *A. (Aleuroplatus) ovatus* n. sp., on *Berberis trifoliata*, at College Station, Texas;

43) *A. (Aleuroplatus) pectiniferus* n. sp., on *Morus* sp. and a *Euphorbiaceae*, at Lahore, India;

44) *A. (Aleuroplatus) plumosus* (Quaintance); was described from Florida; very abundant on cranberries, and collected on this plant at Cranmoor, Wisconsin, New-Egypt and Pemberton, New Jersey;

45) *A. (Aleuroplatus) quercus-aquaticae* (Quaintance);

46) *A. (Aleuroplatus) sculpturatus* n. sp., on *Heliconia*, Panama;

47) *A. (Aleuroplatus) translucidus* n. sp., on orange at Lahore and Wazirabad, India;

48) *A. (Aleuroplatus) validus* n. sp., on unknown host, at Hope, Kingston, Jamaica;

49) *A. (Aleuroplatus) variegatus* n. sp., on leaves of *Psidium* sp., at San José, Costa Rica;

50) *A. (Aleuroplatus) vinsonioides* (Cockerell), on *Nectandra*, at Matanzas, Cuba;

51) *A. (subgen. Orchamas) mammaeiferus* n. sp., on *Codiaeum variegatum*, in the Botanical Gardens at Buitenzorg;

52) *Aleurothrixus* (subgen. *Aleurothrixus*) *acpim* (Goeldi), on *Manihot utilisima*, at Rio de Janeiro;

53) *A. (Aleurothrixus) floccosus* (Maskell); this species was described for the first time on *Lignumvitae* from Jamaica, and later on guava from Brazil; it was reported on orange at Zapotlan, Mexico, but had previously been collected on the same plant at Laguna, Mexico; it is common in the West Indies, and is also found in Florida, British Guiana, Argentina, Chile, Paraguay, and Costa Rica; besides *Citrus* spp. it has been found on *Coccoloba uvifera* (sea grape), *Plumeria* sp., *Baccharis genistelloides*, a coarse grass, and a climbing vine;

54) *A. (Aleurothrixus) howardi* (Quaintance), on the same hosts and in the same localities as the preceding species; reported for the first time in the United States on sea grape at Miami, Florida;

55) *A. (Aleurothrixus) porteri* (Quaintance and Baker), common on citrus in Chile;

56) *A. (subgen. Philodamus) interrogatoris* (Bemis);

57) *Dialeurodes* (subgen. *Dialeurodes*) *citri* (Ashmead), known as the orange white fly, is found on orange in the following States of the United States: Alabama, California, Colorado, Florida, Illinois, Louisiana, Mississippi, North Carolina, Texas, and District of Columbia; specimens have also been received from India (Lahore, Gujranwala, Dehra Dun, Wazirabad, Amritsar, Khasia Hills, Assam, Saharanpur), Japan (Nagasaki), and China (Canton, Peking, Shanghai); the insect also occurs in Chile, Mexico, and Brazil;

58) *D. (Dialeurodes) citrifolii* (Morgan) on orange in the following States: — Florida,

California, Louisiana, Mississippi, and North Carolina; the species is also known from Mexico and Cuba;

59) *D. (Dialeurodes) rodens* (Maskell), on *Drimys axillaris*, in New Zealand;

60) *D. (Dialeurodes) kirkalayi* (Kotinsky), on leaves of *Jasminum* at Georgetown, Demerara, British Guiana;

61) *D. (Dialeurodes) radiipuncta* n. sp., in Ceylon;

62) *D. (Dialeurodes) tricolor* n. sp., on leaves of a myrtaceous plant at Rubato, Brazil;

63) *D.* (subgen. *Rusostigma*) *eugeniae* (Maskell), on *Eugenia jambolana*, in India;

64) *D. (Rusostigma) radirugosa* n. sp., on mango, in Brilliton Is., Dutch East Indies and on a woody shrub at Gercit, Java;

65) *D. (Rusostigma) tokyonis* (Kuwana), on *Ilex integra*, in the locality Shibuya, Tokyo;

66) *D.* (subgen. *Dialeuonemada*) *dissimilis* n. sp., on *Phyllanthus myrsinifolius* at Saharanpur, India;

67) *D.* (subgen. *Rabdostigma*) *radulmealis* n. sp., on mistletoe, at New Ava Eliya, Ceylon;

68) *D.* (subgen. *Gigaleurodes*) *cerifera* n. sp., on *Celastrus buxifolius*, at Cape Town, South Africa;

69) *D. (Gigaleurodes) busckii* n. sp., on leaves of a climbing vine, at Bayamon, Porto Rico;

70) *D. (Gigaleurodes) maxima* n. sp., on *Ficus* sp., at Manila, Philippines;

71) *D. (Gigaleurodes) struthanthi* (Hempell), on *Struthanthus flexicaulis*, orange, *Melichia flava* and unidentified forest tree at Parnahyba and São Paulo, Brazil;

72) *S.* (subgen. *Rachisphora*) *fijiensis* (Kotinsky), on leaves and fruit of a Leguminosae at Rewa, Fiji;

73) *D. (Rachisphora) rutherfordi* n. sp., on *Loranthus*, at Peradeniya, Ceylon;

74) *D. (Rachisphora) trilobitoides* n. sp., on *Harpullia* and *Eugenia operculata*, at Peradeniya, on an unknown plant in the Royal Botanical Gardens, Ceylon;

75) *S.* (subgen. *Dialeuropora*) *decompuncta* n. sp., on *Cinnamomum*, in the Royal Botanical Gardens, Ceylon, and on mulberry, at Lahore, India;

76) *D.* (subgen. *Dialeuroplata*) *townsendi* n. sp., on a fern at Lucerna, Tayabas, Philippines;

77) *Neomaskellia comata* (Maskell);

78) *N. bergii* (Signoret), on unknown host in Java, and on a wild grass at Manila.

934 - West Indian and North American Chalcids. — GIRAULT, A. A., in *Entomological News*, Vol. XXIX, No. 4, pp. 125-131. Philadelphia, April, 1918.

The following should be noted: —

1) *Grotiusomyia nigricans* (Howard); one female reared from a larva of *Eudamus proteus* in St. Vincent, British West Indies.

2) *Gr. flavicornis* Girault; two females reared from a pyralid leaf-miner on oat at Washington, D. C.

3) *Polycystus clypeatus* n. sp.; one female reared from a leaf-miner on maize in St. Vincent.

4) *Sycophila incerta* Ashmead; many females reared from *Ficus laurina*, Barbados, West Indies.

5) *Indarnes carme* Walker, reared with a *Blastophaga* from *F. laurina* in Barbados.

6) *Pseudomphale eudami* n. sp.; reared from the larva of *Eudamus proteus* in St. Vincent.

7) *Closterocerus utahensis* Crawford (*Cl. californicus* Girault); one female from *Symydobius chrysolepis*, on *Quercus chrysolepis*, in California.

8) *Omphalchrysocharis petiolatus* n. sp.; reared from an oscinid on a daisy, at Washington, D. C.

MEANS  
OF PREVENTION  
AND CONTROL

9) *Arthrolytus aeneoviridis* Girault; one female from *Bucculatrix thurberiaella*, on cotton at Phoenix, Arizona.

935 - *Ipoobracon saccharalis* n. sp. and *Microdus diatraeae*, Hymenoptera Parasitic on *Diatraea saccharalis*, a Microlepidopteron Injurious to Sugar Canes, in British Guiana. — TURNER, R. E., in the *Bulletin of Entomological Research*, Vol. IX, Pt. 1, pp. 81-82. London, May, 1918.

Three species of Braconidae have been bred in British Guiana from the larva of *Diatraea saccharalis* (1) :—

1) *Ipoobracon grenadensis* Ashm., previously mentioned by the author (1917) ;

2) *I. saccharalis* n. sp., a parasite of the larva of *Diatraea*, in the Non Pareil Plantation, East Coast of Demerara ;

3) *Microdus diatraeae* n. sp., a parasite of the larva of the same microlepidopteron, at Lusignan, Non Pareil and Ogle plantations, East Coast of Demerara.

A morphological description of both of these two last species is given.

INSECTS, ETC.,  
INJURIOUS  
TO VARIOUS  
CROPS

936 - Weevils Which Affect the Potato, Sweet Potato, and Yam. — PIERCE, W. D., in the *Journal of Agricultural Research*, Vol. XII, No. 9, pp. 601-612 + 7 Plates. Washington, March 4, 1918.

In 1914 the author reported three weevils observed in South America as important pests of the potato tuber. In the paper under review he enumerates the three weevils previously studied, describes a fourth which also attacks the potato, gives notes on the morphology of four other weevils injurious to sweet potato (*Ipomoea Batatas*) tubers and of another described as a new pest of tubers of the yam (*Dioscorea Batatas*)

WEEVILS WHICH ATTACK IRISH POTATO TUBERS : — 1) *Rhigopsidius tucumanus* Heller, reported by the author in 1914 in the following localities : Tucumán, Argentina ; Cuzco, Temuco, and Arequipa, Peru ; Oruro, Bolivia ; Ancud or San Carlos and Castro Islands, Chile.

2) *Premnotrypes solani* Pierce (1914) in the mountain districts of Peru.

3) *Trypopermon latithorax* Pierce (1914), described as a pest of tubers, from Cuzco ; on June 11, 1914, Mr. H. L. SANFORD found numerous larvae of this species in potatoes from La Paz, Bolivia ; the transformation of the larvae into pupae was noticed from June 20 to 26, and an adult emerged on June 26 ; this enabled the author to describe the larva and pupa.

4) *Tryp. sanfordi* n. sp., described from a single specimen collected by Mr. SANFORD on September 24, 1915, from a potato from Cuzco.

WEEVILS WHICH ATTACK SWEET POTATO TUBERS (2). — 1) *Cylas formicarius* Fabricius var. *elegantulus* Summers ; the author gives this name temporarily to the common sweet potato weevil with blueish elytra, red thorax and legs, and black head ; the larva and pupa are described from specimens taken at Victoria, Texas ; the figures of the male are drawn

(1) See R April, 1916, No. 479 (Ed.) — (2) See R., May, 1918, No. 607. (Ed.)

partly from a New Orleans, Louisiana, specimen, partly from a Honolulu, Hawaiian Islands, one; specimens found at Victoria were used for the figures of the larva and pupa.

2) *C. turcipennis* Boheman; two specimens from Palembang, Sumatra, and two from Bay Laguna Province, Philippine Islands, are considered as belonging to this species; an adult was found in Guatemala; the insect was observed by PASCOE at Sarawak, Java and in India.

3) *C. femoralis* Faust, collected from February to April, 1897, on Mount Coffee, Liberia, where it did serious damage; it has also been reported from Kamerun.

4) *Euscepes batatae* C. O. Waterhouse (Scarabee of the Sweet Potato); one of the most serious cosmopolitan pests of the sweet potato, though up to the present it has only been reported from Barbados, St. Vincent, Antigua, St. Kitts, Nevis and Hawaii; having received from Brazil two specimens of this weevil with the statement that they attacked sweet potatoes at Rio de Janeiro, the author undertook research through the undetermined collections of the U. S. National Museum and was thus able to ascertain the existence of the insect in Barbados, Jamaica (Hope, Kingston), Brazil (Campinas, Rio de Janeiro), Hawaii (Honolulu, Kaimuki, Oahu), Guam, Norfolk Island near New Zealand, and Porto Rico (Mayaguez); the wide geographical distribution of the insect makes it appear probable that it is found in many other districts where the sweet potato is grown; a description of the adult, larva and pupa is given; material from Hawaii has been used for the figures of the adult, material from Barbados for those of the larva and pupa.

WEEVIL WHICH ATTACKS THE YAM TUBER. — *Palaeopus dioscoreae* n. sp.; described from two specimens reared from the tubers of yams from Jamaica (Hope, Kingston).

937 - *Physothrips marshalli* n. sp., a Thrips Observed on Potato and Other Plants in the Gold Coast. — BAGNALL, R. S., in the *Bulletin of Entomological Research*, Vol. IX, Pt. I, pp. 65-70 + 3 Figs. London, May, 1918.

The author describes particularly as a species new to science under the name of *Physothrips marshalli* a thrips collected at Aburi, Gold Coast, where it appears to be common.

Females only were found in flowers of *Solanum tuberosum* and *S. Wendlandii*; both sexes, but chiefly females, in flowers of *Ipomoeae Bona-nox*; both sexes with fairly plentiful males, in flowers of *Hibiscus sinensis*, *Thunbergia erecta*, *T. laurifolia*, *Strophanthus gratus* and *Canna*.

Morphological notes are also given on two previously described species, *Phys. funtumiae* Bagn. (1913), and *Phys. kellyanus* Bagn. (1916), the first of which forms the type of a small group of the genus *Physothrips* which includes the two species mentioned above.

*Phys. funtumiae* lives on *Funtumia elastica* and is known in Uganda and Southern Nigeria. *Phys. kellyanus* was described from specimens collected in North Queensland on a composite plant (*Helianthus* sp. ?), and on a South African plant (*Acokanthera spectabilis*) in the Botanic Gardens of

Brisbane,<sup>1</sup> Queensland. The insect has also been found in Victoria on *Hypochoeris radicata*.

938 - **Damage Caused to the Cotton Plant in Algeria by *Gelechia gossypiella*.** — See No. 865 of this *Review*.

939 - **The Sugar-Cane Froghopper in Grenada, Lesser Antilles.** — WILLIAMS, C. B., in the *Bulletin of Entomological Research*, Vol. IX, Pt. 1, pp. 83-87 + Map. London, May, 1918.

During investigations carried out on behalf of the Government of Trinidad on froghoppers (*Cercopidae*) of the genus *Tomaspis* found on sugar cane in that and the neighbouring islands (1), the author stayed a few days in December, 1916, at Grenada to study a small but serious attack of froghoppers there.

The insects were first reported from Grenada by UHLER in 1895, under the name of *T. pictipennis* Stål. In 1912 several specimens found on Para grass (*Panicum barbinode*) were sent from Grenada to the Board of Agriculture at Trinidad. URICH believed these to belong to the same species as that recorded by UHLER; it was, however, not *T. pictipennis*, but a species very similar to that of Trinidad, *T. saccharina* Distant, then known as *T. varia* Fabr. Urich nevertheless believed the Grenada specimens to be distinct from the Trinidad species. At the beginning of December, 1916, froghoppers were reported to be doing serious damage to sugar cane in one part of Grenada.

Froghoppers of one species were found widely distributed in the Island on grass in cane-fields, on the roadside, and also on sugar cane. The author did not visit the north-east of the Island, but it is probable that froghoppers are there too. Their wide distribution shows that they have long been established at Grenada.

The damage was reported from Mount Horne and Nainganfoix. The author visited the first locality and found the principal characteristics of the froghopper attack were quite similar to those found in Trinidad.

A careful comparison of the numerous specimens of the insect found in Grenada and the Trinidad species led the author to conclude that in both cases the insect was *T. saccharina* Distant. This is the first certain record of this insect outside Trinidad.

With regard to the natural enemies of the hemipteron (2), no larvae of the Trinidad Syrphid fly (*Salpingogaster nigra*) (3) were found at Grenada, and if present they must be too rare to have any effect in the control of the insect.

A single dead adult froghopper was found to be infected with *Metarhizium Anisopliae* (4), but this is also too rare to be of any practical use.

(1) See B. Dec., 1910, p. 421; B. Jan., 1911, No. 352; B. Feb. 1911, No. 649; B. May, 1911, Nos. 1558 and 1584, B. Dec., 1912, No. 1698; B. June, 1914, No. 549. (Ed.) —

(2) See B. Nov., 1910, p. 186; B. Feb., 1911, No. 650; B. Dec., 1912, No. 1698; B. Nov., 1913, No. 1306; B. Feb., 1914, No. 188. (Ed.) — (3) See B. Feb., 1914, No. 188. (Ed.) —

(4) See B. Feb., 1911, No. 650; B. Dec., 1912, No. 1698 (Ed.).

Attid spiders, an important control in Trinidad, were very scarce on the canes at Grenada.

Some specimens of the predatory grasshopper (*Xiphidium fasciatum*) known to feed on froghoppers were found in the grass near infested cane fields as well as in other parts of Grenada. It does not, however, appear actually to enter the plantations, but may help to keep down the froghoppers in the areas between, and so prevent a rapid spread of the insect.

The mongoose (mammal belonging to the genus *Herpestes*), which is indirectly partly responsible for the damage done by the insects because of the birds and lizards it destroys, is generally common in Grenada, and in some localities rewards are offered for its destruction.

The author spread over the infested fields in Grenada a mixture, prepared at Trinidad, composed of artificial cultures of *Metarrhizium* spores and rice flour, in the hope of infecting the froghoppers. After leaving Grenada he was informed that several dead infected grasshoppers were observed at Mount Horne, and that in 1917 the insects again appeared in the fields he had visited, but not to the same extent as in the previous year.

*T. saccharina* was found in the following localities of Grenada : St. George, Belmont, on grass among cane ; Morne Rouge, on cane ; St. George Lower Road, on grass ; Woodlands and Calvini, on cane ; St. Davids ; North of Barley's Bacolet, on grass ; La Sagesse, on grass ; St. Andrew, Meneve, Simon, St. Andrew Harbour, on grass ; Lower Simon, Mount Horne, Nain-ganfoix, on cane ; St. Patrick ; St. Mark and St. John were not visited by the author, but there is no doubt that the insect also exists there.

940 - **Hemiptera Living on Cultivated Plants in the Belgian Congo.** — DISTANT, W. L., in the *Bulletin of Entomological Research*, Vol. IX, Pt. 1, pp. 71-73 + 3 Figs. London, May, 1918.

The author describes the following species of hemiptera (fam. *Capsidae*) :—

1) *Lycidocoris mimeticus* Reut. and Popp. : Var. A. (typical form) was found at Lubowa, Uganda ; Var. B. was found on coffee bushes at Eala, Belgian Congo ;

2) *Lyc. modestus* n. sp., on *Cinchona*, at Eala ;

3) *Lyc. thoracicus* n. sp., on indigenous rubiaceous plant, at Eala ;

4) *Chamus beltus* n. sp., on " lionzi " at Eala ;

5) *Ch. tuberculatus* n. sp., on *Psidium Guajava* at Kunnulû, Belgian Congo.

941 - ***Physothrips setiventris* n. sp. and *Phys. lefroyi*, Thrips Injurious to Tea in India.** — BAGNALL, R. S., in the *Bulletin of Entomological Research*, Vol. IX, Pt. 1, pp. 61-64 + 2 Figs. London, May, 1918.

A description is given of the two following species found in India on tea in such numbers that they may be regarded as pests :—

1) *Physothrips setiventris* n. sp., collected on tea at Ringon, T. E., Darjiling district, in June, 1916 ; females were taken on the same host plant at Lebong, in September, 1908 ;

2) *Phys. lefroyi* Bagnall, observed on flowers of tea at Lebong, in February, 1909.

942 - Pests Observed on Tobacco from Réunion Grown in Mauritius. — AUCHINCLECK, G. G., in *Department of Agriculture, Mauritius, General Series, Bulletin No 9*, pp. 6. Port Louis, 1917.

In 1916 to 1917 cultural experiments were made in Mauritius with a variety of tobacco widely grown in the neighbouring island of Réunion under the name of "tabac bleu". Its produce (scaferlati) is imported into Mauritius in large quantities and is largely consumed there. The experiments gave good results, but the plant suffered from insect and fungoid pests.

In the first stages of development the plants on the borders of the plot cultivated at Pamplemousses were seriously attacked by *Achatina ponderosa*. The molluscs were collected by hand and destroyed. To keep the pest away till the tobacco-plants were sufficiently strong lime was spread around them.

The young plants were slightly damaged by larvae of *Heliothis armigera*, which was controlled by collecting it by hand.

Young seedlings are subject to attack from *Pythium de Baryanum* if planted too close. This may be prevented by spreading ashes round the seedlings and thinning out the young plants.

Ants are particularly fond of the seeds. To protect the seedlings against these insects they should be surrounded by a border of earth moistened with paraffin.

The most serious damage was due to a disease of the roots, an anguillulid (*Heterodera*), and a fungus producing spots on the leaves. Steps must be taken in the future to control all these three causes of disease. The disease of the roots, probably due to a *Fusarium*, invaded the small plantation at Beau Bassin. Several plants were killed by the fungus, which, it seems, may be controlled by spreading lime abundantly over the soil and by isolating the infected plot by a trench.

The anguillulid appeared in the Pamplemousses plantation and in a small plot at Réduit. The growth of the plants attacked was arrested, and they turned pale and sickly looking. Some parts of Mauritius seem seriously infested by this worm, and it is doubtful whether tobacco could do well there.

The spots on the leaves are caused by a fungus (*Erysiphe*). Small, round, reddish-brown spots occur on the mature leaves. At Pamplemousses in 1915 the Turkish tobacco suffered severely from this disease, many of the plants being quite unusable. The "tabac bleu" variety remained immune till the plants were fully ripe, and was then attacked, but only slightly. In a wet year, however, the damage might be very serious seeing that badly spotted leaves reduce the value of the tobacco. Moreover, in the case of tobacco, a disease of the leaves is very difficult to treat because anti-cryptogamic sprays would injure the quality of leaves to be used for smoking.

943 - *Agriolimax agrestis*. A Molluscan Garden Pest, in New York State. — BAKER, F. C., in *Science*, New Series, Vol. XLVII, No. 1216, pp. 391-392. Lancaster, Pa., April 19, 1918.

The author previously reported the presence of this slug in market gardens in New York State, where it had done considerable damage to

cauliflowers, lettuces, and potatoes (1). In the summer and early autumn of 1917 the slug became still more troublesome.

At Brewerton it was observed eating cabbages and potatoes; in Syracuse it attacked potatoes, doing much injury in several fields and gardens. In one garden potatoes were so severely attacked that two-thirds of the tubers were destroyed. Several slugs were found in a single potato together with many larvae of a beetle (probably *Agriotus manicus* Say) and isopods. The larvae of the coleopteron were reported as very abundant in potatoes in Syracuse and Rochester, and damage by the slug was reported from Rochester, Canandaigua and Geneva.

It is obvious that the slug is becoming a pest in market gardens and that it must be controlled; when its action is limited to the epigeal parts of the plant this may be done by spreading fine ash round the plant; the copious flow of mucus caused by the irritating action of the ash exhausts the slug. This method, however, is not effective if the soil is penetrated and the tuber attacked below the surface. If the grass round the garden were kept short it would not be possible for the slug to hide there during the day, for it is only active at night. Boards placed round the garden may also be used as traps; during the day the slugs hide under them and may be collected and killed.

*A. agrestis* is one of the most common slugs in western New York,

It is interesting to note that a related species, *A. campestris* Binney, has been observed eating considerable numbers of plant lice (*Phorodon mahaleb* Fonsc.); thus, unlike *A. agrestis*, this is a useful species.

944 - *Stephanitis rhododendri*, Injurious to Rhododendrons, in France. — MARCHAL, P. in the *Bulletin de la Société de Pathologie végétale de France*, Vol IV, Pt. 2, pp 93-95. Paris, 1917.

The presence of a new pest of ornamental trees was observed in the neighbourhood of Paris in 1917. The pest, a hemipteron of the Tingitidae family (Hemiptera-Heteroptera), *Stephanitis rhododendri* Horv., was discovered in nurseries at Châtenay (Seine) and has since been observed at Versailles.

According to information from Versailles the insect was introduced on rhododendron trees imported from Holland tree or four years ago. It was in Holland, in the Boskoop nurseries, that *Steph. rhododendri* was first observed, and HORVATH described it in 1905 from samples collected there. In spite of all attempts to destroy it the insect has persisted in this locality and spread into the neighbouring district. In 1910 it was also reported from England by DISTANT, who believes it to have been introduced into Europe from the Indies, though the name by which it is known in Holland, "japansche luis", implies that it might have been imported from Japan.

The damage done by *Steph. rhododendri*, chiefly in June and July, is similar to that done by *Steph. pyri* Fabr. Certain varieties of rhododendron suffer much more than others. According to RITZEMA BOS the eggs are

(1) See B. May, 1916, No. 600. (Ed.)

laid towards the end of July or the beginning of August on the thick part of the under surface of the leaf, near the main vein. The eggs hibernate and hatch in spring. After three months the wings of the insect are fully developed, thus enabling it to emigrate to other plants. In Holland at least there is only one generation a year.

The best means of controlling the insect is by spraying with nicotine, soap, or pyrethrum, which must be applied so as to reach the under surface of the leaf. The soil must be turned with a spade after the treatment, which should be applied frequently early in spring, before the wings of the insect have developed. In Holland "X. L. All." insecticide is most used, or else a nicotine solution mixed with 2 % soap and 1 % spirit.

Fumigations with tobacco under a cloth arranged as a tent may also be recommended. Where there is a staff accustomed to fumigation with hydrocyanic acid there is little doubt that this method would give the best results.

To prevent the spreading of the insect, care must be taken to use only healthy plants as stock and to examine young plants when transplanting them, carefully picking and burning all leaves attacked by the insect.

945—*Cecidomyid Flies Living on Olea chrysophylla and O. europaea, in Eritrea and Italy Respectively.*—DEL GUERCIO, in *L'Agricoltura Coloniale*, Year XII, 1st. Half-Year, No. 2, pp. 65-102 + 35 Figs. Florence, 1918.

A morpho-biological description is given of the larvae and in two cases, also the pupae, of several diptera belonging to the *Cecidomyiidae* family which live on *Olea chrysophylla* in Eritrea and *O. europaea* in Italy. The injury done by the larvae to the respective host plants is also described. The determination of the diptera—described as species new to science—is based, in the absence of adults, on the characters of the larvae examined.

1) *Rhabdophaga oleiperda* n. sp.; attacks young branches of *O. chrysophylla*. The branches are deformed by the galls caused by the larvae, their growth stops, their leaves drop, and eventually they die. If death does not occur the branches remain sterile. The pupa is described. The larva is attacked by an ectoparasitic chalcid, which seems very valuable in the natural control of this insect.

2) *Hormomyia oleiphila* n. sp. The galls produced by the larva develop on the leaves of *O. chrysophylla* and, more rarely, on the extremity of the petiole. The growth of the leaves is stopped, or is so limited that they hardly surround the diseased part with a small border of blade, or the leaf is reduced merely to the portion occupied by the gall. The leaf surface is thus reduced with corresponding injury to the vegetative system and a relative decrease in the yield of the plant. The pupa of this dipteran is also known. The larva may be controlled effectively with an ectoparasitic chalcid.

3) *Radulella aureocephala* n. sp. The larva of this insect causes the formation of very prominent galls on both sides of the leaves of *O. chrysophylla*. It does not appear to be as important as the two preceding insects, especially the first.

4) *Ferrisia chrysophyllae* n. sp. Leaf galls are formed on *O. chry-*

*sophylla*. In economic importance this insect comes after *Rhabdophaga oleiperda*; to judge by the few leaves examined by the author, when they are attacked they are reduced to about half their normal size.

5) *P. proxima* n. sp. Leaf galls are formed on *O. chrysophylla* causing a marked reduction of the leaves attacked; this reduction is less marked when the petiole is diseased. The economic importance of the insect is equal to that of the preceding one.

6) *P. verrucosa* n. sp. The leaf galls formed on *O. chrysophylla* are similar to those caused by *P. proxima*.

7) *Lasioptera carpophila* n. sp. The larva is described from a specimen found in fruit of *O. europaea* from the province of Teramo. A larva probably identical with the preceding one has been observed in olives from Promontorio Garganico.

The author takes *Dasineura lathierei* and *Lasioptera kiefferiana*, which in Italy attack the vegetative and reproductive organs of *O. europaea*, as types of two new genera which he calls *Gioliella lathierei* and *Gastinella kiefferiana* respectively.

The most important preventative control measure for some of these insects is to prevent their passing from one continent or district to another in attacked produce. Although it has not yet been proved experimentally that *Rhabd. oleiperda*, peculiar to *O. chrysophylla*, can also attack the common olive, the mere possibility is sufficient to justify the above precaution until the contrary has been proved. The same applies to *Gioliella lathierei* and *Gastinella kiefferiana*, so that they may not be carried from Lake Major and the unredeemed lands to central and southern Italy.

When the species of diptera described are already very common, the easiest, best, and most economical way of preventing their spreading and to cure attacked plants is by suitable pruning or topping of the diseased branches. All the parts cut should be immediately burnt. As topping prevents harvest in the year in which it is carried out it is best to prune, whether the plants be small or fairly large, and to spray abundantly with lime water, calcium polysulphide, or lime sulphur mixture, using these liquids alone, or, better still, together with a certain amount of flour, even if damaged, as it makes the mixture more adhesive.

946 - *Hoplia floridana* n. sp., a Coleopteron Injurious to Citrus, in Florida. — FISHER, W. S., in *The Canadian Entomologist*, Vol. L, No. 4, pp. 140-142. London, April, 1918.

Under the name of *Hoplia floridana* a description is given of a coleopteron (fam. Scarabaeidae) collected at Lake Wales, Florida, by Mr. H. L. DOZIER on February 7, 1917; it is described as new to science. The five specimens, two males and three females, found up to the present were taken while feeding on citrus foliage.

947 - *Nezara viridula*, a Hemipteron Injurious to Pecan Trees in Georgia, U. S. A. — See No. 927 of this Review.

948 - *Evetria buoliana*, a Microlepidopteron Injurious to Pines in France — LÉVÊQUE DE VILMORIN, PH., in the *Bulletin de la Société de Pathologie végétale de France*, Vol. IV, Pt. 2, pp. 83-85. Paris, 1917.

For many years the pines of Verrières have suffered from attacks of *Evetria buoliana* Schiff., which destroys a considerable number of buds and deforms the trees to such an extent that they are absolutely unrecognizable. Young trees are particularly attacked.

The microlepidopteron (fam. *Tortricidae*) was described for the first time in 1776, in Austria, and is known in Europe, where, of recent years, notes on it have been published by various authors, amongst them BARBEY, LESNE and TRINCHIERI.

In the summer of 1914 it was reported for the first time in different parts of the United States, where it was probably introduced accidentally on young pines imported from Europe. In order to prevent its being again introduced, the American Government, by its Quarantine Order No. 20 of March 1, 1915, which came into force on July 1, 1915, forbade the importation of all varieties of pine of European origin.

At Verrières *P. ponderosa*, *P. ponderosa* var. *Malletii*, *P. Sabiniana*, *P. Taeda*, *P. contorta*, *P. muricata* are seriously injured, and some specimens have been completely killed by the repeated attacks of the insect.

*P. Thunbergii*, *P. Wilsonii*, *P. Coulteri*, *P. Jeffreyi*, *P. yunnanensis*, *P. uncinata*, *P. Balfouriana*, *P. Pinaster*, *P. monophylla*, *P. leiophylla* and many others are also attacked, but less severely.

The only specimens of *P. sylvestris*, *P. Laricio* and *P. Laricio* var. *aus-triaca* are old and strong, and the damage could not be ascertained.

On the other hand, a series of 5-leaved pines, represented at Verrières by *P. Armandi*, *P. Ayacahuite*, *P. Cembra*, *P. excelsa*, *P. koraiensis*, *P. monticola*, *P. parviflora*, *P. pentaphylla*, *P. Peuce* and *P. Strobis* has, so far, proved immune.

The fine pine from northern China, *P. Bungeana*, is also free from attack, as is a fairly strong specimen of *P. sylvestris* var. *rigensis*, and another of *P. rigida*.

The insect pupates in a gallery hollowed within the bud, in the first fortnight of June, and the moths appear at the end of June or beginning of July. Attacked buds which were placed in a breeding cage on June 1, 1915, gave moths on June 5. In 1917, nearly all the larvae pupated on June 11, and the first moths emerged on June 26. The author found a parasitised pupa, the body of which was filled with a large number of small larvae.

The only method of control seems to be the collection and destruction of infected buds containing larvae or pupae. Nevertheless, although this method has been adopted carefully for many years at Verrières, the ravages of the insect continue to increase. It might be possible to utilise several species of ichneumons, parasites of the larvae of *Evetria*, the presence of which was first observed in 1917 at Verrières. M. LESNE advises that attacked buds should be collected towards the beginning of June, and that, instead of burning them, they should be enclosed in vessels covered

with a fine mesh metallic net which will prevent the escape of the moths, but not that of their parasites.

### INJURIOUS VERTEBRATES.

949—**The Control of Field Mice by Acetylene Gas.**—ΠΑΠΑΓΕΩΡΓΙΟΥ ΠΗΔ.  
(PAPAGEORGIOU, P.) in ΓΕΩΡΓΙΚΟΝ ΔΕΔΤΙΟΝ ΤΗΣ Β. ΓΕΩΡΙΚΗΣ  
ΕΤΑΙΡΕΙΑΣ (*Bulletin of the Royal Hellenic Society of Agriculture*), Vol. X, No. III,  
pp. 3179-3182 + 1 Fig. Athens, 1918.

The author reports the very satisfactory results obtained by him at the Agricultural Station of Thessaly with a new acetylene gas method for destroying field mice. In many parts of the vast cereal-producing plain of Thessaly field mice, aided by favourable conditions, have multiplied so considerably that they are a serious menace to the coming harvest. In the absence of other chemical products, such as strychnine, carbon bisulphide, etc, the author applied calcium carbide, produced in large quantities by a local firm working a water fall at Gorgopotamos, near Lamia. Small pieces of calcium carbide the size of a pea are placed in the holes dug by the mice, a little water poured in and the holes stopped up. The mice are suffocated by the gas. If new holes open in two or three days the procedure is repeated. The method is harmless to those using it, easy to apply, and cheap.

**Mechanical Ploughing.**

**Methods of Ploughing without Ridges**

by

A. TARCHETTI.

*Director of the Mechanical Department  
of the "R. Stazione Sperimentale di Riscoltura" at Vercelle, Italy.*

The most important factors controlling the yield from a machine plough are the way the land is set out and the choice of the most suitable method of ploughing.

As is well known there are two systems of ploughing — ploughing with or without ridges (1).

PLOUGHING WITHOUT RIDGES.

In this method the furrow-slices are turned always to one side and no open furrows are left, thus facilitating work with harrows, drills, binders, etc., but requiring good well-drained soil. It can be performed in two ways:—

1) The *ordinary method* (the most used in Europe) consists in successively turning parallel furrows, by moving backwards and forwards be-

---

(1) Hilling-up (used for maize and other hoed crops) can be considered as a derivation of both the above-mentioned systems, rather than as a special method, as it first requires the land to be worked uniformly, the hills being thrown up afterwards, usually with double-breasted ploughs

tween the headlands. It is also practised on hilly land, as the furrows can all be thrown down-hill. It requires ploughs that can alternately turn the soil to the right (going) and left (returning) as with one-way, balance, and double Brabant ploughs.

2) *The Felleberg method* requires uninterrupted furrows, obtained by keeping the plough turning continually in the field, either from the headlands towards the centre or vice versa. With this method there are thus curved furrows at the corners of the field, therefore leaving small triangular areas unploughed. It evidently necessitates the use of the common single-breasted plough (turning either to the right or left) as in the ordinary motor- or traction-ploughs.

The same type of plough can be used for making ridges, either by gathering-up or casting. This method is too well known to necessitate a description, but, on account of its importance, it will be considered later.

1) **ORDINARY PLOUGHING WITHOUT RIDGES.** — This can be done on land of any shape or size and requires no special setting-out of the land, but the following precautions should be observed: —

a) The furrows should be turned parallel to the longest side of the field, to reduce the number of turns at the headland. However, it may be better to sacrifice the long furrow for the advantage of having the

Fig. 1. — Furrows between two parallel sides of an irregular field.

furrows between two regular and parallel sides, as in Fig. I, so as not to leave wedge-shaped pieces that would have to be finished with a team or by hand.

b) In this case it is best not to carry the furrows up to the irregular lines  $AB-CD$  of the other ends of the field, but rather to stop them on the rectilinear line  $ab-cd$ , so that the work will be easier to finish, either with a team or with the machine itself.

c) The entrance into the field should never (as in any system of ploughing whatever) be forgotten, and the order of the work should be subordinated to it so that, when the work is finished, the machine does not need to pass over the ploughed ground. Thus in the case of Fig. I, where  $E$  is the entrance to the field, the ploughing will be commenced at  $ac$ ,  $a, c, \dots$  up to  $b, d$ , that is, at such a distance from  $BD$  as will allow the machine or the team to pass to finish the headland  $b, d, BD$ . Afterwards, the headland  $ab-AB$  is first ploughed, then the strip  $b, d, -bd$  and finally the headland  $cd-CD$ , the machine leaving the field at the entrance  $E$ .

By ploughing without ridges, the whole of the field can be ploughed, save the small areas at the ends of the headlands necessary for the machine to turn in, proportional to the width of the headlands (1) and which are worked by hand.

When balance ploughs are used the width of the headland is approximately equal to the distance between the two extreme, opposite ploughs. In the case of turnwrest ploughs and double-Brabants, it depends on the breadth of the always-necessary *double, or figure-of-8, turns* that the machine can take, providing that it is not a question of machines with a central gripping-drum, which, up to a certain point, can turn on themselves.

2) FELLEMBERG PLOUGHING. — As is well known, it is difficult to turn perfect furrows on a curve so that this system is not advisable in all our soils (in Italy) where the ploughing is usually heavy and deep, the earth being turned over as evenly as possible.

On the other hand this system is much used in America where the large regular spaces, the friable, light soils, and the shallow ploughing, give a certain liberty as regards beginning ploughing, and where rapid work together with the maximum yield from the machine are required rather than regular and perfect ploughing.

With this system the time lost in turning when not working is certainly at a minimum (theoretically it should be nil), as the fatigue caused by turning when working is also minimised, but, on the contrary, very large triangular plots (the size of which increases with the size of the field and the acuteness of the angle) are left in the corners of the field, thus necessitating their being worked with a team or by hand, or even, if so desired, with the machine, but with a great loss of time.

(1) The headlands are best not ploughed with cable-hauled machines, but rather with a team. But if this is required a free strip should be left along  $AC$ , so that the machine can leave the field with the anchors or anchor-wagon, etc.

In order that ploughing may proceed normally and uninterruptedly the field should first be carefully and visibly marked out (by poles, plaster, furrows, etc.) to show the points and geometrical lines symmetrical to the sides of the area and indicating any changes in direction of the furrows.

Fig. 2. — Felleberg method: application to a square field.

As an example of this procedure let us take a four-sided equilateral field (square or lozenge-shaped) as in Fig. 2. After finding the centre  $O$

Fig. 3. — Felleberg method: finishing the corner of a square field in decreasing arcs.

Fig. 4. — Felleberg method: application to a triangular field.

of the field (where the diagonals  $AC$ ,  $BD$  intersect) a circle  $OM$  is described equal to the maximum turn possible to the machine. Then, round this

circle ploughing is begun, at  $a$ , for example, in a circle concentric to  $O$ . When the machine has arrived at  $b$ , near the starting point  $a$ , it is turned outwards by a distance equal to the breadth of the gang, and the second circle concentric to  $O$  is started at  $a_1$ , and so on, up to the last circle,  $a_n$ , at a tangent to the edge of the field. The spaces in the circle  $OM$  and the triangles  $A, B, C, D$ , are then worked, either by hand, with a team or the machine itself according to their area. In the last two cases sufficient space should be left by the last circle  $a_n$  between the last furrow and the edge of the field to allow the machine, etc., to pass from one corner of the field to another in order to plough the decreasing areas  $mn, m_1 n_1, \dots$  (Fig. 3) at each angle (1).

The procedure is similar in the case when the field is triangular (Fig. 4); the centre  $O$  is at the point of intersection of the bisectors of the angles  $A, B, C$ , but the plots left unploughed are larger owing to the acuteness of at least 2 angles.

If the field is rectangular or rhomboidal (Fig. 5), the points where the bisectors of the angles  $A, B, C$ , intersect are at  $M, N$ . The line  $MN$  is the line of symmetry of the field, and should be visibly marked in a rectangle formed by the lines  $ab, cd$  perpendicular to the parallel sides of the field.

Then, with  $M$  and  $N$  as centres, the half-circles  $b_1 C_m a_1$  and  $c_1 C_n d_1$  (2) with the radii  $MC_m$  and  $NC_n$  respectively and the lines  $ad$  and  $bc$  are marked on the ground, and ploughing of the zone enclosed by these lines is begun as shown in Fig. 6. After opening the median furrow  $C_m C_n$  on the line of symmetry, with an ordinary double breasted plough, ploughing is begun, and furrow 1 is turned throwing the soil to the right. When the limit marked by the half-circle  $a_1 C_m b_1$  is reached the gang is lifted and a figure-of-8 turn made in the direction of the arrow, to open furrow 2 on the return, always throwing the soil to the right and so on, until the machine arrives at  $d_1$ , when the ploughing becomes continuous, turning around the part already ploughed (shaded area of Fig. 5) to complete the work.

Some authors (3) advise a procedure shown in Fig. 7: the first furrow is started at  $M$ , and, at  $N$ , the machine is turned to the right, ploughing a small curve  $Nn$ ; the ploughs are then lifted and a figure-of-8 turn made to return to  $n$ , when the machine ploughs along the line  $n N_1 M_1 m$ ; at  $m$

(1) This method recalls to mind the following very original one, known now for some years, but unsuitable for large areas:—a cable attached to the machine was rolled round a strong post planted firmly in the centre of the field; as the machine advanced, it tended to move in a straight line but, being held by the cable, it was obliged to turn round the post unrolling the cable, and ploughing in the fashion of an Archimedean spiral instead of concentric circles.

(2) To speak exactly, the machine, in describing the curves on starting from the straight line, describes spirals rather than circles.

(3) See "Farm Power", published by the INTERNATIONAL HARVESTER CO., of Chicago. — *Journal d'Agriculture pratique*, 1917, No. 6. — *Le Génie rural*, 1917, No. 66. — See also *R.*, 1917, No. 574.

the ploughs are again lifted, and another figure-of-8 turn made to return to  $n$ , and so on, until having reached the minimum turning radius of the machine at  $c_1$ , it ploughs round the plot already ploughed, as in Fig. 6, that is, it successively describes the half-circles concentric to  $M$

*Fellemberg method.*

Fig. 5. — Application to a trapezoidal field.

Fig. 6. — Preparation of internal area without ploughing in curves.

Fig. 7. — Preparation of internal area by ploughing in curves.

and  $N$  (Fig. 5) and the straight furrows between  $ab$  and  $cd$ . In any case this procedure makes it very difficult to plough on the curved lines  $Nn$   $nN_1$   $M_1m$ . . . . . without considering the fatigue caused by the continual double turns at the end of the furrow (1).

(1) In cases such as Fig. 5, some authors, particularly BERTHAULT (cf. BARRAL and SAGNIER, *Dictionnaire d'Agriculture*, Vol. III, p. 412), have proposed the following method

As is shown in Fig. 5, and as would be expected, the *dead* angles, *i. e.*, these remaining to be ploughed, are all the narrower as the maximum radius of curvature *Ma* is smaller. It will, therefore, be seen that it is advisable to consider a field as composed of a num-

Fig. 8. — Ploughing the internal square by the method of fig. 2.

Fig. 9. — Ploughing the internal square by the method of fig. 5.

ber of rectangular or rhomboidal plots and to plough each of them successively. Thus, the square piece in Fig. 2 can be considered a made up of 2 rectangular plots *Att*, *D* and *tBCt*,, which should be ploughed separately according to the method described above. Again, the field may be considered to be divided into 2 squares, one inside the other, the internal square being ploughed first, either by the method shown in Fig. 2 (Fig. 8) or by that shown in Fig. 5 (Fig. 9), being continued by the Fellenberg method round the square.

Fig. 10 shows the case of an irregular 4-sided field. After finding the bisectors of the 4 angles and their points of intersection *M* and *N*, parallels to the sides *BC* and *AD* are drawn to meet the bisectors of the respective angles *C* and *D* in *c* and *d*, thus forming the triangle *Mcd*. From the apices of this triangle the lines *Ma*, *Mb*, *cc*, *dd*, *cc*, *dd*, *dd*, *dd*, are drawn perpendicular to the sides of the triangle, then, with *M*, *c*, and *d* as centres, arcs of a circle contained between these perpendicular are drawn, completing the triangle *OPQ*. For the interior of this triangle, with *N* as centre, the procedure is that of Fig. 4, then all outside the triangle up to the edge of the field is ploughed.

of ploughing, starting, from outside: — at 1 metre from the bisectors and the median line, parallel lines are drawn on each side enclosing headlands 2 metres wide. The first furrow is turned along the edge of the field and then the work gradually proceeds inwards in straight decreasing furrows, while the ploughs are lifted or earthed at each angle turn at the headlands, which are finally split again. This method, however, does not observe the principle of *continuous* labour proper to the Fellenberg system, and, moreover, it necessitates heavy work at the turns and it results in leaving triangular areas between the bisectors that have to be worked by hand.

## SECOND PART ABSTRACTS

### AGRICULTURAL INTELLIGENCE

#### GENERAL INFORMATION.

950 - **Facilities accorded to Official Agronomists for the Purchase of Automobiles, in Canada.** — SAVOIE, F. N. (Secretary, Ministry of Agriculture), in the *Journal of Agriculture* (Organ of the Minister of Agriculture for the Province of Quebec), Vol. XXI, p. 180, Quebec, June 15, 1916.

LEGISLATIVE  
AND  
ADMINISTRATIVE  
MEASURES

As farmers are asking more and more the aid and advice of the official agronomists, the Minister of Agriculture for the Province of Quebec has authorised all the agronomists to buy an automobile to facilitate their work. In order to encourage the agronomist to take care of the machine he has the choice between 2 systems of purchase : — 1) annual repayments of 20 % + 6 % interest on the cost price ; 2) immediate repayment of  $\frac{2}{3}$  the cost price.

In both cases the automobile remains the property of the agronomist ; the annual licence, fire insurance, running costs (petrol, oil, repairs), are paid for by the Ministry. The systems are based on a buying price of \$ 1 200.

The agronomist has to keep an account of his expenses and the monthly mileage covered on official work.

Both systems were tried in 1917, with satisfactory results.

Some agronomists have travelled more than 10 000 miles. Four chose the repayment by annual amounts, the rest preferring that by  $\frac{2}{3}$ .

951 - **On the Possibility that Man can Live on a Diet Containing No Fat; Researches in Denmark.** — *Ugeskrift for Lægevidenskaben*, Year 63, No. 22, pp. 296-298. Copenhagen, May, 1918.

RURAL  
HYGIENE

Previous researches aiming at ascertaining if there is a minimum of fat required in the human diet have lead to the general conclusion that man cannot live without a certain quantity in his diet, otherwise he will become unhealthy and may even endanger his life. Physiologists are not agreed as to the exact daily minimum of fat required by the human being for continued well-being. VOIT fixed the amount at 56 gm., TIGERSTEDT at 80 or 100 gm., while SOFUS TORUP also indicates the latter figures and says that, during the present war, a characteristic unhealthy state has

appeared which he calls "fedthunger" (fat hunger) and which has appeared in those countries where there is a shortage of fats, a state resembling that of Nansen's companions in the Greenland expedition. Numerous researches, using rats, have been made in the United States on this subject; when the rats received a diet absolutely free from fats, they became diseased, recovery being obtained on giving them the substances that were lacking. But the substances under question acted specifically in this case, some having a positive action, *i. e.*, producing recovery (fat from butter, egg yellow, liver oil, etc.), while others (fat from pig, olive oil, almond oil, etc.) did not bring about recovery or the return of the animals to the normal state. It was concluded that the effect was not due to the fats themselves, and that it was once more a question of "vitamines" (1).

In order to obtain more definite information on the subject, Dr. HINDHEDE made some observations on two strong, healthy persons, one a gardener, aged 31 years, and the other a student, aged 24 years. The subjects received, for more than a year, a diet "practically" free from fats, consisting of bread, potatoes and vegetables, variation being obtained by introducing, at stated periods, sweetened gruel. The two subjects were kept in very good condition while they were fed on bread, potatoes and vegetables; on the contrary, however, they lost flesh when the vegetables were replaced by the sweetened gruel. HINDHEDE admits that young, robust persons can live in perfect health for 16 months (and more, as the experiment is still in progress) on a diet of bread, potatoes, cabbages, rhubarb and apples, while a diet composed exclusively of sweetened gruel could apparently not be tolerated for more than a month. He therefore concludes that the different vegetables contain vitamins similar to those found in fats, and that the latter can be very well dispensed with provided they are replaced by vegetables. This also explains the insufficiency of the sweetened gruel. Owing to present circumstances the diet in Germany is characterised by penury of fats; although, generally speaking, the effects of such a state of affairs have not been so serious as might have been supposed, certain unhealthy conditions have appeared, contrary to the observations of HINDHEDE, amongst which is that called "Kartoffelkrankheit" (potato disease) by DÖLLNER; but it appears that this disease was cured by adding vegetables to the potatoes. Similarly, HINDHEDE attributes all the unhealthy conditions produced in Germany by the lack of fats to the lack of vitamins in the food. He thinks that there is no great need of alarm at the prospect of an eventual total lack of meat and fat, provided that care is taken to supply sufficient seeds, potatoes and vegetables.

In conclusion, HINDHEDE deduces some observations of practical value from his thesis. Those who have little land should devote as much as possible of it to market-gardening. In this way it has been calculated that Denmark could maintain 20 million individuals, if the live stock industry were suppressed. Although the exclusive growth of plants

---

(1) See *R.*, July, 1918, No. 719. (*Ed.*)

is not desirable and as these deductions are obviously as yet insufficiently sure to allow of their practical use, they are of great interest from the physiological point of view in that they apparently show that the human being can, without much risk, do without fats during a certain period.

952 — **The Feeding of Cattle and "Barlow's Disease" in Children Caused by Milk.** — *Nordisk Mejeri-Tidning*, Year XXXIII, No. 24, p. 284. Stockholm, June, 1918.

"Barlow's disease" so resembles scurvy that it is often called infantile scurvy. It appears in children fed exclusively on sterilised and boiled milk. It is obvious that the time required in heating milk has an influence on its vitamine content. Moreover, it is generally believed that milk is richer in vitamins during the summer when the fodder given to the cattle is fresher, than in winter when they chiefly feed on dry fodder. On the other hand, if roots are fed heavily in winter, milk might be produced that is richer in vitamins than the milk usually produced during that season, and thus have the effect of rendering the appearance of Barlow's disease more rare.

In any case, it is safest to pasteurise milk for children at a low temperature, the best method being to heat the milk for 30 minutes at 63° C.

953 — **Bacterial Precipitins and the Detection of *Bact. botulinus* in Preserved Foods by the Thermo-Precipitation Method.** — See No. 1047 of this Review.

954 — **Investigations into the Possibility of Calculating the Experimental Error in Field Experiments.** — GORSKI, M. and STEFANIOF, M. (Landwirtschaftliche Hochschule Dublany bei Lemberg), in *Die landwirtschaftlichen Versuchs-Stationen*, Vol. XC, Pt. 3 and 4, pp. 225-240. Berlin, 1917.

EXPERIMENTAL  
AND  
ANALYTICAL  
WORK

Recently the experimental error has been calculated in field experiments in many different places, but without much attention being paid to the possibility of its practical application.

Practically the only important works on this subject are: — 1) that of TH. PREIFFER and E. BLANCK (*Die landwirtschaftlichen Versuchs-Stationen*, Vol. LXXXIII, p. 331, 1914) in which, according to the authors, too few experimental plots were used; 2) the investigations of TH. REMY (*Landwirtschaftliche Jahrbücher*, Vol. XLIII, p. 453, 1912), which are not very conclusive because not carried out under consistent conditions; 3) the important, but little known work of E. ZALESKI (Anleitung zur Ausführung vergl. Versuche mit verschiedenen Zuckerrübensorten, aus dem Polnischen vom Verfasser übersetzt, 2. Ausgabe, Krakau, 1912), which, unfortunately has not been completely published; 4) the very exact investigations of TULAIKOV (*Journal Opitnoi Agronomii*, 1913); 5) P. EHRENBURG's study (*Die landwirtschaftlichen Versuchs-Stationen*, Vol. LXXXVII, p. 29, 1915), in which the author, basing his own experiments on those of W. B. MERCER and A. D. HALL (*Journal of Agricultural Science*, Vol. IV, p. 107, 1911) (1) shows clearly the agreement of the results obtained with the theory of the least squares: however, in spite of the abundant data EHRENBURG considers his work to be

(1) See R., January, 1912, No. 29. (Ed.)

only an attempt to prove that the experimental error may be calculated in field experiments; he believes the results obtained in the field to follow in general GAUSS' law, so that the calculation of the experimental error may be applied to them. Nevertheless, he considers it necessary to collect more abundant data before the possibility of applying such a calculation to field experiments can be scientifically assured.

In order to supply further control data the authors carried out new investigations and experiments in the grounds of the "Landwirtschaftliche Hochschule" (Agricultural College) of Dublany, near Lemberg, Galicia, in a series of 200 plots of sandy loam soil and 300 plots of loess soil. The plants used were oats.

The arithmetical mean of the crops obtained from each plot, 10.76 square yards in size, was first taken, and the deviation from this average determined for each plot. The experimental error was then calculated

by the formula  $r = 0.674 \sqrt{\frac{\sum v^2}{n-1}}$ , where  $r$  represents the probable error,  $\sum v^2$  the total of the squares of all the deviations without considering their sign, and  $n$  the number of observations.

RESULTS. — Those of the first set of experiments, in sandy loam, agree very well with GAUSS' law of errors. The number of positive and that of negative deviations are practically equal, and the extent of the deviation agrees well with the values calculated. If the extent and the sign of the deviation are considered together, a satisfactory agreement with GAUSS' law is also found.

In the second set of experiments, in loess, there is a yet better agreement between the deviation found and that calculated. On the other hand there is a certain disagreement between the deviation sign; instead of 150 positive and 150 negative deviations, there are 139 of the first and 161 of the second. The difference is, however, not sufficiently large for it to be said that the deviations do not follow GAUSS' law, as this can only be fully applied to an infinite set of observations.

The experimental errors (deviations from the average) in the two sets are accidental errors, to which the theory of the experimental error may well be applied. This does not, however, hold good for all field experiments, but it may be admitted that, in experiments carefully carried out in homogeneous soil, the errors which occur are only accidental.

955 — **Agricultural Experiment Stations of Canada.** — I. *The Canada Year Book* 1916-17, pp. 236-249. Ottawa, 1917. — II. *Dominion Experimental Farms; A Guide to the Experimental Farms and Stations.* Ottawa, 1912. — III. *Annual Reports of the Experimental Farms and Stations.* Ottawa. — IV. *The Agricultural Gazette of Canada.* Ottawa. — V. *Bulletins, pamphlets, circulars of the Dominion Experimental Farms Branch.* Ottawa.

In Canada there are the Dominion Experimental Farms and Stations administered by the Experimental Farms Branch of the central Department of Agriculture of the Government of the Dominion and the Provincial Colleges, Schools and Departments of Agriculture which also conduct agricultural experiments.

DOMINION EXPERIMENTAL FARMS AND STATIONS. — Under the Experimental Farm Stations Act, 1886, were established a Central Experimental Farm at Ottawa for Ontario and Quebec, and four branch Farms:— 1) for the Maritime Provinces at Nappan, Nova Scotia; 2) for Manitoba at Brandon; 3) for the North-west Territories at Indian Head, Saskatchewan; and 4) for British Columbia at Agassiz. After these five Farms had continued in operation for 20 years, the first steps were taken towards their extension in number by the establishment of new Experimental Stations for Alberta, viz., one at Lethbridge in 1906 and the other at Lacombe in 1907. Since this date development in the number of the Farms and Stations, and in the work carried on by them, has been rapid and continuous; and every province has now one or more Farms or Stations. The five original farms established in 1886 are known as "Experimental Farms", those added since are styled "Experimental Stations"; no distinction in the work is expressed by these titles.

*Dominion Experimental Farms and Stations, 1916.*

Farms or Stations	Province	Acreage	Date established
Central Farm, Ottawa . . . . .	Ontario	467	1886
Kapuskasing Station . . . . .	"	1 000	1916
Charlottetown Station . . . . .	Prince Edward Island	100	1909

Summerland Station . . . . .	"	550	1914
Agassiz Farm . . . . .	"	1 400	1886
Sydney Station, Vancouver Island . .	"	125	1912

Summing up, in 1916 there were altogether 21 Farms and Stations with an increased acreage over 1915 of 2 213, or a total average of 11 148, as compared with the original five Farms, having a total area of 3 472 acres.

Ranging over the whole of the wide fields of agriculture, arboriculture and horticulture, the work of the Farms has included experiments and studies relating to the breeding and feeding of farm live stock, the production of butter and cheese, field crops, natural and artificial fertilisers,

cereals, grasses and other forage plants, fruits, vegetables, plants, trees, plant diseases and injurious insects. The Farms are also bureaux of information to which agriculturists resort for practical advice. In addition to the farms and stations included in the foregoing table there are 7 small substations at Salmon Arm, British Columbia, at Fort Vermilion, Grouard and Beaver Lodge in Alberta, and at Forts Smith, Resolution and Providence, in the Northwest Territories.

The more strictly scientific side of the work is carried on at the Central Experimental Farm at Ottawa, and is organised in thirteen divisions as follows : — 1) Field Husbandry ; 2) Animal Husbandry ; 3) Horticulture ; 4) Cereals ; 5) Chemistry ; 6) Forage Plants ; 7) Botany ; 8) Poultry ; 9) Tobacco ; 10) Economic Fibre ; 11) Illustration Stations ; 12) Apiculture ; 13) Extension and Publicity. What was formerly the Entomological Division became in 1914 the separate Entomological Branch of the Department of Agriculture.

Only brief mention is possible of the more striking results already achieved, with some indication of the work now being carried on. In the field of *General Agriculture*, the importance of early sowing was demonstrated by a series of experiments which lasted from 1890 to 1899. As the result of experiments on the branch Farms in the West, the practice of summer fallowing for the conservation of moisture and the destruction of weeds is widely followed in the Prairie Provinces. Experiments continued from 1893 to 1910, have shown over large areas in Canada the economic advantage of applying fresh as compared with rotted farmyard manure. In the *Cereal Division*, notable work has been done in the production of new varieties of grain, especially wheat possessing the qualities of productiveness, an early ripening habit and good baking strength. Varieties of wheat known as Preston, Stanley and Huron are all vigorous and productive, and ripen early ; but the variety that has achieved the greatest success is the Marquis, which is equal to Red Fife in baking qualities, ripens from 5 to 10 days earlier and is superior in productiveness. It is now rapidly superseding Red Fife throughout the Northwest.

Experiments carried on over a series of years by the *Field Husbandry Division*, show the advisability of a rotation which includes a cereal crop, a hay crop (including clover) and a root crop. In the *Division of Animal Husbandry*, extensive breeding experiments are in progress. Important work has been done in the demonstration of effectively ventilated stables and cow barns. The *Division of Horticulture* carries out numerous experiments with apples, plums, cherries, grapes, small fruits and vegetables. Many varieties have in past years been tested, and promising seedlings for different latitudes have been recommended to growers. The object of the experiments with apples has been to obtain, by cross fertilisation and selection, new varieties that will stand the severe winters, also varieties of better keeping qualities. Experiments were begun in 1915 to test the possibility of growing root and vegetable seeds in Canada instead of importing them from abroad. So far as they have gone, the experiments have proved successful and are being continued. In the *Division of Botany*,

investigations of the diseases of cultivated plants are carried on, and advice is given as to remedial measures wherever possible. Weeds are identified and methods of eradication recommended. Wild plants from all parts of Canada are received for identification, and information is furnished as to whether they are edible, medicinal or poisonous. Tests are also made as to the suitability of the climate of Canada for the growth of various plants of economic importance, such as fibre plants (flax, hemp), medicinal plants (opium-poppy, anise, etc.), oil-yielding plants (castor oil, soy bean), and miscellaneous plants (mustard, chicory, etc.). Much has been accomplished in *Arboriculture* not only by setting apart 65 acres at the Central Experimental Farm for the testing of trees and shrubs from all parts of the world, but also by the encouragement given to tree-planting in the western provinces.

The *Division of Chemistry* covers a large field, and the Dominion Chemist, who is also Assistant Director of the Farms, controls a staff of nine fully qualified chemists. Investigations have been conducted to determine the nutritive value of fodder plants by analyses at different stages of their growth. Canadian grown cereals have been analysed to ascertain their quality and nutritive value, and the straw has also been examined to determine its value as fodder. Analyses have been made of soils from different parts of the Dominion. Investigations have been made into farmyard manures. Many experiments have been conducted to throw light on the factors affecting soil moisture, and means have been suggested whereby the desired conditions of moisture may, to a great extent, be obtained and controlled by cultural operations. The influence of environment on the composition of wheat has been studied since 1905, and the work has now been enlarged, through co-operation with the Dominion Meteorological Service at Toronto, to secure a more comprehensive and detailed study of the relationship between weather conditions and crop growth. Analyses of sugar beets have been useful in demonstrating the suitability of soil and climate at widely different points of the Dominion for the growth of roots of high sugar content and purity. Well waters from farm homesteads have been the subject of special study. Numerous analyses are made in conjunction with problems relating to the land, the crop and the animal which from time to time are submitted by farmers for solution. Analyses are also made of dye stuffs, preservatives, pickling solutions, etc., and systematic investigational work with commercial fertilizers is now being carried on. Owing to the scarcity of potash caused by the European war, the preparation of a nitro-potassic fertiliser by the drying and grinding of seaweed was undertaken at a point on the coast of Nova Scotia. The fertilising value of the material so prepared is being tested in the field.

The *Poultry Division* undertakes experiments in the breeding, etc., of farm poultry. Demonstrations in poultry keeping are made, chiefly for the purpose of proving locally that farm poultry rather than the poultry farm is profitable.

Experiments in the growth of *tobacco* are carried on by an expert

from France at Ottawa, assisted by local superintendents at the tobacco stations of St. Jacques l'Achigan, and Farnham, Quebec and Harrow, Ontario. In 1912 a *Division of Forage Plants* was established under the direction of a scientific officer from the Plant Breeding Station at Svalöf in Sweden. The Division has for its object improvement in the quality and yield of grasses, clovers, alfalfas and other forage crops grown in Canada. An Economic Fibre Division was established at Ottawa early in 1916 to investigate the possibilities of the flax fibre industry in Canada. Hemp growing is also being tried.

*Illustration Stations* were started in 1914 by the selection of small areas at different points in Saskatchewan and Alberta, the object being to show to farmers in the district selected the best cultural and crop methods. Early in 1915 the Illustration Station work inaugurated by the Commission of Conservation was taken over by the Experimental Farm Branch. In 1915 a *Division of Extension and Publicity* of the same Branch was formed for the purpose of making the work of the Experimental Farms more widely known amongst the farmers of Canada. The Division issues every four months a publication entitled "Seasonable Hints", which gives timely notes and advice to help the farmer in his current work.

PROVINCIAL AGRICULTURAL EXPERIMENTS. — In *Nova Scotia* at the College of Agriculture, Truro, about 400 acres are devoted to general farming and gardening and to investigations (application of ground limestone; fertiliser experiments; experiments with varieties of oats, wheat, barley, etc.; feeding experiments; influence of various stocks of the apple on the scion; collection of cherries and plums; variety tests of strawberries; hill selection of potatoes; etc.); experiments are also conducted in the chemical, entomological and botanical laboratories.

In *Quebec* the Macdonald College, Ste. Anne de Bellevue, comprises 786 acres divided as follows: — main farm, 584 acres; cereal husbandry plots, 75 acres; poultry department, 17 acres; orchards, 35 acres; vegetable gardens, 25 acres; recreation fields, 50 acres. Experiments are carried on in animal husbandry, cereal husbandry, poultry, chemistry, bacteriology, horticulture, biology and physics. The Oka Agricultural Institute is one of the oldest experimental farms in Canada; a large number of dairy cattle are kept and experimental work is carried on with these and with swine, poultry and bees; horticulture is practised largely; the growth of small fruits is a speciality and the vineyards are celebrated. The School of Agriculture, Ste. Anne de la Pocatière, owns more than 500 acres of land, where besides general cultivation a number of experiments are also carried on.

The *Ontario* Agricultural College and Experimental Farm, Guelph, were established in 1874 to train young farmers in the science and practice of agriculture and to conduct agricultural experiments for the benefit of the province. Research and experimental work is conducted in the departments of field husbandry, animal husbandry, horticulture, chemistry, dairy, poultry, physics, bacteriology, entomology, botany and apiculture.

In *Manitoba*, at the College of Agriculture, Winnipeg, field husbandry

experimental work was inaugurated in the spring of 1915 and was divided into 3 divisions:— cereal crops; forage crops; soil and crop management.

The College of Agriculture, Saskatoon, *Saskatchewan*, has a farm of 880 acres which is devoted to diversified agriculture; investigations are being made to ascertain the carrying power of prairie lands under different crops for the production of meat and milk; in grading up farm flocks from the common range ewes; cheap housing for sheep, swine and poultry; in silage production from crops other than maize, such as oats and peas, sweet clover, alfalfa; another section has been set aside for investigations in tillage, crop production, crop improvements, variety tests and rotations; the effects of different artificial fertilisers with farmyard manure are being tried; garden and fruit crops, trees, shrubs and flowers are being introduced for the purpose of testing varieties and methods of management, under prairie conditions.

A College of Agriculture has been established at the new University of *Alberta*, Edmonton South, where at present over 100 acres of land are available for experimental work in cereals, grasses, clovers, hoed crops, small fruits, vegetables and flowers; work is being started with soils and excellent foundation stock has been secured in pure-bred cattle, sheep and hogs. Experimental work at each of the three provincial Schools of Agriculture at Paretholm, Olds and Vermilion has been carried out by the Alberta Department of Agriculture since October, 1914.

Finally experiments are being carried out by the Live stock and Horticulture branches of the *British Columbia* Department of Agriculture; the Live Stock branch is conducting one experimental plot of 13 acres, another of 10 acres, 11 plots from 4 to 5 acres and 6 one-acre alfalfa plots; work in drainage and the correcting of soil acidity is being carried out in one plot; where plots are located in newly-settled districts, the work partakes largely of tests to determine the best crops and varieties for local conditions; on other plots a rotation system suitable for the district represented is being established, and as far as possible the work is carried on in co-operation with the local Farmers' Institutes, and where practicable the plots are used as a centre of good seed production; the horticultural branch too is operating vine demonstration and experimental orchards of five acres each, which are planted and cared for under a co-operative arrangement by which the owner of the land and the Department share the expense, the agreement covering a five-year period, but in some cases further agreements are being made.

At the University of British Columbia the experimental results obtained by the Department of Agronomy during 1915-16 with all classes of field crops have proved of great value in determining the best methods of bringing heavily timbered uplands under cultivation; the allotments of land made to the Departments of Agronomy and Horticulture are being specially prepared for investigational work, and in Animal Husbandry special attention will be given to feed problems in connection with cattle, swine, sheep and poultry; over 25 000 specimens of the native flora of the province, representing nearly 800 species, have been transferred to the

Botanical garden and constitute the most representative botanical collection of British Columbia.

## CROPS AND CULTIVATION.

AGRICULTURAL  
METEOROLOGY

956 - Chemical Composition, from an Agricultural Point of View, of Rainwater Collected at Montevideo, Uruguay, from 1909 to 1912—SCHROEDER, J., in the *Revista del Instituto Nacional de Agronomía de Montevideo*, Ser. II, No. 1, pp. 29-48. Montevideo, January, 1918.

In a previous report (*Revista del Instituto N. de Agronomía*, Montevideo, 1910, No. 7, p. 123) the author published the results of his observations on the carbonic acid content of the air at Montevideo. These results showed that the amount of the gas present varies greatly with the season and the direction of the wind. The average content is 2.98 volumes per 10 000 volumes of air under normal conditions, at 0°C and 760 mm.

The report under review gives a series of data relating to the amount of nitrogenous compounds, chlorides (expressed as sodium chloride) and organic matter carried to the soil by rainwater during the period 1909-1912. The work done on the chemical composition of rainwater in all parts of the world is first reviewed rapidly, and the author then gives the results of his own observations, which are summarised in tables. These observations, made at the Sayago experiment field at the Agricultural Institute of Montevideo, lead to the following conclusions:—

With a total precipitation of 1504 mm. per annum (in 1912), 1 acre of the Sayago experiment field received 6.88 lb. of combined nitrogen, of which 3.28 lb. was ammoniacal and 3.60 lb. nitrous and nitric. At the end of 24 months of observation (May to September, 1908; October, 1911 to February, 1913) the same area received 7.03 lb. of ammoniacal nitrogen and 6.09 lb. of nitric nitrogen, *i. e.*, 12.23 lb. of nitrous and nitric nitrogen, or 6.10 lb. per acre annually. The nitrogen content of rainwater of 18 tropical countries and of 96 temperate countries (50 observations) is given. A comparative examination shows that the figures obtained at Sayago are slightly higher than those for the tropical and temperate countries.

The author was unable to prove that the seasons had any influence on the amount of nitrogen, which, moreover, he thinks only worth considering as a source of nitrogen for agriculture. The quantity of chlorides (expressed as sodium chloride) carried to the soil by rainwater is 73.60 lb. per acre. The chloride content of the rainwater seems to depend on the direction of the wind while the rain is falling.

The amount of organic matter (calculated in milligrams of oxygen required to burn it) was on an average 750 mgm. of oxygen per 1 000 litres of rainwater. The evaporation residue of rain is, on an average 303 lb. per acre annually, of which 108 lb. disappear on burning and 195 lb. form a non-volatile residue.

In conclusion the author points out that these figures refer to the Montevideo district and not the interior of the country.

957 - Some Notes on the Direct Determination of the Hygroscopic Coefficient. — ALWAY, F. J., KLINE, M. A. and McDOLB, G. R., in the *Journal of Agricultural Research*, Vol. XI, No. 4, pp. 147-166 + Bibliography of 27 Publications. Washington, D. C., October 22, 1917.

SOIL PHYSICS,  
CHEMISTRY  
AND  
MICROBIOLOGY

The hygroscopic coefficient expresses the percentage of moisture contained in a soil which, in a dry condition, has been brought into a saturated atmosphere, kept at a constant temperature, and allowed to remain until approximate equilibrium with this atmosphere has been attained. It has a twofold significance, both serving as single-valued expression of the relative fineness of texture, and, in soil-moisture studies, permitting the approximate estimation of the maximum amount of water available for growth and for the maintenance of plant life — the difference between the total amount of water and the hygroscopic coefficient.

The error is sometimes made of confusing MITSCHERLICH's "Hygroskopizität" with the hygroscopic coefficient as above defined. The former is determined by allowing the exposed soils to come into equilibrium with an atmosphere in contact with a 10 per cent sulphuric acid solution instead of with water, MITSCHERLICH holding that the determination by HILGARD's method gives results much too high on account of the condensation of moisture on the exposed samples.

HILGARD's method was described by him (Report on the Methods of Physical and Chemical Soil Analysis, *U. S. Dept. of Agr., Division of Chemistry, Bulletin* 38, 1893, pp. 60-82) as follows: —

The fine earth is exposed to an atmosphere saturated with moisture for about twelve hours at the ordinary temperature (60° F.) of the cellar in which the box should be kept. For this it is sifted in a layer of about 1 mm. thickness upon glazed paper, on a wooden table in a small water-tight covered box (12 by 9 by 8 inches) in which there is about an inch of water; the interior sides and cover of the box should be lined with blotting paper, kept saturated with water, to insure the saturation of the air.

After eight to twelve hours the earth is transferred as quickly as possible, in the cellar, to a weighed drying-tube and weighed. The tube is then placed in a paraffin bath, the temperature gradually raised to 200° C. and kept there 20 to 30 minutes (rapidity of raising temperature depending upon the amount of moisture in the soil), a current of dry air passing continually through the tube. It is then weighed again, and the loss in weight gives the hygroscopic moisture in saturated air.

Some time later, to avoid the decomposition of the organic matter of surface soils, HILGARD modified the method to the extent of using an air bath, raising the temperature to only 110° C, keeping the sample in for an hour, weighing, drying again, and continuing the process until a practically constant weight was obtained.

The authors have tested this method by studying the following points: — rapid loss of hygroscopic moisture; suitability of trays of various materials; influence of time of exposure; effect of great fluctuations in the temperature of the room; effect of grinding; influence of size of absorption boxes and the number of tables; concordance of determinations:

in practice ; reliability of the method described by HILGARD ; modification of method when sample contains gravel or pebbles ; they arrive at the following conclusions : —

The amount of hygroscopic moisture absorbed increases with the rise of temperature. Drying of mineral soils at temperature of  $100^{\circ}$  to  $110^{\circ}$  C. does not appreciably decrease their hygroscopicity. Intractable samples may be reduced in a steel mortar to pass a 1 mm. sieve without appreciably affecting their hygroscopicity.

Twelve hour's exposure in the absorption boxes is sufficient only when the soil layer is very shallow. In practice a longer interval is found more convenient, 20 to 24 hours proving very satisfactory. An exposure of more than 24 hours gives higher values only in the case of very fine textured soils.

A soil containing the amount of moisture corresponding to its hygroscopic coefficient loses water very rapidly when exposed to an ordinarily dry atmosphere, but in determining the hygroscopic coefficient the time necessary to transfer the soils from the absorption boxes to weighing bottles is so brief that the loss during the transfer is too small to appreciably affect the accuracy of the results.

HILGARD'S method for the determination of the hygroscopic coefficient carried out exactly as he describes it, gives reliable results. However, the loose sheets of glazed paper used are very inconvenient when many determinations are to be made and may be advantageously replaced by shallow trays, either of aluminium or of copper. Trays of glass, graniteware, and vulcanized rubber give satisfactory results, but are less convenient, while those of tin plate or zinc, although satisfactory at first, soon corrode. Pasteboard trays lined with glazed paper give results much too low, unless the period of exposure be greatly prolonged, and even those of paraffined pasteboard lined with glazed paper give somewhat low results. Any considerable increase in the size of the absorption boxes over that recommended by HILGARD or the use of a larger number of exposed samples within the boxes of the same size cause too low results, unless the time of exposure be greatly increased.

958 — **The Relationship Between Absorption and Coagulation With Respect to the Mineral Colloids of the Soil.** — DOMINICIS, A. DE, in collaboration with CHIARERI, P. (Laboratorio di Chimica agraria della R. Scuola Superiore di Agricoltura di Portici), in *Le Stazioni Agrarie sperimentali italiane*, Vol. 4, Pt. 9-10, pp. 451-479. Modena, 1917.

In two earlier papers (*Rendiconti della Società Chimica italiana*, Vol. V, p. 285, 1913 ; *Le Stazioni sperimentali agrarie italiane*, Vol. XLVIII, p. 525, 1915 ; *Annali di Chimica applicata*, Vol. IV, p. 284, 1915) the author gave the results of a series of investigations into the relationship (resulting from an objective examination of facts) between absorption and coagulation. The general plan of the investigation was to determine the relationship between that which is absorbed and that which is coagulated, considering that each time a saline solution acts on a colloidal solution the resulting coagulation always determines a lowering of the concentration of one of the electrolytic constituents of the dissolved salt. The constituent thus acted on is that which, by reason of its charge, acts on the coagulation in

such a way that, when it is not a question of colloids easily subject to reciprocal replacement (as certain zeolites and soil in general), the saline solution may become acid or alkaline, according to the circumstances. In his previous papers the author showed this relationship to exist. The present paper gives a further experimental contribution which aims at making more clear the principles derived from the interpretation of the results. The method adopted in the new investigations did not differ from that of the preceding ones and consisted of verifying whether the ratio between the monovalent alkaline metals (ammonium, potassium and sodium) also exists for the bivalent alkaline-earth metals (calcium, barium, strontium and magnesium):— 1) by a study of the relationship with regard to the concentration of the active electrolyte; 2) with regard to the duration of the action of this electrolyte; 3) with regard to the absorbing power of the different metals; 4) with regard to the valency of these metals. The results, which agree with those of the previous investigations, confirm the following general principles:—

1) There is a real and constant relation between absorption and coagulation.

2) The action of the electrolytes determines a single process in the unstable hydrosols consisting of coagulation by absorption. When atoms and ions of opposite sign come into contact they attract each other reciprocally, causing the neutralisation of their respective charges and the formation of insoluble absorption combinations. This causes a lowering of the concentration either in the colloidal solution or in the electrolyte solution.

3) Considered separately, the two processes proceed in parallel, as the function of identical factors and in function one of the other, that is, they advance as the opposed signs of charge between the atoms and ions drop, and are seen to be connected by the relation of cause and effect.

4) The existence of this relation is of great importance as regards the physical-chemical properties of the soil, which are always influenced by it in a manner advantageous to fertility.

959 - **Influence of Nitrates on Nitrogen-Assimilating Bacteria.**—HILLS, T. L. (Research Bacteriologist, Idaho Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. XII, No. 4, pp. 183-230 + 31 Tables + Bibliography of 49 Publications. Washington, D. C., January 28, 1918.

By far the greatest amount of work on the relation of nitrates to plant growth has been done in the realm of the higher plants. Very little attention has been given to the effect of nitrates on the lower plants, especially bacteria. Because of the relation that exists between higher plants and bacteria the author considered it advisable to study the effect of nitrates on certain groups of soil bacteria, including not only their reproduction but also some of their physiological properties. The soil bacteria studied were especially those forms concerned with the fixation of atmospheric nitrogen. The work followed two lines of investigation: First, the influence of nitrates on *Azotobacter* was determined. Here studies were made on the effect of nitrates on the growth of the organism in soil and also the effect

of these salts on the nitrogen-fixing property of these bacteria. The action of *Azotobacter* on nitrates in solution, the relation of nitrates to pigment production and to the formation of volutin bodies (1) were studied. Second, the influence of nitrates on the growth of *Bacillus radiculicola* in soil was studied. The action of *B. radiculicola* on nitrates in solution and the possible nitrogen-assimilating properties of the legume in the presence of nitrates were investigated. Also the influence of nitrates on gum production was determined. The latter part of the investigations included a study of the relation of nitrates to nodule formation on alfalfa.

The results are summarised as follows:—

1) Small quantities of potassium (10 to 100 mgm. in 100 gm. of dry soil), sodium, and calcium (10 to 150 mgm. in 100 gm. of dry soil) nitrates caused a great increase in the number of *Azotobacter* in sterilised soil. Ammonium nitrate in the same quantities caused a less marked increase. Higher concentrations were not so favourable to the growth of the organisms.

2) Potassium and sodium nitrates in the concentrations studied (as much as 150 mgm. of  $\text{NO}_3$  in 100 cc. of medium) caused an increase in the amount of nitrogen assimilated by *Azotobacter* on agar films. Calcium nitrate in the same amounts brought about a decrease in the amount of nitrogen fixed to a point even below that representing the amount assimilated in the absence of nitrates. In soil cultures nitrates of sodium and calcium caused an increase in total nitrogen, which was more marked in the unsterilised cultures than in those cultures sterilised and inoculated with a pure culture of *Azotobacter*. However, the increase in total nitrogen is not commensurate with the increase in the number of *Azotobacter* noted under the same conditions.

3) Under aerobic conditions *Azotobacter* in liquid cultures reduced nitrate to nitrite, but not to ammonia. More atmospheric nitrogen was assimilated in the presence of nitrate than in the absence of this salt.

4) Pigmentation occurred when potassium and sodium nitrates, and especially calcium nitrate, were used with *Azotobacter*, the colouration increasing with the concentration of the salt. This effect was more marked in *Azotobacter* strains which produce little or no pigment in the absence of nitrates.

5) All three nitrates studied caused an increase in the number and size of volutin bodies in *Azotobacter* cells. From all appearances these salts also tended to hasten the development of these bodies.

6) The number of *Bacillus radiculicola* in sterilised soil was increased by the addition of small quantities (as much as 50 mgm. nitrate in 100 gm.

(1) The presence of volutin bodies, or metachromatic granules in *Azotobacter* has been shown by BONAZZI. These substances, according to MEYER, are reserve food materials other than fat droplets, glycogen, and similar substances reacting with iodine stain which occur in the cytoplasm of the cells of various bacteria. With Millon's reagent they give no reaction. He believes that these bodies are composed of nucleic-acid compounds but are not nuclear proteins. (Author).

of dry soil) of potassium, sodium, ammonium, and calcium nitrates. This increase was not so marked as in the *Azotobacter* cultures. *B. radiculicola* appeared to be much more resistant to higher concentrations of nitrates than *Azotobacter*.

7) *B. radiculicola* under aerobic conditions did not reduce nitrates in solution to nitrite, ammonia, or elemental nitrogen. The presence of nitrates did not materially influence the small amount of atmospheric nitrogen fixed under these conditions.

8) When grown on agar films, *B. radiculicola* fixed a small amount of nitrogen, varying from 0.15 to 0.43 mgm. of nitrogen in 100 cc. of the medium. The addition of various amounts of potassium, sodium, and calcium nitrates increased to a slight extent the amount of nitrogen assimilated.

9) In liquid cultures all three nitrates caused a large increase in the amount of gum obtained by precipitation with acetone.

10) The presence of large amounts of potassium, sodium, and calcium nitrates proved detrimental to the formation of nodules on alfalfa. *B. radiculicola* did not appear to lose its infecting power when grown on media containing varying amounts of sodium and calcium nitrates. Alfalfa seedlings grown in the presence of large amounts of nitrate did not produce nodules when inoculated with a viable culture of *B. radiculicola*. Nitrates in soil cultures prevented the re-formation of nodules once removed and also caused a decrease in the number of nodules already present.

950 - New Coprolite Works in the United Kingdom. — *The Board of Trade Journal*, Vol. C, No. 1118, p. 532. London, May, 2, 1918.

MANURES  
AND MANURING

The Financial Secretary to the British Ministry of Munitions recently stated in the House of Commons that the initial expenditure by his Department on the new coprolite works — on plant, wages, buildings, and railways — was £31 279. The value of coprolites produced to date was negligible, but deliveries were anticipated to commence at the end of April at a rate which would shortly rise to 1 200 tons per week, and that a total production of some 80 000 tons, of a value of approximately £280 000 would be secured.

961 - Effect of Sulphur on Different Crops and Soils (1). — SHEED, O. M. (Kentucky Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. XI, No. 4, pp. 91-103. Washington, D. C., October 12, 1917.

There has recently been some discussion as to the importance and supply for plant growth of sulphur in its various compounds in soils and whether or not it may be a limiting element in crop production.

While it is one of the essential elements, the amounts found by the old method of ashing plants were so low in most cases that it was generally assumed there was an abundant supply of its compounds in soils for all crop requirements. More recently, however, it has been demonstrated by improved methods of analysis that most plants contain much more sulphur

(1) See R. 1911, Nos. 1145, 1397, 3730 — 1912, Nos. 780, 1279 — 1913, Nos. 234, 478, 941 — 1914, No. 503 — 1915, Nos. 4, 69, 798, 1280 — 1916, Nos. 150, 729. (*Ed.*)

than was formerly thought to be the case, owing to the fact that in many instances by the old method the bulk of the sulphur was lost on ashing the plant, and therefore was overlooked. The question then arose as to whether there is an ample supplement of sulphur compounds in soils for crop needs and especially for the best growth of those which are now known to have a high sulphur content.

Some investigators contend that, although some soils are low in sulphur, lower in many cases than in phosphorus, this is compensated for by the amount brought down in the rainfall; and as a result it will never be a limiting element in crop production. There are others, however, who maintain that the sulphur brought down in the rainfall will not equal the loss of this element in the drainage. To establish the point whether the application of sulphur compounds may be beneficial for the maximum production of crops high in sulphur when they are grown on soils that are low in this element, numerous experiments have been carried out. The results were in some cases decidedly beneficial, in others indifferent and in still others injurious. In order to avoid the difficulty arising from the use of the element to be tested in combination with others — which makes the results not easy of interpretation — the writer used flowers of sulphur mixed, at the rate of 100 and 200 lb. per acre, with soil to which the necessary fertilising ingredients were added, together with calcium carbonate. Eight surface soils, taken to a depth of  $6\frac{2}{3}$  in., each representing a distinct type in Kentucky and more or less impoverished by cultivation were selected. Soybeans, clover, oats, alfalfa and wheat were grown in the greenhouse on these soils.

The results show that the sulphur increased the production of some crops, had no effect on others, and on some was injurious, depending on the crop and the soil on which it was grown. There was a preponderance of gains, however, from the sulphur application, but these were generally small.

Analyses of some of the crops show that the sulphur increased the total and sulphate-sulphur content of the plant, and the greater the application, the greater the increase. Where sulphur was applied to clover and alfalfa, the excess sulphur in those plants was in the form of sulphate, while in soybeans part of the excess was in another form. In the soybeans which showed an increased sulphur content, no corresponding increased protein content was always found. In five instances out of eight, however, soybeans grown in soil where sulphur was added show an increase in the total weight of protein.

It was found that, of the 16 varieties of field and garden seeds examined — maize, beans, cowpeas, alfalfa, millet, oats, soybeans, wheat, hemp, timothy, rye, tobacco, peas, onions, bluegrass, clover — some, the 10 last, contain sulphates while others, the first 6, do not, but that, on germinating, all except two — maize and clover — form a greater or less amount of sulphate. The highest sulphate content obtained in the ungerminated seed was 0.048 % in clover, and the increase due to germination varied from none, in maize, to 0.035 %, in the onion. There was a slight loss in only one sample, clover.

962 - **An Estimate of the Amount of Fertilisers Required for Food Production in Norway.** — *Tidsskrift for Det Norske Landbruk*, Year XXIV, No. 5, pp. 208-211. Christiania, 1917.

The Supplies Committee of the Norwegian Agriculturists' League has estimated the amount of fertilisers required in Norway for agricultural purposes to assure the food supply of that country for 1918.

In Norway 590 520 tons of grain are consumed annually; on adding the amount required for sowing the total annual amount is 659 414 tons. The annual production of grain is 344 312 tons, but it could be increased to 413 364 tons by raising the yield per acre from 13.5 to 16 cwt. There would thus be a deficit of 246 050 tons, which could be provided for (assuming a yield of 16 cwt. per acre) by bringing another 620 246 acres under cultivation to cereals, the area requiring a complete fertiliser. On the other hand, increasing the annual production by 69 052 tons would require enough fertiliser for 74 133 acres over and above the area already under cereals, so that a complete fertiliser would be required for  $308\,887 + 74\,133 = 383\,020$  acres.

Assuming that the complete fertiliser would be made up, per acre, of 134 lb. calcium nitrate with 15 % of nitrogen, 178 lb. of 16 % superphosphate and 89 lb. of potash salts containing 37 % of potash, the amount of fertiliser required to produce sufficient food to balance the production and consumption in Norway would be: — 200 039 tons of nitrogenous manures calculated as 15 % calcium nitrate; 3 051 tons of phosphatic manures calculated as 16 % superphosphate; and 15 255 tons of potassium salts containing 37 % of potash.

Normally there are 1 294 866 acres of meadowland. If the area required for cereals is subtracted from that figure, there will remain 988 440 acres of meadowland. The fertiliser required per acre will be 178 lb. of nitrate, 89 lb. of superphosphate, and 89 lb. of potash salts, which gives a total of 39 368 tons of calcium nitrate with 15 % nitrogen, 19 684 tons of phosphatic manures reckoned as 16 % superphosphate or basic slag, and 19 684 tons of 37 % potash salts.

To this estimate of the fertiliser requirements for 1918 must be added the average consumption of previous years, which, according to the statistics consists of 8 858 tons of 15 % calcium nitrate, 41 336 tons of 16 % superphosphate or basic slag and 6 988 tons of 37 % potash salts.

Summing these figures the total fertilisers required in Norway to provide for food production is 70 862 tons of 15 % calcium nitrate, 91 531 tons of 16 % superphosphate, and 41 336 tons of 37 % potash salts.

963 - **Plants Tolerating Salt.** — FENZI, E. O., in the *Bollettino della R. Società Toscana di Orticoltura*, Year XLIII, Nos. 5-6, pp. 37-39. Florence, 1918.

Salt soil and brackish water are found in South Italy and in all the larger Italian islands along the coast of Tripoli, Eritrea and Somalia. So that these soils may be cultivated the author publishes the following list compiled partly from investigations recently made in Algeria by M. J. BRICHET and partly from his own experiments: —

AGRICULTURAL  
BOTANY,  
CHEMISTRY  
AND  
PHYSIOLOGY  
OF PLANTS

1). — PLANTS WHICH DO WELL IN SOILS FREE FROM CHLORIDES EVEN IF THEY ARE IMPREGNATED WITH WATER CONTAINING MORE THAN 1.5 % OF SALT (SODIUM CHLORIDE).

a) Agricultural and industrial plants. — Cotton, *Medicago arborea*, maize, sorghum (*Sorghum* spp.), tobacco.

b) Vegetables, etc. — Sorrel, garlic, beet, white beet, artichoke, cardoon, carrot, various kinds of cabbage, chicory, onion, water melon, bean, various kinds of lettuce, aubergine, capsicum, pea, tomato, leek.

c) Fruit trees. — Apricot from seed or ungrafted, quince *id.*, almond *id.*, apple *id.*, olive, pear ungrafted, plum *id.*, vines of different varieties.

d) Flowering and ornamental plants. — *Achyranthes*, *Ageratum*, amaranth of different varieties, *Antirrhinum*, *Coreopsis*, *Dahlia*, *Datura* of different varieties, *Escholzia*, marigold (*Calendula*), *Gaillardia*, *Gazania*, *Geranium* and *Pelargonium* of different varieties, *Iris* of different varieties, sunflower. *Mirabilis*, *Lippia repens*, camomile (*Anthemis*), *Mesembryaceae* of different varieties, poppies *id.*, *Petunia id.*, stock *id.*, *Zinnia id.*

e) Flowering and shade trees. — Laurel (*Laurus nobilis*), bitter orange, *Acacia eburnea* (= *A. horrida*), *Buddleia madagascariensis*, *Casuarina* of different varieties, *Cestrum elegans* and other species, *Duranta Plumieri*, *Muehlenbeckia platyclada*, *Robinia Pseudoacacia*, *Schinus Molle*, *S. terebinthifolius*.

II. — PLANTS CAPABLE OF GROWING AND DOING WELL IN SOILS CONTAINING NOT MORE THAN 5 % OF CHLORIDES, EVEN IF IMPREGNATED WITH WATER CONTAINING NOT MORE THAN 3 % OF CHLORIDES. — *Aberia caffra*, *Acacia cyanophylla*, *A. cyclopis*, *A. Farnesiana* and other species, *Ailanthus glandulosa*, locust tree, (*Ceratonia siliqua*), *Caesalpinia Gilliesi*, *Cupressus funebris*, *C. macrocarpa*, *Eucalyptus cornuta*, *E. robusta* and other species, *Pittosporum Tobira* and other species, *Pistacia atlantica*, *P. Lentiscus*, *P. Terebinthus*, *Parkinsonia*, *Phillyrea*, *Pinus halepensis*, *Punica Granatum*.

III. — PLANTS CAPABLE OF LIVING AND DOING WELL IN SOIL CONTAINING UP TO 5 % OF CHLORIDES, EVEN IF IMPREGNATED WITH WATER CONTAINING THE SAME PROPORTION OF CHLORIDES. — *Agave americana* and many other species, *Artemisia arborescens* and other species, *Atriplex Halimus*, *A. lentiformis* and other species, *Bupleurum fruticosum*, *Grithum maritimum*, *Juniperus macrocarpa*, *J. phoenicea*, *Melaleuca hypericifolia* and other species, *Myoporum laetum*, *id.*, different varieties of rose bay, *Opuntia Ficus-indica* and other species, *Phoenix canariensis*, *Ph. dactylifera*, *Pircunia dioica*, *Pinus Pinaster*, *P. Pinea*, *Sabal Palmetta* and other species, *Washingtonia filifera* and other species.

As is seen, the plants of the first group tolerate moderate quantities of salt, those of the second tolerate it in fairly large quantities, and those of the third in very large quantities.

- 964 - **A Physical and Chemical Study of the Kafir Kernel, in the United States** (1).  
 — BIDWELL, G. L., in the *U. S. Department of Agriculture, Bulletin* No. 634, pp. 5 + 1  
 Fig. Washington, April 4, 1918.

The grain of non-saccharine sorghums have hitherto been used almost exclusively for cattle feeding, but now they are used in ever-increasing quantities as a human food and for the preparation of starch and alcohol. For this reason the Bureau of Chemistry of the U. S. Department of Agriculture made a physical and chemical study of kafir kernels, using Dawn Kafir (Dwarf Blackhull) C. I. 340. The tegument of this variety is thin, and the endosperm horny without and starchy within. It is broadly ellipsoid and somewhat flattened on the inner surface. Imagining the kernel to lie on a flat surface, the vertical diameter was called the thickness, the shorter horizontal diameter the width, and the long diameter the length. The averages of 50 measurements were: — *thickness*: — maximum 2.74 mm., minimum 2.16 mm., average 2.46 mm.; *width*: — maximum 3.71 mm., minimum 2.95 mm., average 3.33 mm.; *length*: — maximum 4.57 mm., minimum 3.07 mm., average 3.90 mm.; *weight of 1000 kernels* 23.5 gm., — *Average volume of 1 kernel*, 16.78 mm<sup>3</sup>. The grain is composed of 6.1 % by weight of bran, 10 % of germ, 83.9 % of endosperm, 35 % of which is starchy, the rest horny. The endosperm is surrounded by a very friable, more or less granular layer, very rich in colouring matter, and soluble in ether and chloroform; it contains no tannin. The distribution of various components of the different parts of the grain, expressed in percentages of the total quantity of each component (the germ, bran and endosperm respectively) in the whole grain is as follows: —

Ash, 77.9, 7.2, 14.9; ether extract, 75.2, 9.9, 14.9; crude protein, (N × 6.25), 15.5, 2.3, 82.2; crude fibre, 19.1, 49.7, 31.2; nitrogen-free extract, 4.1, 5.5, 90.4.

The corresponding parts of kafir and maize kernels resemble each other in composition and appearance; it may, therefore, be assumed that kafir could be used as a substitute for maize.

- 965 - **Two New Vegetable Globulins:— Stizolobin and the Globulin of Buckwheat.**  
 — I. JOHNS, C. O. and FINKS, A. J. (Bureau of Chemistry, U. S. Department of Agriculture), Stizolobin, the Globulin of the Chinese Velvet Bean, *Stizolobium niveum*, in *The Journal of Biological Chemistry*, Vol. XXXIV, No. 2, pp. 429-438 + 13 Tables + Bibliography of 4 Publications. — II. JOHNS, C. O. and CBERNOFF, I. K., The Globulin of Buckwheat, *Fagopyrum esculentum*, *Ibid.*, pp. 439-445 + 6 Tables. Baltimore, May, 1918.

Chinese Velvet Beans (*Stizolobium niveum*) are being grown in ever increasing quantities in the United States, and, in 1917, covered an area of more than five million acres in the South, an increase of over 100 % of the area cultivated the preceding year. They are used especially as a cattle food, and contain 26.43 % of protein (N × 6.25). By extraction with a sodium chloride solution, and separation by dialysis or precipitation with ammonium sulphate, the authors obtained a globulin which they called

(1) See also R., April, 1918, No. 444. (Ed.)

"stizolobin". The amino-acid content of this globulin determined by VAN SLYKE's method was:—Cystine, 1.20; arginine, 6.72; histidine, 2.65; lysine, 8.27. The lysine content is very high. Stizolobin also contains tryptophane. Analyses of various samples of this globulin by the method mentioned above gave the following percentages:—Carbon, 53.03%; hydrogen, 7.05; nitrogen, 16.33; sulphur, 0.56; oxygen (by difference), 22.94%.

II. — By the method already described (extraction with a solution of sodium chloride, etc.) the authors isolated from buckwheat flour (*Fagopyrum esculentum*) a globulin containing basic amino-acids in the proportions given below according to VAN SLYKE's method:—Arginine, 12.97%; histidine, 0.59%; lysine, 7.90%; cystine, 1.00%. Like stizolobin this globulin is remarkable for its high lysine content, and also contains tryptophane. Several analyses gave the following average percentages for the various constituents of the globulin:—Carbon, 51.69; hydrogen, 6.90; nitrogen, 17.44; sulphur, 1.16; oxygen (by difference), 22.81.

966 — **The High Calcium Content of Some Cucurbitaceous Vines.** — WILKINS, L. K., in *New Jersey Agricultural Experiment Station Bulletin* 310, pp. 20 + Bibliography of 50 Publications. New Brunswick, N. J., April 16, 1917.

In this bulletin data are presented concerning the calcium content of the vines and fruits of some of the cucurbitaceae: namely, pumpkins, preserving citrons, squashes, cucumbers, and cantaloupes. The percentages of N,  $P_2O_5$ ,  $K_2O$ , and  $MgO$  for these cucurbitaceae are also recorded. Furthermore, the crop yields and the removal of plant-food on an acre basis are reported.

The vines were found to have a very high content of calcium, higher than has usually been reported or was believed to exist in most plants. In nearly every instance the mature vines contained calcium at the rate of over 5% of  $CaO$ , rising to as much as 8.75% in one instance.

The amount of calcium in the vines varied at different stages of growth. The tendency was towards an increasing percentage from the early to the later stages of development. In no instance was it less than 3% of  $CaO$  at the first stage taken, nor did it often fall below 6% at the last stage.

The calcium content of the cucurbitaceous fruits was low. In fact, in no instance did it reach as high as 1%. The seeds of the fruits were still lower in calcium, averaging less than 0.25% of  $CaO$ .

In a comparison with the content of N,  $P_2O_5$ ,  $K_2O$ , and  $MgO$ , the percentage of  $CaO$  was almost invariably higher than that of any of these materials in the case of the vines. With the fruits the  $CaO$  percentage was in every instance lower than the percentage of N and  $K_2O$ , and frequently lower than  $P_2O_5$ , but usually higher than the  $MgO$  percentage.

The fact of an increase, as the plants approach maturity, of the  $CaO$  content in the vines attended by a low percentage of  $CaO$  in the fruits, when associated with the fact of a decrease, as the plants approach maturity, of the N,  $P_2O_5$ , and  $K_2O$  content in the vines attended by a relatively high percentage of the same in the fruits, would suggest that a relation

exists between calcium and one or all of these substances in the life processes of the above cucurbitaceae.

On an acre basis the weight in pounds of the CaO content of the vines was found to be much greater, as a rule, than that of the N,  $P_2O_5$ ,  $K_2O$ , or MgO content. The largest amount of CaO was 165.95 lb. in the case of the Yellow Crookneck squash. The largest quantity of any of the other substances was 70.93 lb. for  $K_2O$ , likewise for the Yellow Crookneck squash.

With the fruits the weight in pounds on an acre basis showed the CaO content to be low — exhibiting a tendency toward the reverse of the results obtained with the vines. The largest amount of CaO was 10.06 lb. for the preserving citron fruits. The highest for the other substances was 62.17 lb. of  $K_2O$  for the cantaloupes.

Taking the entire crops, vines and fruits together, on an acre basis, the content in pounds was found in the majority of cases to be greater for the CaO than for any one of the other substances N,  $P_2O_5$ ,  $K_2O$ , or MgO.

967 — **Inulin in the Sunflower-Jerusalem Artichoke Graft** (1). — COLIN, H. and TROUARD RIOLLE, Y., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLVI, No. 21, pp. 856-858. Paris, May 27, 1918.

By grafting reciprocally Jerusalem artichoke (*Helianthus tuberosus*) and sunflower (*H. annuus*) and then analysing the stems above and below the incision, it was found that at whatever level the scion is inserted in the stem and whether the graft be sunflower on Jerusalem artichoke or Jerusalem artichoke on sunflower, there is always, on both sides of the incision, a discontinuity in the polarimetric sign of the soluble carbohydrates in the scion and the stock. The resulting rotatory power is always positive in the sunflower and negative in the Jerusalem artichoke. Inulin is never found in the sunflower. It would, therefore, seem that:—

1) The inulin of the Jerusalem artichoke never enters the sunflower used as stock, or, at least, is very rapidly transformed;

2) Jerusalem artichoke on which is grafted a sunflower scion still forms inulin, not only in the tubers, but throughout the stem, at the expense of the dextrorotary sugars which it derives from the scion.

968 — **Reactions of the Phosphorus of the Thickened Root of the Flat Turnip.** — HARTWELL, B. I., HAMMET, F. S. and WESSELS, P. H. (Agricultural Experiment Station of the Rhode Island State College), in the *Journal of Agricultural Research*, Vol. XI, No. 8, pp. 359-370, Bibliography of 11 Publications. Washington, D. C., November 19, 1917.

In earlier publications of the Rhode Island Agricultural Experiment Station (*Bulletin* 154; 18th *Annual Report* 1904-1905, pp. 253-285) it was shown that the percentage of total phosphorus in flat-turnip roots (*Brassica rapa*) grown in different soils generally varied in the same direction as the variation in the amount of phosphorus which was available to the plant.

In this paper is recorded the work undertaken with the object of ascer-

(1) See R., April, 1918, No. 399. (Ed.)

taining whether the amount of any portion of the phosphorus of the turnip root is correlated more nearly than the total phosphorus with the relative amount available in soils.

Preliminary indications were derived from the successive extraction of dried turnips with ether, alcohol, and 0.2 per cent hydrochloric acid; but, since it was next found that larger amounts of phosphorus could be extracted from fresh than from dried turnips, all subsequent observations were made on fresh turnips.

Coincident with the introduction of phosphorus into a nutrient solution in which turnips were growing, the appearance of "inorganic" phosphorus and the disappearance of starch were traced microscopically in the different tissues; whereas upon withholding phosphorus the disappearance of inorganic phosphorus and the appearance of starch were similarly observed. About four-fifths of the total phosphorus of fresh turnips was extracted with water. When the latter was acidulated, somewhat less was secured because of partial precipitation.

Only a small per cent of the extracted phosphorus failed to pass through dialyzers. Different precipitants of inorganic phosphorus were tested as to their ability to recover phosphate added in a standard solution to the dialyzates. The phosphorus in the precipitate formed by adding acetic acid to turnip juice was not in phospho-protein compounds. There was no phytin in the juice. The presence of a phosphatase was not shown.

Although the proportion of inorganic to total phosphorus in turnips was frequently made larger by phosphatic applications to the soil in which they were grown, this was not always shown to be the case by such methods as were used.

In most instances the phosphorus in the juice was so largely inorganic and constituted so large a proportion of the total that the determination of the latter seemed about as useful as of any portion for furnishing indications regarding the relative amount of soil phosphorus at the disposal of the turnip.

**969 - Injurious Action of Magnesium Carbonate on Plants.** — COUPIN, H., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 24, pp. 1006-1008. Paris, June 17, 1918.

On account of its insolubility in water, magnesium carbonate, so common in the soil, is generally considered incapable of any injurious action on plants, and, consequently, of having any influence on the life of plants and on their geographical distribution. Nevertheless, this salt dissolves in small quantities in water containing carbonic acid, as occurs near roots which give off carbonic gas during respiration. In order to investigate the effect of the carbonate thus dissolved the author carried out various germination tests, some in fresh water, some in the same water containing an excess of magnesium carbonate. After a few days in the same environment — darkness and a constant temperature of 24°C — the results were compared.

Apart from a few exceptional cases (e. g. that of stone pine) magnesium carbonate was decidedly injurious to plants but in a manner and to a degree

which varied according to the species. This noxiousness manifested itself: — 1) by decreased length of the main root; 2) by a considerable reduction of the number and size of the rootlets; 3) by black or brown colour of the roots and rootlets; 4) by reduction of the absorbent hairs (when, as is rather exceptional, they form in an aqueous environment); 5) by shorter aerial parts (except in the case of common cress). In no case did magnesium carbonate appear to have any useful effect, at least under the conditions of the experiment.

970 — **Absorption of Nutrients as Affected by the Number of Roots Supplied with the Nutrient.** — GILE, P. L. and CARRERO, J. O. (Porto Rico Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. IX, No. 3, pp. 73-95 + 22 Tables + 2 Figs., + Bibliography of 13 Publications. Washington, D. C., April 16, 1917.

In the course of several investigations on the mineral nutrition of rice (*Oryza sativa*) it became necessary to know whether the plant could absorb an optimum amount of the mineral element which was supplied to only part of the roots if all the other essential elements were supplied to all the roots. At first thought it would seem that the plant could absorb sufficient of the element supplied to only part of its roots if sufficient selection could be exercised in the absorption of the different nutrients by individual roots. So far as known, no quantitative study has been made of this point; and the tests reported in the article under review were carried out for this reason. The present work does not deal with the effect of the medium on selective absorption by roots, but with the effect of localization of the supply.

The absorption of nitrogen by rice and maize and of phosphorus, potassium, and iron by rice was tested in water cultures, one-half the roots being maintained in a nutrient solution lacking one of these elements. Tests were also made, varying the portion of roots in the complete and incomplete solutions.

The results show that, under the conditions described, the plant does not absorb a maximum amount of the element, and the fewer the roots supplied with the element, the smaller the total amount absorbed. This applies when the total amount of the element supplied is equal to or in excess of the needs of the plant. A curve was plotted showing approximately what portion of the maximum absorption can be expected with any fraction of the roots supplied with the element. With nitrogen and phosphorus the total amount absorbed by plants with half their roots in the complete solution was 0.76 of that absorbed by plants with all their roots in the complete solution. The similar figure for potassium or iron was 0.66. Increasing the concentration of the element in question in the complete solution did not appreciably alter the results.

The amount of the element absorbed per gram of roots increased greatly as the number of roots in the complete solution was diminished. The results are explained on the basis of the rate of utilisation and transference of the elements in the plant. Attention is called to the bearing of these results on the method of applying fertilisers. The results obtained agree with MITSCHERLICH'S formulation of the law of minimum.

- 971 - **The Formation of Nitrites from Nitrates in Aqueous Solution by the Action of Sunlight, and the Assimilation of the Nitrites by Green Leaves in Sunlight.** — MOORE, B., in the *Proceedings of the Royal Society, Biological Sciences, Series B*, Vol. 90, No. B 627, pp. 158-167 + Bibliography of 8 Publications. London, June 1, 1918.

The thermo-chemical studies of FAURE, THOMSEN and BERTHELOT have shown that the reactions during the formation of different oxides of nitrogen are endothermic. This is also true of the reaction during the formation of nitrites from nitrates, which can only occur by the transformation of other forms of energy (such as that of light) into chemical energy. The author's studies showed that dilute solutions of nitrates exposed either to the sun or to rays from a source of light rich in light-energy of short wavelength, are transformed into nitrites. This is a case of endothermic photo-chemical reaction similar to that concerned in the synthesis of starch in the presence of chlorophyll and sunlight. If a layer of glass is interposed between the source of light and the solution of nitrates, transformation is greatly retarded. This shows that the most active rays are those of short length (ultra-violet). When green leaves are immersed in a solution of nitrates comparatively little nitrite accumulates, the green leaves having the capacity in the sunlight of rapidly absorbing the nitrites thus formed. The author concludes that the nitrates of the soil assimilated by the plant are transformed into nitrites in the presence of sunlight, and that the last phases of the synthesis of nitrogenous compounds take place within the green leaf under the action of this light.

The presence of nitrites and nitrates in atmospheric air cannot be attributed, as many workers have thought, to the action of electrical discharges during storms, because it has never been possible to find any real relation between the nitrate and nitrite concentration of atmospheric air and rainwater on one hand, and frequency of storms on the other. The author observed that freshly-collected rainwater contained as much nitrite (about 0.5 part per million) as rain caught during a thunderstorm. ILIOVAY showed that dew also contains nitrites. The formation of nitrates and nitrites must, therefore, depend on a more constant and evenly distributed factor, such as sunlight, rather than on fortuitous electrical discharges. Rainwater collected for a considerable time contains no nitrites as they have all been oxidised to nitrates, but if it is exposed to strong sunlight or ultraviolet rays nitrites are again obtained.

The nitrites of rainwater and dew are one of the principal sources of nitrogen for plants when the soil has not been enriched with nitrogenous fertilisers. The author, therefore, points out the great importance of the action of sunlight in supplying these compounds so essential to the formation of organic matter.

- 972 - **Choice of Material for Isolating Inflorescences in Selection Work.** — FRUWIRTH, C., in *Zeitschrift für Pflanzengücht*, Vol. V, Pt. 4, pp. 391-395. Berlin, 1917.

The nature of the covers used to isolate the inflorescences is not without influence on the fructification because a certain amount of light may be necessary for the normal development of the seed, especially at

the beginning of setting, as was observed by SCHOLZ for the poppy and LUBIMENKO for the pea and wheat.

The author made similar observations for: — *Triticum sativum* (winter and spring wheats); *Hordeum distichon erectum* and *H. distichon nutans*. *Pisum arvense* and *P. sativum*, *Phaseolus vulgaris*, *Papaver somniferum*, *Arrhenatherum elatius*. During his investigations he used covers of various strength, from parchment bags, which allow the light to pass fairly well, to small wooden boxes lined with black paper used for wrapping up photographic plates. In this last case no seed formed while with the less stiff and opaque covers the number of seeds formed decreased. On the other hand, the amount of light absolutely necessary is not the same for all plants, but varies from one species to another, as is shown by the Table: —

	Black paper bag		Parchment bag		No cover	
	Number of inflorescences	Number of seed formed	Number of inflorescences	Number of seed formed	Number of inflorescences	Number of seed formed
<i>Pisum arvense</i>	5 flowers	0	5 flowers	8	5 flowers	14
Barley Nolča Imperial	5 ears	55	5 ears	94	5 ears	112
Wheat 104 Crieuener	5 "	88	5 "	129	5 "	196

The covers used to isolate inflorescences must, therefore, be fairly transparent as the absence of seeds formed is often attributable to insufficient light rather than phenomena of self-sterility.

973 — **The Selection of Barley in Algeria.** — NICOLAS, G., in *Travaux du Laboratoire de Botanique de l'Université d'Alger*, pp. 1-29 + 5 Plates. Algiers, 1918.

In 1911 the author began a series of experiments with the intention of improving barley in Algeria. He dealt with:— 1) the importation of foreign varieties with well known, stable characters and already selected; 2) reciprocal crosses between Algerian barley, or between Algerian and exotic barleys, in order to fix in a single type any desirable parental characters while eliminating any undesirable ones. Unfortunately the war has interrupted the work, which was already considerably advanced, as will be seen from this article.

**SELECTION OF NATIVE BARLEY.** — In order to ascertain the degree of purity of the samples (100 ears), the well known *polygons of variation* were worked out, considering the most important characters. In this way may be chosen the *density* or *compactness* of the ears, using the formula  $D = 10 \frac{a}{l}$ , where  $l$  is the length of the rachis in centimetres,  $a$  the number of grains in 2-rowed barley and  $\frac{\text{number of grains}}{3}$  in 6-rowed barleys.

Thus in an ear of 2-rowed barley having 52 grains and a rachis 13 cm. long, the compactness will be  $\frac{52 \times 10}{13} = 40$ . If, for 100 ears of a given variety, the following series of values is found:—

Compactness . . . . .	30	31	32	<b>33</b>	34	35	36	37	•
Corresponding number of ears .	0	9	22	<b>34</b>	21	11	3	0	

the average compactness of this variety is 33. If these values are represented graphically, taking those for compactness as abscissae and those for the corresponding number of ears (frequency) as ordonates, the *polygon of variation* is obtained, the summit of which is unique in this case and corresponds to the compactness 33. The existence of a single summit shows that the material has a high degree of purity.

If, on the contrary, the following values are found :—

Compactness . . . . .	28	<b>29</b>	30	<b>31</b>	32	33	<b>34</b>	35	
Corresponding number of ears .	5	<b>15</b>	12	<b>25</b>	20	8	<b>12</b>	3	

the polygon has 3 distinct summits, an evident sign that the barley under question is a very impure mixture of different varieties.

With the help of this method of analysis, the author has examined a very large number of samples from various localities in Algeria, and he has studied their behaviour during the period 1911-14. He thus found that most Algerian barleys are heterogenous mixtures of various forms, from which valuable material could be obtained by selection.

Only 2 barleys, No. 13 and No. 20, remained pure during the whole period of the experiments. The first came from Mecbtas, near Boghni, at an altitude of 1594 ft.; the author has selected two initial varieties —  $\delta$  and  $\beta$  — from it; the latter (*Hordeus hexastichon pallidum*  $\beta$ ) remained pure up to 1914, as is shown by the values :—

Compactness . . . . .	26	27	28	<b>29</b>	30	31	32	33	34
Corresponding number of ears .	3	10	18	<b>28</b>	20	12	5	3	1

IMPORTATION OF FOREIGN BARLEYS. — The Swedish (Svalöf) varieties Svanhals, Primus, Hannchen, Chevalier and Prinzess have been tested. The last one gave the best results, especially in fresh clay soils. Thus, at Adélia, it produced 13.54 cwt. per acre from 1911-13. The only defect noticed is a slight degeneration in the quality of the grain; whilst Prinzess barley gives 79.18% of dry extract in Sweden and central France, at Adélia (according to M. PETIT, Director of the School of Brewing at Nancy) the content falls to 72.69 %, but always remaining 2 % higher than that of the native Algerian barleys.

CONCLUSIONS. — 1) The native Algerian barleys represent a mixture of various forms, so that individual selection cannot fail to give positive results.

2) The exotic varieties selected can be introduced into Algeria with the possibility of success, as is shown by the results obtained with Prinzess barley, produced and selected in Sweden, under very different conditions to those in Algeria.

3) The author proposes to extend and continue his work by making a series of crosses; the use of acclimatised foreign varieties and of native types will provide excellent material for the progressive improvement of a cereal so important to Algeria and the surrounding districts.

974 - **Selection of Rice in the Philippines.** — I. GUTIERREZ, M. E., in *The Philippine Agriculturist and Forester*, Vol. VI, No. 5-6, pp. 135-152 + 3 Figs. Los Baños, January-February, 1918. — II. Goco, A. A., *Ibid.* pp. 154-167.

The recent work by JACOBSON on rice and by MENDIOLA on maize may be said to be the only contributions to selection work in the Philippines where the many forms and the lack of uniformity in the types of the cultivated plants offer the breeder abundant material and the possibility of obtaining good results simply by individual selection without the more complicated work of hybridisation. The authors' attempts to improve the native rices by individual selection have met with such success that great hopes are entertained for the future.

I. — **LOWLAND RICES.** — Four Ilocano or bearded rices were studied, namely, 5 893 Ganadc, 5 894 Iray, 5 895 Binalayan and 5 896 Dequet a Bolilising, as well as two Tagalog or smooth varieties, 5 892 Binangbang and 5 891 Binicol. Shortly before harvest about 100 samples of each variety were collected, and the seeds of each plant sown separately in rows which numbered 177. In a series of tables are given the analytical results obtained for the descendants — grain yield, quality of grain, number and length of culms, duration of the vegetative period, degree of uniformity. With few exceptions the grain yield of the selected varieties was much superior to that of the original varieties, there being a difference of as much as 100 % in some cases. There was a tendency to correlation between the productivity, degree of uniformity of the lines and tillering.

In rice, which is essentially self-fertilising, natural hybridation is rare, so that it is interesting to note some cases in which this phenomenon occurred. During his selection work the author found a plant, 5892-0808 Binangbang with seed of varying red colour. The plant was a heterozygote, as was shown by an examination of  $F_1$  (13 plants with white seed, 5 with light red, and 12 with red seed), derived probably from a natural cross between two varieties of Binangbang rice, one with white seed and one with red seed.

II. — **UPLAND RICE.** — The varieties selected were Kinandang Pula, Pinursigue, Inintiw, Kinamaleg, Kinagaykay, Guluyang Pula. The results obtained were: — 1) with simple mass selection the yield was raised from 20.20 cwt. of paddy per acre to 23.62 cwt., even without fertilisers; 2) the descendants of the parents of the same variety differ greatly in productivity, tillering, length of culms, etc., thus allowing individual selection to be carried out successfully; 3) by selecting No. 22 of the Pinursigue variety a yield of 51.32 cwt. of paddy per acre was obtained.

975 - **Apparent Mutations of Colour in the Beetroot Due to the Effect of Vicinity, in Sweden.** — BIRGER, K. (Seed Selection Station of Weibullsholm, Landskrona, Sweden), in the *Zeitschrift für Pflanzenzüchtung*, Vol. V, Part 4, pp. 357-372. Berlin, 1917.

The multiple variations of colour and form repeatedly observed in beets of the same pure line have not yet been satisfactorily explained. According to the author's latest researches these phenomena are simply due to the effect of vicinity for: — 1) the beet has a high degree of auto-

sterility ; 2) its pollen may easily be carried by the wind or insects over as much as 600 yards ; 3) the gauze, muslin and other tissues used to isolate the inflorescences are not sufficiently close-textured to prevent the passage of wind-borne pollen. Cross-pollinisation may thus occur in spite of ordinary precautions and thus produce forms and characters that appear quite new, especially as regards the colour of the root.

The colour is due to 2 pairs of factors : —  $Yy$  and  $Rr$   $Y$  produces yellow, and, together with  $R$ , produces red. White is produced when  $R$  is alone, and also by the simultaneous absence of  $Y$  and  $R$ . Below are shown the results of crossing types each having one of the two factors  $Y$  and  $R$  as homozygotes.

Parents ( $P$ ) . . . . .	$YY\ rr$ (yellow) $\times$ $yy\ RR$ (white).
$F_1$ generation . . . . .	$Yy\ Rr$ (red)
$F_2$	$F_3$
1 $YY\ RR$ (red) . . . . .	Constantly red.
2 $YY\ RR$ (red) . . . . .	Dividing into 3 reds: 1 yellow.
1 $YY\ rr$ (yellow). . . . .	Constantly yellow.
2 $Yy\ RR$ (red) . . . . .	Dividing into 3 reds: 1 white.
4 $Yy\ Rr$ (red) . . . . .	Dividing into 9 reds: 3 yellows: 4 whites (as in $F_2$ ).
2 $Yy\ rr$ (yellow). . . . .	Dividing into 3 yellows: 1 white.
1 $yy\ RR$ (white) . . . . .	Constantly white.
2 $yy\ Rr$ (white) . . . . .	Constantly white.
1 $yy\ rr$ (white) . . . . .	Constantly white.
<hr/>	
or 9 red: 3 yellow:	
4 whites	

On using these gametic formulae to examine the results of one of the many hybridisations studied by the author, it will be seen that many of the chromatic aberrations and variations observed in a pure line can be explained as phenomena due to proximity of the plants.

Thus, for example, the cross No. 8 : — Yellow Intermediate ♀ ( $YY\ rr$ , yellow)  $\times$  Rote Eckendorfer ♂ ( $YY\ RR$ , red) gave an  $F_1$  with 13 individuals having a red root and an  $F_2$  with 365 individuals having a red root and 154 with a yellow root, in the ratio 3 : 1, corresponding to the theoretical values of 389.25 and 129.75. In the  $F_3$  the progeny of the red-rooted individuals should also be red-rooted, or at any rate with red and yellow roots in the ratio 3 : 1 (see the above scheme). This is what actually happens, save for Nos. 3 605 and 3 606, which give an  $F_2$  for the former of 9 reds : 3 yellows : 4 whites and for the latter 3 reds : 1 white. It seems that these two numbers are new crosses produced spontaneously in the  $F_1$  of the cross No. 8.

The white-rooted individuals of the  $F_2$  should produce, in the  $F_3$ , exclusively white progeny ; on the contrary, in many cases red-rooted types appear ; these beets should be considered as due to proximity of the plants.

Among the plants of No. 385 of the  $F_4$ , the author chose 45 with

white roots and planted them in a special plot; at the right moment 15 of them were isolated in the usual way; the other 30 were left to flower in the open air. The results obtained in the  $F_5$  are quite convincing: — out of 360 descendants of plants isolated under hoods, only 4, or 1.1 %, had red roots, owing to the small amount of foreign pollen that had penetrated through the hoods. On the other hand, out of 5458 descendants of the uncovered plants, 314, or 5.75 %, had a red or yellow colour. Three groups can thus be distinguished: — 1) with red variations only; 2) with red and yellow variations in almost equal amounts; 3) with yellow variations only.

The 45 white-rooted plants isolated by the author were on the experiment field of the Weibullsholm Station, at a distance of some 600 yards from a plot of the yellow *Ovoïdes des Barres* beets. If the pollen of the latter variety, could, in spite of the distance and other obstacles, arrive to the beets planted at Weibullsholm, it would be easy to explain the phenomena noted in the  $F_5$  by the aid of the following scheme:

*Mother plant*: — yy RR (white).

*Progeny*: — 25 % yy RR (white); 50 % yy Rr (white); 25 % yy rr (white).

*Ovoïdes des Barres*: — YY rr (yellow).

*Possible combinations between the Progeny and Ovoïdes des Barres*: —

- 1) yR ♀ × Yr ♂ = Yy Rr (red).
- 2)  $\left\{ \begin{array}{l} yR \text{ ♀} \times Yr \text{ ♂} = Yy \text{ Rr (red).} \\ yr \text{ ♀} \times Yr \text{ ♂} = Yy \text{ rr (yellow).} \end{array} \right\}$  in equal parts.
- 3) yr ♀ × Yr ♂ = Yy rr (yellow).

In this case there were 6 descendants with red variants, 10 with red or yellow variants, 3 with yellow variants, and the values found are sufficiently close to those calculated.

976 — **A Further Note on the Genetics of *Fragaria*.** — RICHARDSON, C. W., in the *Journal of Genetics*, Vol. VII, No. 3, pp. 167-170. London, May, 1918.

In continuation of previous work on the genetics of *Fragaria*. (*Journal of Genetics*, Vol. III, No. 3, Feb. 1914), the author gives further results he has obtained with regard to flower colour, double flowers, hairiness of stems and leaves, and sex.

**FLOWER COLOUR.** — As stated in the previous paper (1), the cross pink flowering *vesca* × white flowering *vesca* produced pink flowering  $F_1$ 's. These selfed produced 20 pink, 57 pale pink, 10 white or very nearly white (of the latter at least 3 were absolutely white). Thus the ratio found of 15:1 corresponds well to that calculated: — 81.57 pink to 5.43 white. The excess of white flowers may be due to the difficulty in distinguishing between very light pinks and pure whites.

**DOUBLE FLOWERING.** — The cross double flowering *vesca* × single produced in the  $F_1$  single flowers with occasional extra petals. In the  $F_2$  there were 60 single to 24 double flowers, 37 single to 13 double, or a to-

(1) Summarised in *R.*, June, 1914, No. 513.

tal of 97 single to 37 double flowers. This gives the ratio 3:1, corresponding to the expectation 100.5 single and 33.5 double flowers.

The cross single flowered  $\times$  double flowered produced single in the  $F_1$ . The  $F_1$  generation selfed produced 58 single and 25 double giving a ratio of 3:1 corresponding to the expectation 62.25 single to 20.75 double.

**HAIRY LEAF STEMS AND FRONT OF LEAF.** — The factor "hairy" is dominant as regards the factor "glabrous". In a cross *F. Virginiana*  $\times$  *F. Chilensis* the  $F_1$ 's had "hairy" stems and the front of the leaves was hairy. The  $F_1$ 's selfed produced 32 "hairy" to 10 not "hairy"; 32 leaves were "hairy" and 10 glabrous; with a ratio of 3 to 1 in each case.

**SEX.** — The results of the various crosses are given in the following table.

Crosses		Distribution of sexes in $F_1$	
		Females	Males or hermaphrodites
<i>F. chinensis</i> ♀	$\times$ <i>F. chilensis</i> ♂	26	21
<i>F. chinensis</i> ♀	$\times$ <i>F. Virginiana</i> ♂	18	14
<i>F. Virginiana</i> ♀	$\times$ <i>F. mexicana</i> ♂	20	15
<i>F. Virginiana</i> ♀	$\times$ <i>F. Virginiana</i> ♂	17	16

The total obtained was 183 females to 155 males or hermaphrodites. There is thus a dominance of the female, which seems to fit a 9:7 ratio. The difficulty here is the classification, as an apparently male plant (e g., a *F. Virginiana*) may sometimes set a fruit or seed. This is why the author finds it simpler to group all sterile flowers with the sex to which they appear to belong, and to consider males and hermaphrodites as one sex.

**CEREAL  
AND PULSE  
CROPS**

**977 — Wheat, Yields per Acre and Prices, by States, for the 50 Years 1866-1915 in the United States.** — U. S. Department of Agriculture, Bulletin No. 511, 16 pp. of tables. Washington, February 13, 1917.

The year 1915 completed the first 50 years during which the United States Department of Agriculture has collected annual data on the yield and value of the most important crops in the different States of the Union. The bulletin under review gives the annual figures for wheat from 1866 to 1915. The tables referring to the different States are preceded by general figures for the production in the whole of the United States and six divisions of the country; — 1) *North Atlantic*, including the States of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey and Pennsylvania — 2) *North Central, East*: Ohio, Indiana, Illinois, Michigan and Wisconsin — 3) *North Central, West*: Minnesota, Iowa, Missouri, North Dakota, South Dakota, Nebraska, and Kansas — 4) *South Atlantic*: Delaware, Maryland, Virginia, West Virginia, North Carolina, South Carolina, Georgia and Florida — 5) *South Central*: Kentucky, Tennessee, Alabama, Mississippi, Louisiana, Texas,

Oklahoma and Arkansas — 6) *Far West*: Montana, Wyoming, Colorado, New Mexico, Arizona, Utah, Nevada, Idaho, Washington, Oregon, and California.

The 10 year averages of wheat yields in bushels per acre for the whole Union and for these 6 divisions respectively were:

	United States	North Atlantic	North Central, East	North Central, West	South Atlantic	South Central	Far-West
1866-1875 . . . .	11.9	13.7	12.2	13.5	8.4	8.5	15.7
1876-1885 . . . .	12.3	14.1	13.9	12.0	8.9	8.0	14.1
1886-1895 . . . .	12.7	14.2	13.8	12.4	8.8	9.6	14.2
1896-1905 . . . .	13.5	16.2	13.4	13.1	10.8	11.6	17.3
1906-1915 . . . .	15.0	18.1	16.3	13.6	13.0	12.4	22.4

978 - **Cultivation of Manitoba Wheat in Touraine, France** (1). — SCHREIBAU, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 17, pp. 528-530. Paris, May 15, 1918.

The author gives the following conclusions deduced from an investigation made by M. MARTIN (Director of the Agricultural Department of Indre-et-Loire):—In the least successful experiments Manitoba wheat gave 7 to 11.92 cwt. per acre. Everywhere else the yield varied from 9.54 to 16.72 cwt.; the average might without exaggeration be placed at 11.14 cwt. per acre. These figures are all the more remarkable because the average yield of winter wheat is 8.34 cwt. There is no doubt that 1917 was a very favourable year for wheat growing in that district; May and June were wet and there was no excessive heat in July. In spite of all disadvantages M. MARTIN considers Manitoba wheat excellent for Indre-et-Loire. Thanks to this new variety it will be possible to sow wheat in spring which could not be sown in autumn.

The author shows the extent to which Manitoba wheat is penetrating and spreading in countries where it was totally unknown — Piedmont, Greece, etc. Most of the reports received by the author favour its cultivation. The fact that some tests have not given the hoped-for results is due to insufficiently sorted seed. To prevent this farmers should ask for 110 to 120 lb. of Manitoba for every 100 lb. of seed to be sown. This wheat is too small to pass through a sorter; it is sufficient to pass it through a 2 mm. mesh sieve to eliminate foreign, broken, or small and malformed grains and obtain excellent seed. In a good lot the waste will not exceed 10 % and may be used for making flour. Failure often results from using too little seed. As Manitoba tillers little 1.59 cwt. per acre should be the smallest amount used. The actual amount must, however, be determined by the farmer, who must bear in mind that it should be sown more thickly than ordinary varieties, and greater quantities be used the later it is sown.

(1) See also No. 1051 of this *Review*. (Ed.)

979 - **Red Clover and its Varieties, in New South Wales, Australia.** — BREAKWELL, E., in *The Agricultural Gazette of New South Wales*, Vol. XXIX, Pt. 2, pp. 105-109 + 1 Fig. Sydney, February 2, 1918.

There are many strains of red clover (some workers recognise as many as thirty) most of which are named after the regions where they were produced. It is impossible to distinguish any difference in the structure of the various strains except in the character of the stem. Thus, the stem of New Zealand Cow Grass and Perennial Red are solid, whereas those of the American strains, such as Giant Hybrid and Broad Red, are hollow. On the other hand the various strains differ in important cultural characteristics, such as duration (1 to 4 or 5 years) and the amount of foliage produced.

The maintenance of a clover pasture is generally considered to depend on the production of self-sown seed and the setting of seed due to pollination by bumble-bees. These insects do not exist in New South Wales and some years ago an unsuccessful attempt was made to introduce them there. At the Yanco Experiment Farm it was found that of 20 heads of flowers examined, more than 80 % of the flowers had not set seed. In 1917 at the Glen Innes Experiment Farm it was found that a plot of Chilean clover had produced 250 lb. per acre, a very fine crop. Among the insects visiting the plants Italian bees were very plentiful at Glen Innes, butterflies and ants at Yanco. Clover pastures lasting many years are common in New Zealand as a result of harrowing in the seeds dropped from the plants from time to time. This method has been adopted at Glen Innes.

The varieties grown in New South Wales are:— Cow Grass, Perennial Red (the two most largely grown), Giant Hybrid Red, Broad Red, American Red and Chilean Red. The yields are usually good, and at Glen Innes very high ones have been obtained. Chilean Red Clover was first introduced by the Hawkesbury Agricultural College; in the experiments at Hawkesbury and Glen Innes, Yanco, Grafton and Bathurst Experiment Farms as well as in those made by farmers, it always surpassed all the other varieties previously tested. Its principal characteristics are:— permanence, resistance to drought and frost and heavy yield (at Glen Innes in 1916, 4 tons 5 cwt. of hay per acre). The New South Wales Department of Agriculture is undertaking the supply of acclimatised Chilean clover seed, among which there are practically no hard seeds, difficult to germinate. The vitality of the seed in seven days was over 90 %.

980 - ***Enneapogon mollis* in Ascension Island.** — STAFF, O., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 6, pp. 217-219 + 1 Photograph. London, 1917.

In Ascension Island, formed of barren volcanic matter, except for one peak with scanty endemic vegetation, a new wild grass, identified at Kew as *Enneapogon mollis* Lehm (= *Pappophorum molle* Kunth.) appeared unexpectedly in 1917. This plant transformed stretches of previously desert land along the coast and in the plains (it also grows in brackish places) into large green meadows. Where the soil is best it grows to a height of 3 feet.

It appears to be an annual and is found particularly in tropical desert

districts such as that described, on the coast of Angola, in Great Namaqualand, from whence it extends through the Kalahari Desert to Bechuanaland and Griqualand. It has also been found in the Sudan, Abyssinia, Eritrea, and Somaliland, Madagascar, and, on one occasion, in the Punjab.

Nothing definite is known of its value as a fodder plant, but there is no doubt that it would be very important as such in all arid countries. As a similar plant is mentioned *Schmidtia bulbosa* Stapf of North Rhodesia, a perennial, very nourishing grass, suited to the same conditions as *Enneapogon mollis*, the cultivation of which in Ascension Island is recommended if it will succeed there.

981 - **Experiments on Steppe Pasture in the Dehesa de Nuestra Señora del Pilar, the Central Steppe of Spain.** — ESTEVE, F., in the *Revista de Montes*, Year, XLI, Nos. 970 to 976, pp. 423-429, 472-476, 512-515, 559, 585-593, 665-666. Madrid, June to September, 1917.

The Dehesa (pasture land) de Nuestra Señora del Pilar, at Caracena del Valle (municipality of Castillejo del Romeral, province of Cuenca), at an altitude of from 2 624 to 3 608 feet, is an estate of 4 940 acres,  $\frac{2}{3}$  of which are wood and pasture land. Whereas this estate could previously feed a fairly large number of cattle, at the time the author began to improve it could barely support 1 000 sheep, which had to be given fodder during a great part of the year. According to the author the gradual deterioration of pasture land occurs as a general rule in Spain, and is due to the fact that nothing is done to renew it, so that the pasture grass gradually gives place to weeds, which the animals refuse. The result is that, though a century ago Spanish stock breeding occupied one of the first places in the world, Spanish pasture-land today can with difficulty support 27 lb. of live weight per acre as compared with 450 lb. in some countries where intensive cultivation is practised. While the author was improving the estate in question Dr. E. REYES' important work, *Las estepas de España y su vegetación*, was published. This work decided the author to extend his research and to investigate the problem of the improvement of mountain pasture-land in Spain. The investigations include: — 1) Pure seeds, *i. e.*, the use of commercial seed belonging to a single botanical species under various conditions, with a study of the habit of growth and the quality and quantity of the product, the age at which the plant begins to produce and that in which it is producing fully, its economic duration, acclimatisation, etc.; 2) Experiments in improvement by cultivating forage crops on the central steppe; 3) Experiments with different seed mixtures; 4) re-planting and cultivation of the mountain pasture-land of Nuestra Señora del Pilar; 5) a study of the bushes and trees growing on these pastures, and the acclimatisation of these plants. A table shows the numerous species used as pure seed, giving for each one: — the agricultural value (product of *purity* by the *germinating capacity*, expressed in per cent); the amount of seed required per acre; whether the species in question does or does not belong exclusively to the flora of the steppes. The basis of the various mixtures of forage seed used

were; 1) dry-land alfalfa; 2) sainfoin; 3) clover. For example, in 1916, a dry year in which the seeds were very late, two cuttings of Group 2, gave the following yields of green forage per acre: — mixture of 85 % of sainfoin (*Onobrychis sativa* var. *bifera*) + 15 % of tall oat grass (*Arrhenatherum elatior*) 11.15 cwt. of forage; mixture of 45 % of sainfoin + 55 % of great burnet (*Poterium Sanguisorba*), 66.90 cwt.; mixture of 70 % of sainfoin + 30 % upright brome grass (*Bromus erectus*), 49.38 cwt.. For each seed the author determined the percentage of the "supplement" or amount of extra seed to be used for the mixture as compared with the amount required for pure seed.

Judging by the vegetation of the various plots, alfalfa does best with cocksfoot (*Dactylis glomerata*). With this grass wild alfalfa (*Medicago sativa* var. *sylvestris*) produces more than when sown with great burnet. Mixtures with a basis of Provence alfalfa gave more forage than those of wild alfalfa. Sainfoin and great burnet do well together, especially for pasture land. The mixture sainfoin + tall oat-grass produces yet more, and the mixture sainfoin + brome grass is good in poor, dry soils. Of the mixtures with a basis of clover those with red clover (*Trifolium pratense*) gave the best results; those with a basis of white clover (*T. repens*) also did well, but those with a basis of Swedish clover (*T. hybridum*) did not give good results. Timothy (*Phleum pratense*) was the grass which did best with red clover.

On a plot prepared for irrigation various species were grown in lines 8 1/2 inches apart for the production of seed. These are only harvested every two years, and in 1916 some of the species were cut. They gave the following yields in green forage per acre: — cocksfoot, 45.16 cwt.; brome grass, 44.60 cwt.; tall oat grass, white clover, bird's foot trefoil, 44.60 cwt each; serradella (*Ornithopus sativus*), scorpion senna (*Coronilla scorpioides*) and crown vetch (*C. varia*) 31.86 cwt. each.

The list of forage plants belonging exclusively to the steppe flora which have been found at Castillejo include: 13 Gramineae, 10 Leguminosae, 1 Liliaceae, 1 Rosaceae, 1 Umbelliferae, 1 Gentianaceae, 1 Convolvulaceae.

#### FIBRE CROPS

982 — **The Time at Which Cotton Uses the Most Moisture.** — McCLELLAND, C. K. (Georgia Agricultural Experiment Station), in the *Journal of the American Society of Agronomy*, Vol. X, No. 4, pp. 185-189 Washington, April, 1918.

It is known that cotton requires less water than a crop of maize or oats, indeed, drought during the period of filling and ripening of the seeds causes a notable reduction in the yield of these cereals, whereas drought during the period of the ripening (opening) of cotton bolls is beneficent. The ripening period of grain, however, corresponds to the blooming (filling) period of the bolls, and drought at this period causes a large number of the cotton buds to drop.

By experiments made in 1915 and 1916 at the Georgia Experiment Station the author determined by means of potometer cultures the amount of water required by cotton during its growth. In each of the 11 weeks (from the 1st week of July to the 3rd week of September) in 1915, 10 plants grown in potometers consumed the following quantities of water respectively

(in litres):—19.4, 77.1, 169.7, 193.7, 285.0, 232.8, 271.9, 293.0, 112.5, 263.0, 150.2. In each of the 10 weeks between that ending July 25 to that ending October 7, 1916, 11 cotton plants in potometers consumed the following number of litres of water respectively:—24.75, 103.50, 157.50, 128.25, 139.50, 85.50, 49.00, 27.00, 85.50, 49.50. From the 1st to the 7th of these weeks the number of flowers opening on the 11 plants was:—0, 33, 44, 105, 85, 74, 42. There appears, therefore, to be a correlation between the period of the highest rate of flower-opening and that during which the plants consume the most water. If this be so, it would be advisable to cultivate the soil sufficiently late for it to conserve its moisture during the summer months, *i. e.*, a little later than is usually done in the United States.

983 - **Zapupe** (1). — *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 6, pp. 239-240. London, 1917.

Zapupe fibre first came into prominence a little more than 10 years ago. In 1907, in the State of Vera Cruz, there were over 5 million plants in various stages of growth. The following three cultivated species have been identified by TRELEASE: — *Agave zapupe* Trel. (local names:— blue zapupe, zapupe azul, zapupe de Estopier, zapupe de San Bernardo of Tuxpan, Vera Cruz); *A. Lespinassei* Trel. (local names:— zapupe de Tepezintla, zapupe de Vincent of Juana, Ramirez and Tuxpan); *A. Deweyana* Trel. (local names:— cultivated green zapupe, zapupe de Huasteca, zapupe de Fantoyuca, zapupe verde of the region between Tampico and Vera Cruz). None of these species are known in the wild state, but TRELEASE distinguishes a fourth, *A. aboriginum* (2), known in the district between Tampico and Vera Cruz as wild zapupe, zapupe cimarrón, zapupe silvestre, zapupe de Sierra Chontla; this is said to be cultivated sometimes. In the *Diplomatic and Consular Reports* (No. 4453, p. 5, Tampico; Washington, 1910) it was stated that in 1909 the planting and cultivation of zapupe continued to attract much attention and that several 3-year old plantations were cleaning and exporting fibre. In 1910, besides the planting done by private individuals, many companies had formed for the cultivation of zapupe (*Ibid.* No. 4665, p. 9, Vera Cruz; Washington, 1911). In 1911 a Belgian syndicate made arrangements for developing this fibre plant in the Vera Cruz district (*Ibid.*, No. 4873, p. 9, 1912). In 1913 it was reported that its cultivation had ceased, and that no fibre had been exported that year (*Ibid.*, No. 5365, p. 15, Tuxpan, Vera Cruz; 1914). A sample of zapupe fibre (species indefinite) from Mexico was valued in 1913 at £ 30 to £ 32 per ton; in the same year sisal fibre realised up to £35 per ton. In countries where the conditions are suited to *Agave* cultivation it is best to grow sisal hemp, which is better known and, which notwithstanding previous statements, is apparently not inferior to zapupe.

984 - **The Mulberry as a Textile-Fibre Plant.** — See No. 1040 of this Review.]

(1) See R. 1911, No. 1744; 1913, No. 938. (*Ed.*) — (2) Five species are described by TRELEASE (*Transactions of the Academy of Sciences, St. Louis*, Vol. XXVIII, 1909), the four mentioned above and *A. Endlichiana selvatica.* (*Ed.*)

CROPS  
YIELDING OILS,  
DYES AND  
TANNINS

985 - "Sélé", "Cocorico" and *Ximenia americana*, African Oil-Yielding Plants.  
— PIERAERTS, J., in the *Annales du Musée Colonial de Marseille*, Year XXV, Ser. 3,  
Vol. IV, (1916), Pt. 2, pp. 1-21. Marseilles-Paris, 1917.

Of the three seeds examined by the author, the first two came from the Belgian Congo and the third from British Africa.

I. SÉLÉ. — The plant known locally by this name appears to be popular among the natives in certain parts of the Belgian Congo. The author examined a specimen from Mowbasa (Bengala district) prepared locally by :— 1) roasting the seed, decortication and winnowing ; 2) disintegration of the kernel by pounding ; 3) separation of the oil by boiling water ; 4) removal of the supernatant oil and clarification by standing and filtration.

The tests made by the author led him to conclude that sélé is essentially composed of a mixture of glycerides of oleic, linoleic, stearic, palmitic and lauric acids. It also contains a small quantity of an acid of a higher molecular weight, which could not be identified owing to the lack of a sufficiently large sample of raw material.

Sélé oil is an excellent edible oil, with an agreeable, sweet flavour, which, if carefully prepared by modern methods, would not have the burnt taste of the sample examined. Its value is increased by its good keeping qualities. It is without any doubt suitable for soap-making, and its relatively high glycerine content should make it much sought after by manufacturers of this product. It is useless for the manufacture of stearin products as its solid acid content is too low. It may be considered as a semi-siccative oil to be classed with cottonseed oil.

II. COCORICO. — This plant is a variety of *Citrullus vulgaris*. Cucurbitaceae with seeds containing fats are widely distributed in many parts of the Belgian Congo. The increasing cultivation of them from year to year is not only due to their easy adaptation to the quality of the soil, but especially to the fact that they need no cultural care. These Cucurbitaceae indeed grow so rapidly and vigorously that they prevent the invasion of weeds. In his paper on native agriculture in the eastern province of the Belgian Congo, THARIN (1) states that, in 1914, there were about 500 acres of oil-yielding Cucurbitaceae among the plantations along the Lokandu-Schuka road alone.

It should be noted that in the Belgian Congo the term "cocorico" has no very precise botanical signification. In the Upper Ituri it is applied to the seeds of a variety of gourd or melon called "maboke" or "n'du" in the Kilendu language, whereas in the eastern province a distinct variety of maboke which ripens more slowly and is said to contain less oil is known as cocorico.

The oil examined by the author was prepared on April 25, 1914 at Yangambi (Stanleyville district) by a method called "arabisée", which is in reality only a variation of the method already described for sélé oil. The only difference appears to be that in the "arabisée" method decortication precedes roasting.

A chemical analysis showed cocorico oil to be a valuable product with

(1) *Bulletin agricole du Congo belge*, Vol. VI, 1915, p. 147.

all the desirable qualities of sélé oil. Cocorico seed contains 37.50 % of oil which, in ratio to the kernel, is 50.46 % of the dry matter content. The cake is rich in nitrogen and would make an excellent nitrogenous fertiliser. So long as it contains no injurious or toxic substances (which is very improbable) cocorico-seed cake would be a valuable food for cattle or poultry, especially if mixed with starch or sugar. The tegument of cocorico seeds contains an appreciable amount of nitrogen and would make excellent composts.

In spite of the unquestionable value of its oil nothing at present indicates that cocorico might form an important export even if modern extraction methods are used and a higher yield obtained. The author considers the low unit yield of cocorico and the difficult and slow decortication of its seed make it useless for commercial purposes. On the other hand the home trade in cocorico oil and that of similar Cucurbitaceae should be encouraged in the Belgian Congo both locally and between the different districts.

III. *Ximenia americana*. — This bush belongs to the Oleaceae family and is usually found in the tropical districts of the old and the new continent. It is particularly abundant in America and the west coast of Africa. Dr. E. HECKEL (1) described in detail the botanical variations of this plant as well as its food value and toxic properties.

The *Ximenia* is known by many local names peculiar to the different countries in which it is found. In Jamaica it is called "mountain plum" or "sea plum", in Gabon, "elozy", "zégué", or "sealemon". In South Africa, whence the sample studied by the author came, it is called "zuur pruium" (acid plum).

The value of the "sea plum" lies particularly in the high oil content of its seed. In all probability the plant will be largely used commercially as soon as it is better known and cultivated more carefully and intensively.

Among the new properties found in it the author draws particular attention to the hexabromide test and the special properties of the solid acids. According to its percentage of bromine derivatives insoluble in ether, *Ximenia* should come immediately after linseed and candle-nut oil in the list of siccative oils, with respect to the linoleic acid content.

The oil extracted from this plant is used by the South African natives to make candles and to anoint their bodies. The fruit is said to make excellent preserves.

986 — *Elaeis Poissonii*, a New Species of Oil Palm, in the Cameroons. — FAUCHÈRE, in the *Bulletin de l'Office Colonial*, Year XI, Nos. 121-122, pp. 80-83. Melun, January-February, 1918.

In a paper sent to the author (Inspector of Agriculture, Secretary of the Council of Colonial Agriculture of the Acclimatisation Society) M. E. ANNET reports the occurrence in the Cameroons of a variety of oil palm, the commercial value of which appears to be very great. M. ANNET has made a new species of this form of *Elaeis* and has dedicated it to

(1) HECKEL, Les graines nouvelles ou peu connues des colonies françaises. Paris, 1898, p. 27. (Author)

EUGENE POISSON, one of the first to study oil palms in Dahomey and who, towards 1903, did much to further the commercial utilisation of the palm. The new species has, therefore, been called *Elaeis Poissonnii*. It is remarkable for its fruit which is enclosed in a sort of fleshy sheath formed by the development of six staminodes contained in the female flower which, in the other varieties of *Elaeis* hitherto described, are always atrophied. The fruit, which is generally fairly large, weighs from 10 to 20 gm.

M. ANNET distinguishes two varieties — var. *tenera* and var. *dura*. A comparison of these two varieties with each other and with the var. *Lisombe* of *Elaeis nigrescens* (the best form of oil palm known at present) gave the following figures with respect to the different parts of the fruit and the yield in oil:—

	<i>Tenera</i>	<i>Dura</i>	* <i>Lisombe</i>
Oily Pulp . . . . .	76 %	44 %	61.5 %
Sheath. . . . .	37	18	
Pericarp. . . . .	39	26	
Nuts . . . . .	24 "	56 "	38.5 "
Shell . . . . .	13	42.6	27.5
Kernel. . . . .	11	9.8	17
	100	100	100
Oil yield of the pulp . . . . .	70.25 %	38.6 %	63.15 %
" " of the whole fruit. . . .	53.50	55.8	38.35

These figures show that it would be of great value to cultivate the *tenera* variety. M. ANNET obtained the following figures for ten fruits of each of the chief varieties of *Elaeis* in the Cameroons:—

	Weight in grams			
	of the fruit	of the pulp	of the kernel	of the oil
Dibope . . . . .	123.0	51.5	23.0	27
Lisombe . . . . .	121.5	76.5	20.5	47
Dura . . . . .	171.0	74.2	18.1	44
Tenera . . . . .	168.5	128.3	19.4	90

987 - The Oil Content, Keeping Qualities and Commercial Possibilities of Para Rubber Seed.—SPRING, F. G. and DAY, F. W. F., in *The Agricultural Bulletin of the Federated Malay States*, Vol. VI, No. 5, pp. 231-244. Kuala Lumpur, February, 1918.

This paper gives a report of the experiments carried out by the Department of Agriculture of the Federated Malay States and reproduces data previously obtained by the Imperial Institute (1).

A few years ago there were wide areas of land suitable for growing *Hevea*. There was, therefore, a large demand for the seeds, which realised good prices. Now, however, as many of the plantations have come to maturity the production has increased enormously and the demand has greatly decreased, so that the problem of using the seed for other purposes arises. The average production in the Malay Peninsula may be estimated at 306

(1) See R. 1913, No. 1362 and R. 1914, No. 240. (Ed.).

lbs. per acre. In a seven-hour day one child, paid 18 cents a day can collect about 5 000 seeds; 1 000 seeds dried in the sun to constant weight weigh 81b. 6 oz., of which the shells weigh 3 lb. 2 oz. and the kernels 51b. 4 oz.

To test the keeping properties of the whole seed and the husked seed, samples were placed in gunny sacks and in wooden boxes as follows:—

A) *Whole seeds*. — 1) put in sacks the day after being collected; 2) put in boxes the day after being collected; 3) packed in sacks after having been sun-dried for three weeks.

B) *Husked seeds*. — a) shelled after being dried in the sun for 16 days:— 4) put in sacks; 5) put in boxes; b) shelled the day after being collected:— 6) packed in sacks.

The samples of Group 1 were in excellent condition after 4 months and good after having been stored for 6 months. Those of Group 2 varied; one began to deteriorate after 3 weeks, and others were slightly mouldy after 2 ½ months or 4 months; another was in good condition after 6 months. The samples of Group 3 were in excellent condition after 4 months' storing. Those of Group 4 were in good condition after 2 ½ months; one sample was slightly mouldy after 4 months, another had kept well but was infested with insects after 6 months. The seeds of Group 5 were in good condition after 6 months, but those of Group 6 began to deteriorate at the end of 3 weeks and were decayed after 4 months.

Crushing the whole seed of three samples in good condition and extracting with petroleum ether gave:— 51.8 to 53.3 % of oil by weight in the kernel; 23.5 to 31.4 % in the whole seed; 8 to 23 % of acidity (mgm. of KOH per gm. of oil); a sample of decayed seed gave slightly different results — 46.2, 23.2, 34 %. (In all these determinations the limit of accuracy is within 0.5 % only). *Hevea brasiliensis* seeds can, therefore, keep for a fairly long time. The oil yield and composition of good and decayed seeds differ little.

The dried husks contain 0.70 % and the dried kernels 1.83 % of ash, containing respectively 37.8 and 44.8 % of matter soluble in water; 7.9 and 18.6 % of magnesia; 38.6 and 37.2 % of potash; 16.8 and 28.6 % of phosphoric acid. The nitrogen and protein contents are:— 0.22 and 1.39 % for the shells, and 2.45 and 15.3 % for the kernels, respectively. The last figure corresponds to 27.8 % of protein residue in the cake after 45 % of oil has been extracted.

988 — **The Effects of Tapping and Wintering on the Food Reserves of *Hevea*.** — RUTGERS, A. A. L., in *Mededeelingen van het Algemeen Proefstation der A. V. R. O. S., Rubberserie*, No. 1, pp. 1-7 + 3 Plates. Batavia, 1917.

RUBBER, GUM  
AND  
RESIN PLANTS

The author studied the effects of tapping and wintering on the food reserves of *Hevea* in order to solve the following points:— 1) Does not the system of tapping used at present remove a larger quantity of food reserve than the tree is able to store up? 2) During wintering does not the plant draw upon these reserves to such an extent that, in order not to exhaust them, it would be better to stop tapping?

The conclusions of other workers (1) (CAMPBELL and BATESON) on this subject agree. They state that the effects of tapping on the food reserves of the wood and bark are exceedingly slight and limited to the immediate neighbourhood of the incision. On the other hand, the effects of wintering are more serious. The amount of reserve food contained in the wood and bark remains normal till the new leaves begin to develop. About a fortnight later, when the leaves have reached the normal size, the starch in the bark and wood has disappeared to a depth of 5 to 10 mm. For this reason these workers consider tapping should be stopped during the growth of the leaves till one week after the development of the tree's foliage is complete.

The author does not consider this opinion to be well-founded. He calculates the disappearance of the starch in the bark and wood to a depth of 10 mm. to represent a decrease of about  $\frac{1}{6}$  of the total reserve food of the plant, leaving  $\frac{5}{6}$  of this reserve available. Four or six weeks after the development of the leaves the reserves will again be totally replaced. Seeing that tapping only removes very small quantities of starch within a limited radius round the incision, the author does not consider there is any serious physiological reason for stopping tapping during wintering.

989 - **Value of the Results Obtained by the Use of Apparatus for Estimating the Rubber in Latex.** — RUTGERS, A. A. L. and MAAS, J. G. J. A., in *Mededeelingen van het Algemeen Proefstation der A. V. R. O. S., Rubber Serie*, No. 3, pp. 1-24 + 20 Tables. Batavia, 1917.

The authors wished to test the value of the results obtained with certain patented apparatus at present in use for the estimation of rubber in latex, such as DRING and FAGE'S "Metrolac" (2), and GRIFFIN'S "Latexometre". Many workers (ULTÉE, GORTER, etc.) agree as to the small value of determinations obtained thus. The many tables given by the authors and compiled from four series of estimations made with different apparatus by different people confirm this opinion. The results which were in each case checked by weighing the dry samples, showed a deviation between the *actual* values obtained by weighing and by the apparatus, but an agreement in the *relative* values. The use of the apparatus is, therefore, justified in so far as it gives relative and comparative data. The deviations in the absolute values are probably due to faults in setting up the apparatus and to the influence of temperature. As a matter of fact the values found do increase as the temperature rises.

990 - **Bibliography of the Publications on Rubber Which Have Appeared Between 1910 and 1916.** — RUTGERS, A. A. L., in *Mededeelingen van het Algemeen Proefstation der A. V. R. O. S., Rubber-serie* No. 5, pp. 84. Batavia, 1917.

The author considers the publications previous to 1910 especially of historical interest, or of interest only to specialists, and therefore refers only to the work of R. MARZAEN: — "*Wissenschaftliche Arbeiten über Kautschuk, Gutta-percha und Balata*" (published in the *Gummi-Zeitung*, Years I to XXV, Berlin, 1886 to 1910). He also leaves aside all publications of an

(1) See R. 1915, No. 814 and 917. — (2) See R. 1917, No. 1207. (Ed.)

economic or financial character, dealing with commerce, planter's societies, etc. The bibliography under review, therefore, is of interest solely to planters and those who prepare the product, and is drawn up eminently for practical purposes. It is divided into six chapters:— 1) General cultural methods; 2) Preparation, coagulation, vulcanisation; 3) Pathology; 4) Cultivation in various countries — Java, Sumatra, other Malay countries, Ceylon, Brazil; 5) Reports, conferences, miscellaneous; 6) Periodicals.

991 — **Measurement of the Growth of Sugar Cane; Observations Made in the Dutch East Indies.** — KUYPER, J. (Inspecteur der Cultuuraafdeeling te Pasoeroean), in the *Archief voor de Suikerindustrie in Nederlandsch-Indië*, Year XXVI, No. 5, pp. 163-165 + 9 Tables + 25 Diagrams. Soerabaja, January, 1918

SUGAR CROPS

To measure the growth in height of sugar cane the author uses a specially constructed apparatus consisting of a high, square, wooden rule graduated in centimetres fitted with a slider to which is attached a small copper plate graduated in millimetres.

The numerous measurements made by the author and given in the form of diagrams, show that the time between the appearance of two successive shoots varies between 5 and 7 days for the local varieties observed. Night growth usually exceeds day growth, but the latter is much influenced by rain, which may cause a day growth superior or equal to night growth. The moisture content of the air has practically no influence, or only very rarely has any perceptible effect.

992 — **Analysis of "Cocoa Tea", a New Substitute Used in Great Britain.** — BAKER, J. L., and HULTON, H. F. E., in *The Analyst*, Vol. XLIII, No. 507, pp. 189-197 + 4 Tables. London, June, 1918.

STIMULANT,  
AROMATIC,  
NARCOTIC  
AND  
MEDICINAL  
PLANTS

The present war conditions have stimulated research for substitutes of all kinds. One of the most recent which it has been attempted to introduce into Great Britain is a beverage made from cacao shell which remains after the seed has been roasted. This substitute is known as "cocoa-shell tea".

The data published on this residue and the attempts made to utilise it are rapidly reviewed. They show that beverages made from this material are not very highly valued, nevertheless these shells have recently been put on the market at prices out of all proportion to their food value, which has been exaggerated. The authors consider this matter should be remedied, and that the use of cacao shells cannot be objected to so long as they are sold at a reasonable price in conformity with their food value. The results of the analysis of several samples are given in the tables; the average figures are:— Moisture 4.68 %, fat 3.56 %, total ash 10.52 %, nitrogen 2.42 %, crude protein ( $N \times 6.25$ ) 2.42 %, crude fibre 15.42 % matter soluble in cold water 21.0 %. The content in matter soluble in hot water was also estimated to determine the practical value of the substitute. A mixture was made by boiling 3 parts of cacao shell with 100 parts of water and then straining. The figures obtained were higher than those for the content in matter soluble in cold water. This was partly due to the fact that a certain quantity of matter in suspension passed through the strainer.

993 — Trials with Réunion Tobacco in Mauritius, in 1916-1917 — AUCHINCLECK, G. G., in the *Department of Agriculture, Mauritius, General Series, Bulletin* No. 9, pp. 12. Port Louis, 1917.

In Mauritius there is a large importation and consumption of Réunion tobacco (chiefly used for strong cigarette tobacco). Owing to this, cultivation tests of this variety have been started in the Pamplémousses Botanic Gardens and in two other localities in the island, on a total area of about  $3\frac{1}{4}$  acres. The results were completely satisfactory; from 195 992 sq.ft. 535 carottes of 11 kg. each were obtained. No verdict can as yet be given as to the quality of the tobacco, as the special preparation necessary requires from 18 to 24 months.

The Réunion tobacco called "tabac bleu" is notable for its uniform foliage and growth (probably resulting from prolonged selection) and, so it appears, a greater resistance to diseases and pests than that of the Virginian, Sumatra and Turkish tobaccos so far tested at Pamplémousses.

994 — Medicinal Plants of the Italian Colonies. — *L'Agricoltura coloniale*, Year XII, 1st Half Year, No. 1, pp. 54-56. Florence, March 21, 1918.

Towards the end of January, 1918, the MOLTENT chemical-pharmaceutical company asked the *Agricoltura coloniale* for a list of the medicinal plants of the Italian colonies in order that the pharmaceutical produce to be obtained from them might be studied. The *Agricoltura coloniale* immediately wrote to the agricultural departments of Tripoli, Bengasi, Asmara and Mogadiscio asking for information on the native plants of the colonies which might best be cultivated for medicinal purposes. The Royal Agricultural Department of Tripoli sent the following list:—

1) Plants already widely grown in Libia or the cultivation of which could be introduced or increased:—

*Cupressus sempervirens*, *Mirabilis Jalapa*, *Lepidium sativum*, *Papaver somniferum*, *Nigella arvensis*, *Rosa* sp., *Acacia Farnesiana*, *Poinciana Gilliesii*, *Trigonella Foenum-graecum*, *Punica Granatum*, *Lawsonia alba* (the measures adopted by the government to suppress adulteration have given good results), *Coriandrum sativum*, *Cuminum Cuminum*, *Zizyphus Spina-Christi*, *Ricinus communis*, *Nerium Oleander*, *Hyoscyamus* sp.

It would probably be possible to grow successfully:—

*Glycyrrhiza glabra* and *Myrtus communis* in Cyrene; *Cassia obovata*, *Sinapis nigra* and *Datura Stramonium* in Tripoli.

2) Wild plants of the coastal districts which by reason of the present political situation can be harvested and utilised:—

*Juniperus phoenicea* (Cyrene), *Asphodelus microcarpus*, *A. pendulinus*, *Urginea maritima*, *Cynomorium coccineum*, *Atriplex Halimus*, *A. mollis*, *Polygonum equisetiforme*, *Papaver Rhæas*, *Adonis microcarpus*, *Thapsia garganica* (Cyrene), *Peganum Harmala*, *Malva sylvestris*, *Calotropis procera*, *Solanum villosum*, *Withania somnifera*, *Ajuga Iva*, *Citrullus Colocynthis*, *Diotis maritima*, *Matricaria aurea*.

3) Useful wild plants which, on account of the present political situation, cannot be harvested:—

*Callitris quadrivalvis*, *Cornulaca monacantha*, *Aihagi maurorum*, *Balanites ægyptiaca*, *Halophyllum vermiculare*, *Thymus capitatus*, *Globularia Alyssum*, *Artemisia Herba-alba*.

995 - Pine-Apple Growing in the Azores. — LUZ, T., in *Bioteria*, Pt. 3, pp. 123-127 + 2 Figs. Braga, 1918.

FRUIT  
GROWING

As the climate of the Azores does not permit the growing of pine-apples in the open they have been grown in greenhouses since the beginning of the 19th century in the islands of San Miguel and Terceira. In the second island exportation has practically ceased since the last thirty years or so, and the few pine-apple greenhouses left are used almost exclusively for local requirements. In the island of San Miguel, on the other hand, there are about 3 000 greenhouses which supply a large export trade.

The San Miguel greenhouses are double, about 165 feet long and 34 feet wide, and are built of wood and iron, covered with glass. An aisle leads up the centre, separating two beds raised slightly above the level of the soil. Propagation is by cuttings after the fruit has been gathered and the leaves removed. When the surface layer of soil has been removed a layer of clean dry leaves is laid down, over which is thrown another layer of the previous year's soil, in which the cuttings are placed; these are in their turn covered with a layer of new, good quality humus. When the leaves ferment they produce much heat which causes the cuttings to germinate. When the new shoots are four months old they are separated from the cuttings and planted, in squares at intervals of 1 foot in another greenhouse where the beds have been prepared as in the first one. After seven or eight months they are transplanted in the final greenhouse, prepared as the other two, in squares at intervals of 20 to 24 inches. Five months after transplanting fumigation is carried out. Dry straw and bits of plants are burnt in the central aisle and for three days the greenhouse remains full of the smoke produced. One month after this fumigation the plants flower all together and the fruit ripens at the same time, thus leaving the house free immediately after the harvest. Two years elapse from propagation to the harvest — five months in the nursery, seven in the first hothouse, and twelve in the second. During the period of fructification the temperature must be kept at 25 to 30°C. In summer the houses are ventilated to prevent excessive temperatures. Plantation and harvesting may be done at any time of the year. The most common varieties are "Jamaica" and "Cayenne".

The fruit to be exported is carefully packed in pine-wood cases with double-bottoms through which the peduncle is passed. Each case contains from 1 to 6 or 8 fruits.

During 1903-1916 the annual export from San Miguel was from 1 to 1 ½ million of fruits (in round figures) with a value of from 300 000 to 450 000 *milreis* (£ 66 500 to £ 100 000 *at par*). Before the war the principal importing countries, in decreasing order of importance, were:— United Kingdom, Germany, United States, France, Italy.

## FORESTRY

997 — The Douglas Fir: Its Importation and Cultivation in Central Europe (2). — BERKHOUT, A. H., in *Mededeelingen van de Landbouwhoogeschool en van de daaraan verbonden Instituten*, Vol. XIV, Pt. 1, 2 and 3, pp. 47-56 + 5 Tables. Wageningen (Holland), 1918.

The American tree commonly known as the Douglas fir was discovered in North America in 1792 by the explorer ARCHIBALD MENZIES and imported into Europe by DAVID DOUGLAS in 1827. The Douglas fir has many names in America — red fir, black fir, hemlock, swan pine, etc. The confusion of botanical names is no less great and is due to the fact that botanists disagree as to the genus to which it belongs; they call it *Abies Douglasii* Lindley, *Pinus Douglasii* Sab., *Pinus taxifolia* Lamb; *Picea Douglasii* Link, *Tsuga* or *Pseudotsuga Douglasii* Carr. There are many varieties of Douglas fir — blue, green, blueish-green (*glauca*), etc.; the last of these has smaller cones and is of slower growth. Douglas fir is one of the most widespread trees in America and is found particularly in the Rocky Mountains, Sierra Nevada, Colorado, and British Colombia. Its geographical distribution is between 43 and 52° north latitude. A well-aerated, very light soil containing a certain proportion of sand and stones, suits it best. It can stand a damp atmosphere better than excessive drought and should be sheltered from continuous winds. In the State of Washington it does very well up to 1150 feet, and in Oregon up to 1800 feet; above this altitude its growth is more restricted. According to MAYR Douglas fir is very resistant to frost in its native country, indeed, it grows in districts where the temperature is sometimes below -25°C. If its importation into Europe has not always given the expected results this is due to the fact that care has not always been taken to use seed from a district in which the environmental conditions are similar to those of the district in which plantations are to be made. It has also been shown that the poor sandy soil, as well as the marsh soil or excessively clayey soil of central Europe, do not suit it. The young plants may also be attacked by a fungus — *Botrytis Douglasii* — and by a canker — *Pestalozzia funera* Desm.

The rapid growth and excellent quality wood of the Douglas fir make it one of the most profitable trees for silviculturists. Data collected by HANZLICK on several plantations show this tree to have attained the following average weights and diameters (in the middle): — in 20 years, 29.83 feet and 0.35 feet; in 40 years, 76.32 feet and 0.69 feet; in 60 years, 101.25 and 1.01 feet; in 100 years, 125.55 feet and 1.34 feet. This fir may reach a height of 330 feet and a diameter of 16.40 feet. On the damp west coast of North America it generally attains in 80 years a height of 130 feet and a diameter of 2.62 feet. Of two neighbouring plantations at the Experiment Station of Wageningen one of these plantations of 18 years had an average height of 38.15 feet and an average diameter of 0.45 feet. The

(1) See R., March and April, 1912, Nos. 486 and 627; R., December, No. 1090; R., Jan. and Dec., 1915, Nos. 95 and 1330; R., May and August, 1917, Nos. 408 and 708. (Ed.)

(2) See also R., Jan. and Feb., 1915, Nos. 61 and 194. (Ed.)

data show that this tree had a diameter of 0.49 feet at Wageningen *five years earlier than in its native country*. Growth is not less rapid in other parts of Europe. In Germany (Oldenburg), a 37-year old plantation had an average height of 59.04 to 65.60 feet and an average diameter of 1.95 feet. Similar figures were obtained in England.

The wood of Douglas fir is solid and very resinous and used for many purposes, such as building wood, props and supports for mines and ship-yards. As timber and wood for commercial purposes it polishes very well and is used for cabinet work, and for making parquet and wainscoting. In Germany, the wood of a 25-year old tree had a specific weight of 0.536 and a resistance to pressure of 443 to 531 kg. per sq. cm.

The author foresees more numerous plantations of this tree in all central Europe, especially in places sheltered from strong winds and in clearings. The necessity of the choice of seed suited to the district, *i. e.*, from a country where the climatic conditions are as similar as possible, is emphasised. In Holland such seed-control is assured by the "Nederlandsche Heide-Maatschappij" (Dutch Association for the Development of Land).

998 - The Utilisation of the Dead Leaves of Forests. — See No. 1042 of this Review.

## LIVE STOCK AND BREEDING.

999 - Purifying Water for Stock. — *Queensland Agricultural Journal*, Vol. VIII, Pt. 4, p. 209. Brisbane, October, 1917.

HYGIENE

Water containing mud in suspension is easily clarified by dropping hot wood ashes into it, or by the application of lime or alum. These two substances make the water hard. Chloride of iron may be also used; it is quite harmless, and a valuable reconstituent and tonic for all animals. One lb. of chloride of iron will clarify 1 000 to 2 500 galls. of water and much reduce the bacterial content.

A simple method of purifying water without boiling has been devised by Dr. NAISMITH and Dr. GRAHAM. The method consists in adding a level teaspoonful of chloride of lime (containing  $\frac{1}{3}$  available chlorine) to a cupful of water. Dissolve, dilute with 3 more cupfuls of water, allow to stand for a few seconds; this stock solution, kept in a tightly stoppered bottle, may be used for 5 days. Add a teaspoonful to 2 galls. of water to be purified; stir well to bring the weak chlorine solution in contact with all the bacteria, and allow to stand for 10 minutes. This will destroy all typhoid and colon bacilli, or other dysentery producing bacilli in the water. The water will be without taste or odour and the trace of free chlorine added rapidly disappears.

1000 - Cut-throat Grass (*Panicum Combsii*) and Salt Sickness; Investigations in the United States. — PIPER, C. V. (Office of Forage Crop Investigations, Bureau of Plant Industry, U. S. Department of Agriculture), in the *Journal of the American Society of Agronomy*, Vol. X, No. 4, pp. 162-164. [Washington, March 20, 1918.

Cut-throat grass (*Panicum Combsii*) has so far been described for Florida, Georgia, and the south of Alabama, Mississippi and Louisiana, as

a rare species found especially on the edges of ponds. The author found it in great abundance in Polk County, central Florida, where it forms most pure growths of tufty bushes with tough, wiry leaves, almost erect, and from 6 to 18 inches long. Breeders in the district use it as a winter forage for fattening adult steers and non-pregnant cows, but believe it causes abortion in pregnant cows and a disease known as "salt sickness" in young animals. This disease which has frequently been studied in Florida is characterised by chronic anaemia, loss of flesh, loss of appetite, thin, pale blood, white mucous membranes, etc. STOCKBRIDGE, FRENCH and ENNIS (*Florida Agricultural Experiment Station Report*, 1900-1901, pp. 43-58, 1902) believe the cause of salt sickness to lie in the food and recommend as remedies alimentary correctives and tonics, as well as a change of pasture as a preventative and curative measure. Lime water, gentian, or iron salts ( $\frac{1}{2}$  oz. air-slacked lime or  $\frac{1}{8}$  oz. of iron sulphate in 3 gallons of water, the first *ad lib.*, the other once a day) have always proved useful. On the other hand C. F. DAWSON (*Florida Agricultural Experiment Station Bulletin* 64, 1902) believes salt sickness to be chronic Texas Fever (piroplasmosis) and that the food eaten is but a secondary cause.

1001 - **Gossypol, a Toxic Substance in Cottonseed** (1). — WITHERS, W. A. and CARRUTH, F. E., in the *Journal of Agricultural Research*, Vol. XII, No. 2, pp. 83-101 + 10 Tables + 1 Plate + Bibliography of 19 Publications. Washington, January 14, 1918.

Raw cottonseed kernels contain about 0.6 % of gossypol and are highly toxic to rats. Ether extraction renders the material non-toxic and gives a highly toxic extract containing about 2 % of gossypol. Gossypol fed in milk diets in amounts equivalent to those contained in the raw cottonseed diets proved as toxic as raw cottonseed. Gossypol may be quantitatively removed from the ether extract by precipitation as its insoluble anilin compound ( $C_{30}H_{28}O_9 \cdot 2C_6H_5NH_2$ ). The extract is thus rendered non-toxic to rats. Gossypol prepared from this compound possesses its original toxic properties.

Cottonseed meal is much less toxic than raw cottonseed, owing mainly to the oxidation of gossypol during cooking.

Cottonseed meal, ether-extracted cottonseed, and gossypol were fed to small pigs in pens under comparable conditions. Cottonseed meal was found to be definitely injurious, while the ether-extracted raw seed did not appear to cause cottonseed-meal poisoning. Gossypol was toxic to pigs.

If the presence of an injurious substance in the meal is disregarded, a diet of cottonseed meal and maize meal has nutritive limitations which may, under restricted conditions of living, lead to failure of pigs to thrive. Such failure is a phenomenon distinct from cottonseed-meal poisoning. Outdoor exercise, access to forage and soil, and improved diets tend to postpone or avert cottonseed-meal poisoning of swine. The deficiency hypothesis that cottonseed-meal poisoning of swine is similar to beriberi is untenable.

1002 — **Observations on the Etiology of Epizootic Lymphangitis** (1). — VELU, H., in the *Bulletin de la Société de Pathologie exotique*, Vol. XI, No. 5, pp. 351-357. Paris, May 8, 1918.

The author gives an account of his observations on the etiology of epizootic lymphangitis, resulting from work carried out in the research laboratory of the "Service de l'Élevage" at Casablanca.

1) *Contagion*. — Epizootic lymphangitis is transmitted by simple direct or indirect contact; immediate contagion is the rule. Inoculation takes place through the harness or grooming, infected hands of veterinary surgeons or farriers, soiled grooming tools, etc.

Experiments on the part played by flies gave negative results, without proving, however, that they play no part.

2) *Penetration*. — Transmission commonly occurs by means of some skin (harness wound, kick, fracture, injury, war wound, etc.) or mucous (auto-inoculation) erosion. Any break may serve as an entry to the RIVOLTA cryptococcus, which appears to be a saprophyte common in warm, damp climates. In Morocco, where the cryptogamic flora is extremely rich, epizootic lymphangitis is an ordinary complication of all severe wounds or fistulous sores that do not receive regular antiseptic dressings.

With the present state of our knowledge the disease cannot be transmitted with certainty. The positive results obtained by DELAMOTTE and other workers should be accepted with caution, as the exceptionally long period of incubation allowed by them does not exclude the possible intervention of other factors of infection. Other authors, however, have obtained negative results.

As a general rule, the primary lesions in epizootic lymphangitis are dermal or intradermal. The author attempted to ascertain whether inoculation in the dermis would lead to the appearance of the disease. In the more fortunate cases the result was the formation of a single abscess which proceeded towards recovery without the formation of secondary boils. Intravenous injection of large doses of pus were never followed by even the slightest reaction. The insertion of virulent matter into the bone marrow did not give good results. It was even found impossible to cause the formation of specific lesions by auto-inoculation.

BRIDÉ, NÈGRE and TROUETTE have found that hypodermic injections of yeasts cause the formation of abscesses; the organism shows a greater intolerance to each new injection; instead of acquiring immunity against the yeasts it appears to become accustomed to expell them. The author has observed similar phenomena in the case of the cryptococcus during attempts at pyovaccination.

1003 — **Preliminary Report on the Virulence of Certain Body Organs in Rinderpest**. — BOWNTON, W. H., in *The Philippine Agricultural Review*, Vol. X, No. 4, pp. 410-433. Manila, 1917.

The following results were obtained while endeavouring to devise a

(1) See R., June, 1917, No. 561; R. August, 1917, No. 734; R. Feb., 1918, Nos. 177 and 178; R., March, 1918, Nos. 310 and 311. (Ed.)

method of securing the aggressins of rinderpest. Since the virus of rinderpest cannot at present be satisfactorily cultivated under artificial conditions, it was decided to try to extract the virus from the tissues of animals suffering from this disease. From the symptoms, lesions, and microscopical findings, it is quite evident that the virus attacks primarily the involuntary muscles and endothelial lining of the capillary vascular system and the parenchymatous tissue. From the results obtained by the intravenous injection of various drugs and disinfectants it is quite evident that the virus of rinderpest does not have its fountain head of development in the blood stream. The real place where the virus multiplies appears to be inside the tissue cells where the disinfectants can not penetrate, the virus in the blood stream being merely a surplus which is thrown off from these tissue cells. In following this line of reasoning the writer decided to consider certain tissues where lesions were more or less pronounced, as cultures and extracts were made from them. The tissues used by him were liver, spleen, lymph glands, heart, intestines, thymus, skeletal muscle, larynx, pharynx, and the back of the tongue from animals which were either bled to death for virulent blood or from animals which had died after a regular course of the disease.

The tissues were taken from the animal as soon after death as possible. The amount of tissue desired was weighed, ground in a sterilised meat grinder and placed in a sterilised flask where twice as much phenol solution was added. This material was thoroughly agitated two or three times a day and kept in the refrigerator at 15-16°C., or it was agitated continuously for 48 hours at room temperature, then placed in the refrigerator for 24 hours, and then filtered through gauze and the filtrate replaced in the refrigerator until used for injection to carabaos.

The results may be summarised as follows :—

Water extracts of the liver, spleen, and lymph glands 3 days old and a 0.5 % phenol extract of liver, spleen, lymph glands, heart muscle, caecum and colon 5 days old are highly infectious to susceptible animals. On the other hand, the skeletal muscle, the larynx, pharynx and base of tongue and the pancreas are not suitable tissues for making extracts in the case of rinderpest. A 0.5 % phenol extract of liver, spleen and lymph glands holds the virus of rinderpest in a virulent form for periods of time varying from 8 to 55 days. A 1 % phenol extract of liver, spleen, caecum and lymph glands 17 days old are highly infectious and a 1 % phenol extract of liver and spleen 21 days old are virulent to susceptible animals. When glycerin is added to a 2 % phenol extract which had been agitated for 48 hours the virus of rinderpest is readily destroyed. In a 2 % phenol extract of lymph glands 8 days old the virus of rinderpest is destroyed. It is advisable to use a 0.75 % phenol extract not over 15 days old. The tissues best adapted for this work are the liver, spleen, lymph glands, heart, fourth stomach, caecum and colon.

From the results obtained in working with rinderpest it is very plausible that similar or even better results may be obtained with the virus of hog cholera along these lines.

1004 - Observations on the Control of *Rhipicephalus annulatus australis*, in Queensland, Australia. — THOMSON, F., KEOGH, G., and TUCKER, G., in the *Queensland Agricultural Journal*, Vol. VIII, Pt. 6, pp. 302-307. Brisbane, December, 1917.

The Queensland cattle tick (*Rhipicephalus annulatus australis*) lives as a parasite on cattle only. The females, gorged with blood, drop to the ground, where three days later they begin to lay; they continue for 10 to 21 days, each one laying from 1 500 to 3 000 eggs. These hatch during a period of 21 to 42 days. The larvae climb on to leaves, fence posts, and similar objects, where they can live without food for several months. If they find no host they eventually die; if they attach themselves to an animal they pierce the skin and feed on the blood. After 7 days of parasitic life they pupate, and after another 7 days the adults emerge. The adults live on the host for another 7 days; during the last 24 hours the females gorge themselves with blood, then drop to the earth, and the cycle re-commences.

The Department of Agriculture of Queensland recommends the following dip against ticks: — commercial arsenic, 1 700 gm.; caustic soda, 800 gm.; tallow, 800 gm.; vegetable tar, 1 litre; water, 800 litres. The animal must be completely covered by the solution, and should even be made to swim in it. This method has been employed in Queensland for about 20 years with excellent results. There is no doubt that an animal which has been twice dipped at intervals of 8 days is perfectly free from ticks and may be sent into an immune district without danger of its carrying the parasite there.

Of recent years breeders have tended to reduce the concentration of the dip, by reducing the amount of arsenic to 1 400 and even 1 200 gm. per 800 litres of water, and to replace dipping by spraying. A series of experiments made at the Stock Experiment Station at Townsville showed conclusively that: — 1) the official formula must not be diluted; 2) spraying, even if repeated each week for several months is not as efficient as dipping at intervals of one or two weeks; consequently spraying is inefficient as a control.

1005 - Thymic Acid and Thymol in the Treatment and Prevention of Intestinal Coccidiosis in Cattle. — TREMONA, P. (R. Scuola Superiore di Medicina Veterinaria di Torino), in *Il Nuovo Ercolano*, Year XXIII, No. 10, pp. 113-115. Turin, May 31, 1918.

According to observations of the author, Dr. SANLORENZO and others, intestinal coccidiosis or red scur frequently affects cattle in the marshy regions to the north-west of the province of Venice. In confirmation of the results obtained by Dr. SANLORENZO, the author obtained recovery in 4 to 6 days by administering thymic acid at the rate of 15 gm. for adults and 10 gm. for calves. In order to prevent the disease, he dosed the healthy animals for 3 days with 5 gm. of thymol per head per day.

1006 - Life History of *Ascaris lumbricoides* and Related Forms. — RANSOM, B. H. and FOSTER, W. D. (Zoological Division, Bureau of Animal Industry, U.S. Dept. of Agric.), in the *Journal of Agricultural Research*, Vol. XI, No. 8, pp. 395-398. Washington, D. C., November 19, 1917.

The life history of *Ascaris lumbricoides*, the common intestinal round-

worm of man, and of *A. suum* or *A. suilla*, of very common occurrence in the intestine of pigs, has been recently studied by F. H. STEWART, of the Indian Medical Service. In spite of their different names, these worms are the same parasite, or forms so closely related that they are morphologically indistinguishable. As a result of his investigations STEWART was led to a conclusion contrary to the usually accepted opinion that the infection of man or pig with *Ascaris* results from the ingestion of the eggs of the parasite. He concluded that it is necessary in the life cycle for the eggs to be swallowed by rats or mice and that in these animals the embryos hatching from the eggs undergo certain migrations and developmental changes, after which they may be transferred in the faeces or saliva of the rats or mice to food or other materials likely to be ingested by human beings or pigs, and thus ultimately reach their final hosts. The authors have reviewed and repeated STEWART's experiments, and from the various contributions of other investigators toward the solution of the problem of the life history of *A. lumbricoides* and related parasites, and their own experiences, arrive at the following conclusions:—

The development of *A. lumbricoides* and closely related forms is direct, and no intermediate host is required. The eggs, when swallowed, hatch out in the alimentary tract; the embryos, however, do not at once settle down in the intestine, but migrate to various other organs, including the liver, spleen, and lungs. Within a week, in the case of the pig *Ascaris*, the migrating larvae may be found in the lungs and have meanwhile undergone considerable development and growth. From the lungs the larvae migrate up the trachea into the oesophagus by way of the pharynx, and this migration up the trachea may already become established in pigs, as well as in artificially infected rats and mice, as early as a week after infection. Upon reaching the alimentary tract a second time after their passage through the lungs, the larvae, if in a suitable host, presumably settle down in the intestine and complete their development to maturity; if in an unsuitable host, such as rats and mice, they soon pass out of the body in the faeces.

Heavy invasions of the lungs by the larvae of *Ascaris* produce a serious pneumonia which is frequently fatal in rats and mice and apparently caused the death of a young pig one week after it had been fed with numerous *Ascaris* eggs. It is not improbable that ascarids are frequently responsible for lung troubles in children, pigs, and other young animals. The fact that the larvae invade the lungs as well as other organs beyond the alimentary tract and can cause a serious or even fatal pneumonia indicates that these parasites are endowed with greater capacity for harm than has heretofore been supposed.

Age is a highly important factor in determining susceptibility to infection with *Ascaris*, and susceptibility to infection greatly decreases as the animal becomes older. This, of course, is in harmony with the well-known fact that it is particularly children and young pigs among which infestation with *Ascaris* is common, and that *Ascaris* is relatively of rare occurrence in adult human beings and in old hogs.

1007 - "Askaron", a Toxic Constituent of Intestinal Worms, especially of Ascarids, and its Biological Action. — SHIMAMURA TORAI and FUJII HAJIME, in the *Journal of the College of Agriculture, Imperial University of Tokyo*, Vol. II, No. 4, pp. 189-258 + 4 Figs. + Bibliography of 12 Publications. Tokyo, 1917.

The authors have isolated from the mesenteric liquid of dried and powdered ascarids (*Ascaris lumbricoides* of the pig and *A. megalocephala* of man) an extremely toxic propeptone, for which they propose the name of "askaron". This propeptone produces all the symptoms of poisoning observed in ascariadasis and following on injections of the mesenteric liquid or aqueous extract of ascarids. It is also present in other intestinal worms. The authors have found it present (with the same toxic properties) in *Filaria immitis*, the larvae of *Gastrophilus*, *Sclerostomum vulgare*, *Oxyuris curvula*, *Trichocephalus depressiusculus*.

The ether and alcoholic extracts of dried, powdered ascarids are non-poisonous even in strong doses, but they always have a haemolytic action not possessed by "askaron".

The most sensitive among the experimental animals were found to be horses, then guinea-pigs, dogs and rabbits; rats and mice were refractory. The chief symptoms of "askaron" poisoning are troubled breathing, dilatation of the peripheral blood vessels, increased secretions and excretions, nervous disturbances, depression of the temperature and arterial pressure; on autopsy, are observed:—dilatation of the lungs (in guinea-pigs); hyperaemia and haemorrhagic exudation in the gastro-intestinal canal, in the endocardium and internal organs (particularly the lungs); partial coagulation of the blood. The fatal dose of crude "askaron" per kg. of live weight, given intravenously, is 0.004 mgm. for the horse, 0.8 mgm. for the guinea-pig, 2 mgm. for the dog, and 5 mgm. for the rabbit.

In the horse, the instillation of even very dilute solutions (up to 1 in 10 000) of crude "askaron" always produces a copious lachrymal secretion, which is supposed to be due to the volatile constituents of the "askaron". On repeatedly giving instillations, the reaction becomes weaker and weaker, but never wholly disappears.

After a first poisoning by "askaron", great resistance is quickly developed; the "askaron" obtained from different species is reciprocally immunising and to an equal degree.

"Askaron" is primitively toxic; the normal serum of the horses contains no antibody against "askaron". The horse can be actively immunised against a dose of askaron 400 times the mortal one; this great immunity is probably due to cellular resistance.

"Askaron" should be considered as a metabolic product of the worms.

1008 - I. Morphology of Normal Pigs' Blood. II. Effects of Muscular Exercise and the Heat of the Sun on the Blood and Body Temperature of Normal Pigs. — PALMER, C. C. (Veterinary-Research Laboratories, Minnesota Agricultural Experiment Station), in: I. *Journal of Agricultural Research*, Vol. IX, No. 5, pp. 131-140. Washington, DC., April 30, 1917; II. *Ibid.*, Vol. IX, No. 6, pp. 167-189 + Bibliography of 9 Publications. May 7, 1917.

I. — The work reported in this paper was undertaken with the view

of establishing normal data under conditions which exist in Minnesota as a basis for future studies and so corroborate the work of other investigators.

After an historical review of the subject, the author describes his own experiments and summarises the results obtained as follows:—

The number of erythrocytes in the blood of the pig varies under different conditions. It is lower in young animals than in old. It also varies according to the condition of the animal. A well-nourished pig in good condition will show a higher count than a pig in poor condition and of the same age. It was about equal in the blood of male and female animals.

The leucocyte count was lower in young animals, but individuals of the same class may show considerable variation. It seems to be higher in male than in female animals.

The percentage of haemoglobin was higher in older animals; it was higher in male than female animals.

The specific gravity of the blood was higher in older animals.

The clotting time was less in younger animals.

Five classes of leucocytes can be recognised in the blood of the pig:—Lymphocytes, large mononuclears, polymorphonuclears, eosinophiles, and mast cells. Results of the differential counts by various workers are fairly uniform. The percentage of lymphocytes and large mononuclears is higher in young animals. Older animals show a higher percentage of polymorphonuclears, eosinophiles, and mast cells than young animals. Differential counts in male and female animals are about the same.

II. — This work was carried out, in part, along with the preceding one. The author's summary is given below.

1) Blood examinations in normal resting pigs, covering a period of 24 hours, may be quite uniform; but in some animals there is marked variation throughout the period.

2) Observations made upon a number of animals leads to the conclusion that muscular exercise does not cause an increase of red corpuscles in the peripheral circulation of the pig.

3) Results based on only one or a few experiments may lead to wrong conclusions, owing to the variability in the blood of pigs.

4) Evidence given by work with the pig tends to confirm the theory of perspiration being responsible for the increase in the number of red corpuscles following muscular exercise in man.

5) Muscular exercise in the pig is usually followed by a leucocytosis.

6) This leucocytosis is probably the result of muscular exercise forcing leucocytes into the general circulation from the tissues.

7) Muscular exercise leads to marked changes in the differential counts. The mononuclear elements are decreased, and the polymorphonuclear elements are increased. The height of the curve is reached several hours after exercise, and the normal proportions do not return for many hours.

8) Exposure to the sun causes similar changes in the differential curve.

9) These changes under both conditions are the result of increased rate of aging of the leucocytes, the cells becoming older faster than young cells are being produced.

10) Muscular exercise and heat of the sun lead to a marked increase in body temperature.

11) Body temperature changes are more pronounced in fat pigs than lean ones, but even in pigs weighing 75 to 100 pounds marked changes are likely to occur.

12) Increased atmospheric temperature and increased percentage of humidity lead to increased body temperature.

13) Blood examinations of pigs which are to be used for clinical records should be taken from animals which have been confined in a small cool pen for at least 24 hours, and better, 48 hours. The animals must be kept absolutely quiet and not worried. Feeding and watering should be regular. The daily blood examinations should be made at the same time on each day.

14) Temperature records which are to be used for clinical records should be taken from pigs kept in a cool, shady pen. The animals should not be exercised or worried when the temperatures are taken. If the animals are chased around the pen when endeavouring to obtain the temperature, the last temperatures taken may show a marked rise. For tuberculin work where the temperatures are used it would be best to keep them confined in a crate throughout the test.

15) The condition of the animal (amount of fat), the temperature of the atmosphere, and the percentage of humidity are factors which should be considered in determining the normal temperature of the pig.

**1009 - Investigations into the Action of the Thyroid Gland, in the United States. —**

I. ALLEN, B.M., The Results of Thyroid Removal in the Larvae of *Rana pipiens*, in *The Journal of Experimental Zoology*, Vol. XXIV, No. 3, pp. 499-520 + 4 Tables + 8 Figs. + 1 Plate. — II. SWINGLE, W. W., The Acceleration of Metamorphosis in Frog Larvae by Thyroid Feeding and the Effects upon the Alimentary Tract and Sex Glands, *Ibid.*, pp. 521-543 + 1 Table + 14 Figs. + Bibliography of 11 Publications. Philadelphia, January, 1918.

I. — Although numerous investigations have been made into the effects of removing the thyroid gland from young and adult animals, there are no data on the results of removing this gland from animals at a very early stage of their development. Such an operation is exceedingly difficult in the embryonic stages of reptiles and birds, and almost impossible in that of mammals. The author, therefore, used amphibians for this purpose, taking as subjects tadpoles of *Rana pipiens*, of which the metamorphosis offers a very wide field of observation. It was found that the complete removal of the thyroid gland does not affect the course of early development till the hind limbs have begun to grow; further differentiation then ceases and metamorphosis does not occur. The general soma development, that of the limbs, alimentary tract and brain (the anterior portion of the head is of abnormal form, lengthened and broadened) were specially studied. No other organ seemed to show any further differentia-

tion, except the gonads, which were unaffected by the removal of the thyroid gland. This coincides with WEISSMANN's hypothesis of the independence of the germ plasma from the soma. The administration of thyroid extract to these larvae caused a resumption of growth even four months after it has ceased, thus corroborating the results of the following investigations.

II. — Other workers have observed that thyroid feeding greatly hastens the differentiation and metamorphosis of tadpoles. In this manner GUDERNATSCH obtained from frog larvae in a very short time perfect frogs no larger than flies. The author continued these experiments with a special view to the influence on the reproduction organs. Frog larvae were fed a powdered thyroid extract mixed with 30 % its weight of flour. Immediately after the administration of this food the subjects ceased to grow, eight days later limb buds were observed with a hand lens. Pigmentation was rather more marked than in the control animals, and in a very short time the subjects had all the characteristics of adult frogs, with the exception of the gonads and germ cells, the development of which was similar in the experimental and the control animals.

*Results.* — 1) There is no immediate physiological connection between the thyroid gland and the reproduction organs of amphibians.

2) With this exception the administration of thyroid extract to frog larvae has a marked influence on the bodily changes of the animals, all the organs and systems passing rapidly from the larval condition to that of the adult.

#### FEEDS AND FEEDING

##### 1010 — Effect of Time of Digestion on the Hydrolysis of Casein in the Presence of Starch.

— MCHARGUE, J. S. (Laboratory of Chemical Research, Kentucky Agricultural Experiment Station), in *Journal of Agricultural Research*, Vol. XII, No. 1, pp. 1-7. Washington, D. C., January 7, 1918.

The Van Slyke method for protein analysis (*Journal of Biological Chemistry*, Vol. X, No. 1, pp. 15-55, 1911) was worked out upon mixtures of relatively pure amino-acids and was not intended to be applied directly to crude sources of protein contained in cereals and feeding stuffs. Notwithstanding this fact, GRINDLEY, SLATER et al., of the Illinois Experiment Station, published in 1915 the results of the determination of the amino-acids contained in cottonseed meal, tankage and alfalfa hay, applying the Van Slyke method directly to the proteins contained in these different feeds. A little later NOLLAU, of the Kentucky Experiment Station, published his results, obtained by the same method, on about 25 different sources of crude protein contained in various seeds and feeding stuffs. In December 1915, GRINDLEY, SLATER et al., published a second paper on the amino-acid content of various feeds, including wheat, oats, barley and soy bean, a number of which had been analysed by NOLLAU. They obtained results which did not agree well with those of NOLLAU. HARTH and BENTLEY, of the Wisconsin Experiment Station, commenting on this lack of agreement have stated that whether accurate determinations of any or all the amino-acids can be secured when the hydrolysing proteins are in contact with hydrolysing carbohydrates must first be ascertained before these data can be accepted as final. HART and SURE have

published results obtained upon the hydrolysis of casein, alone and in presence of a number of different carbohydrates, on a 48-hour digestion and concluded that their work on casein and GORTNER's work on fibrin hydrolysed in the presence of cellulose *definitely* show the inapplicability of direct hydrolysis for the estimation of amino-acids in feeding stuffs by the Van Slyke method. But it occurred to the author that a duplication of the experiment of HART and SURE, carried on at varying lengths of time of digestion, would afford more conclusive evidence on this subject, as it is by no means to be taken for granted that results obtained on a 48-hour digestion will be the same as those carried on for a shorter length of time. Accordingly he planned the experiments described in the paper under review, and which led to the following conclusions:—

The Van Slyke method for protein analysis, when applied to mixtures of casein and starch in the proportion of 1 to 5, and hydrolysed from 12 to 15 hours with 20 per cent hydrochloric acid gives results for the amino-acid groups that are comparable with those obtained by Van Slyke upon casein alone.

A digestion period of more than 15 hours with 20 per cent hydrochloric acid on a casein-starch mixture brings about a redistribution of the nitrogen contained in the histidin and cystin groups.

The insoluble residue obtained from a casein-starch digestion after being thoroughly washed contains nitrogen, which is not seriously affected when distilled with calcium-hydrate suspension, very small amounts being split off as ammonia or remaining in the filtrate. This indicates that the nitrogen is in an inert form and its estimation should not be included in the humin determination.

1011 — **The Influence of the Food on the Vitamine Content of the Milk.** — See No. 952 of this *Review*.

1012 — **Aquatic Plants Which May Be Used as a Food for Cattle: Investigations in Holland.** — *Nederlandsch Weekblad voor Zuivelbereiding en Veeveest*, Year XXIV, No. 10, p. 2. Doetinchem, June, 1918.

In view of the present scarcity of cattle food various sources of such food have been studied, among others three aquatic plants: 1) *Lemna trisulca* (duckweed); 2) *Elodea canadensis* (water-weed, ditch-moss, water-thyme); 3) *Azolla* sp. The experiments made at the cattle Food Control Station of Wagenningen showed that those plants may well be utilised as a cattle food. They may be fed either fresh or washed to cattle and pigs. As at the season when these plants may be gathered there is usually sufficient green fodder, it is of special use to preserve them. As artificial desiccation would be too expensive for this purpose, it is more practical to ensilage them.

Analysis of fresh duckweed, water-weed and *Azolla* gave the following figures for each plant respectively.: — Albuminoids, 1.8, 1.4, 2.3 %; fats, 0.2, 0.1, 0.3 %; starch, 2, 1.9, 5.1 %; crude fibre, 0.6, 11.0, 2.0 %; moisture, 94.3, 94.6, 88.0 %; ash, 1.1, 0.1, 2.4 %.

After desiccation these plants retain good albuminoid and starch

contents. This is shown by the following percentages (dry matter basis for duckweed, *Azolla* and water-weed respectively; — Albuminoids, 31.5, 2.6, 18 %; fats, 3.5, 1.8, 2.5 %; starch: 35, 35.2, 42.5 %.

1013 — **Digestible Hay Cake and Hay Paste.** — GAIN, E., in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 17, pp. 539-543. Paris, May 15, 1918.

In order to utilise hay to better advantage the author states the principles by which he was governed in making digestible hay cake and hay paste, with the intention of giving later the physiological characteristics which he is still studying and which may support his claims for its practical value. He tested the use of cake prepared by his method on horses, which ate it readily. The *method of raising the yield of hay* by making *cake* and *paste* includes physical and chemical-biological procedures which permit the modification of the physical condition, digestibility, nutritive ratio and adipo-protein ratio. The aim is to increase the quantity of useful nutritive matter.

A. — PHYSICAL PROCESSES. — Crushing and partial cooking.

It is sufficient to crush, sift and pass the powder through an electro-magnet to remove the metallic particles. By mixing the product with water, cake, lozenges, etc. may be made. Crushed oats may be incorporated. Better results may be obtained by partially cooking the cake by drying at 60°C., followed, if desired, by rapid superficial heating. The author also tested short treatment in the autoclave.

B. CHEMICAL AND BIOLOGICAL PROCESSES. — Special chemical, diastatic and fermentation treatments, to affect the chemical composition to a more marked degree than by the physical processes.

The nutritive ratio (or food quotient of hays) and the adipo-protein ratio may easily be altered; by changing them the coefficient of digestibility is modified. To the crushed hay may be added other products: — concentrated foods such as oil cakes (1 to 5 % only), small fodder seeds or flours, young leaves of forest trees, reeds, sedges, etc., and even foods with a specific action or simple chemical addition (e. g. glycono-phosphates).

C. — FERMENTATION OF THE HAY POWDER BY COMPRESSION. — The ferment actions capable of influencing the real value of hay vary in nature. They may be concerned with the different immediate principles, especially the liberation of useful elements, by attacking more or less severely the ligneous covering in which they are often enclosed. *Hay from stomachs* often give a useful flora capable of acting on the powder to be made into cake. The author made several tests with the classical diastases, *hay from ox's stomach* and *hay from sheep's stomach*, commercial yeast, a hay infusion, and, finally with partial sterilisation and the dissociative action of steam under pressure in the autoclave.

One of the chief elements of the value of hay lies in the seeds of the plants composing it. The harvest is, however, hastened so that the hay may be tender and ripe seeds are rarely found in hay. With digestible hay cake it would be advantageous to harvest later.

A small part of the hay might be fed as paste, the preparation of which

only requires crushing, sifting and kneading with 3 or 4 times more water than powder, by weight. The product is very similar in appearance to hay from sheep's stomach. It may be dried in the air, compressed, or fed fresh mixed with other food. Crushed seed, nettle leaves, leaves of young trees, sedges, reeds, etc., may be added.

1014—**The Zebra and its Hybrids as Domestic Animals.**—FAWCETT, W., in *La Hacienda*, Vol. VIII, No. 8, pp. 242-245 + 9 Figs. Buffalo, N. Y., May, 1918.

HORSES

For more than a century attempts have been made in various countries to utilise the zebra and its hybrids for agricultural purposes. The zebra can be bred as a domestic animal. The first hybrids were obtained by crossing a female zebra and an ass, then by crossing a female zebra with a horse, and also by crossing a mare with a male zebra. A zebra  $\times$  ass cross was obtained by LORD CLIVE towards the end of the 18th century; later on similar crosses were obtained in France and Italy. Further crosses were also obtained, especially in Great Britain, Australia and France. Crosses were obtained in Brazil in 1899 and 1900 and also in Scotland (by Prof. COSSAR EWART) between small pony mares and male zebras. HERR HAGENBECK has obtained crosses between female zebras and pony stallions.

The different species of zebra (1) have all been used for crossing, and some seem better suited than others. Burchell's zebra (which was used by Prof. EWART for crossing) has been used very often; the mountain zebra, common in South Africa, has been used. For other crosses, especially those carried out by the U. S. Government, Grevy's zebra was used. This latter is somewhat larger than the others being 52 and 56 in. high; an adult animal weighs from 770 to 880 lb. It occurs in Abyssinia and Somaliland, but it is gradually becoming rarer and rarer, while it is with difficulty transported from the place of capture to countries across the sea. Although it has never been domesticated, it is docile and would probably be easy to domesticate and rear. The male shows great dislike of mounting large mares, even if he has grown up with them from a foal. On the other hand he readily mounts small mares or she-asses.

The hybrids obtained in the United States are very vigorous and resist the cold of temperate regions as well as does the ass. They show a decided improvement over the parents as regards their form, movements, and way of standing. The average weight at birth is 48 lb.; at 1 year 275 lb., when the average height is 48 in.

The cross she-ass  $\times$  zebra are very obstinate and hard-mouthed, which constitutes an obstacle to their use as working animals. On the contrary the cross mare  $\times$  zebra is more docile and tractable, and can be used like the mule, over which it has the advantage of being much better shaped.

In crosses made in the United States between mares and zebras, the stripes in the coat of the hybrid were indistinct and the characters of the

(1) Three species of zebra are recognised:—*Equus zebra*, the common or mountain zebra *E. burchelli*; *E. grevyi*. The latter is heavier than the others, with closer and darker stripes. (F. E. BEDDARD, *The Cambridge Natural History*, Vol. X, pp. 244-245, London, 1909).

mother predominated. In other crosses made in South America and Europe the characters of the father were predominant and the stripes were still more marked than those of the father.

## CATTLE

1015 - **The Origin and Improvement of Cattle in Colombia.** — GONZALES, T. L., in *Revista agrícola, Órgano del Ministerio de Agricultura y Comercio*, Year IV, No. 1, pp. 12-23 + 2 Figs. Bogotá, January, 1918.

The first imported cattle in Colombia were brought there by the Spanish "conquistadores"; they included 37 animals, male and female, and were imported from Andalusia by RUIZ DE LUGO in 1570. The conditions were very favourable to their development, especially in the large plains of San Martín and Casanare and their numbers increased in an astonishing manner. Later there were imported into Colombia some of the cattle which had been introduced by the French and English into North America in the 16th and 17th centuries and had become acclimatised there. Finally a few selected and improved cattle were imported from the United Kingdom.

Colombia is specially suited to the production of butcher's cattle and the breeding animals sought for are those of beef breeds. The best results on the American Continent have been obtained with the Hereford, Short-horn, Angus and Galloway breeds; of these the author considers the first the most suited to all the environmental conditions of Colombia. At one time zebu were bred in Colombia, but their hybrids with the native cattle were not satisfactory, of bad form and savage nature, and producing only a medium meat.

The decree No. 77, passed in 1917 to encourage the importation of breeding stock for improving Colombian cattle and the crossing of its breeds with foreign selected breeds so as to produce stronger animals, of more rapid development and better form, granted breeders importing animals for the improvement of cattle a third of the total expenses incurred till the animal reached its destination, including the price paid for it. A sum of 50 000 *gold pesos* (£ 9 900 *at par*) has been allocated for the buying of breeding stock to be sold by auction.

## GOATS

1016 - **The Angora Goat in Madagascar.** — CARONGEAU, in the *Revue agricole et vétérinaire de Madagascar et Dépendances*, Year II, No. 17, pp. 110-112. Tananarive, March, 1918.

The author brought to Madagascar three male and three female Angora goats from the Naivasha Experiment Farm (Australia). The animals were sent to the ostrich farm at Tuléar where a small herd has been formed under the direction of the veterinary surgeon, M. GRANDMOUGIN.

At the end of 1915 a small herd of native goats was formed for breeding with the males. Excellent results were obtained. In 1916 the herd included 5 pure-bred males and 11 pure-bred females, as well as 9 cross-bred kids of the first generation.

On December 31, 1917, M. GRANDMOUGIN stated that the angoras had adapted themselves remarkably, to such an extent, indeed, that their vitality may be said to be superior to that of the native goats. It was possible to cure Angora goats suffering from scab, whereas, in Madagascar

goats living under the same conditions, the disease made slaughtering unavoidable, whatever treatment was adopted.

The herd is composed of 80 animals including 30 pure-breds, of which 8 are males, and cross-breds of the first and second generation. The animals pass the whole day on pasture land and receive no supplementary ration.

It has thus been proved that it is possible to breed Angora goats successfully in Madagascar. Numerous breeding centres could be formed throughout the south, as the Angora does well where the Merino can no longer live.

1017 — **Mussels as Food for Pigs: Investigations in Demark.** — *Ugeskrift for Landmand*, No. 23, pp. 313-314. Copenhagen, June, 1918.

PIGS

The following investigations were undertaken at Rosvang (under the direction of Inspector LÆGAARD) with a view to determining the efficiency of mussels as a food for pigs.

In the first experiment all the animals received per head in 10 days 66 lb. of "Mælkeriaffald" (skim and butter milk); those of Group I received in addition 56.1 lb. of barley, those of Group II 41.3 lb. of barley + 22.4 lb. of mussels ("mulsingekod") replacing 14.4 lb. of barley. The increase in live weight for one animal at the end of 10 days was 17.8 lb. for Group I and 8.6 lb. for Group II (fed on mussels).

As this experiment was made at a season when mussels are small a second one was made under much the same conditions but with younger animals. In this case the difference between the two groups was much smaller. In Group I (full grain ration) the increase in live weight per head at the end of 10 days was 13.8 lb.; in Group II (grain ration partially replaced by mussels) it was 12.5 lb.

At the end of the second experiment the quality of the meat was examined, and the flesh and fat of the pigs fed on mussels was found to have a very marked oily smell and flavour, and the melted fat a brown colour. For this reason it is advisable to stop feeding mussels some time before slaughtering. It should also be remembered that raw mussels (with the shells) only supply 10 to 14 % of flesh, so that 2 lb. of shelled mussels will replace 1 lb. of grain in the ration, whereas 16 lb. of mussels with shells are required. After boiling the mussels it was found possible to keep them in buttermilk for four or five days, even during the hottest part of summer, and the same buttermilk could then be used as food.

1018 — **Experimental Modification of Germ Cells and the Effect of Daily Inhalation of Ethyl Alcohol and other Poisons on the Progeny of Poultry.** — PEARL R., I. General Plan of Experiments with Ethyl Alcohol and Certain Related Substances, in *The Journal of Experimental Zoology*, Vol. XXII, No. 1, pp. 125-164 + 3 Figs. + 6 Tables + Bibliography of 43 Publications. — II. The Effect upon the Domestic Fowl of the Daily Inhalation of Ethyl Alcohol and Certain Related Substances, *Ibid.*, Vol. XXII, No. 1, pp. 165-185 + 4 Figs. + 6 Tables. — III. The Effect of Parental Alcoholism, and Certain Other Drug Intoxications, upon the Progeny. *Ibid.*, Vol. XXII, No. 2, pp. 241-310 + 7 Figs + 15 Tables. Philadelphia, January and February, 1917.

POULTRY

The aim of the experiments described was to determine whether it is

possible to modify hereditary factors in any special manner and to observe the effect of such modification from the point of view of inheritance. The problems studied were :—

1) Does the continued administration of ethyl alcohol (or other similar narcotic poisons, such as methyl alcohol and ether) to the domestic fowl induce precise and specific changes in the germinal material, thus causing new, heritable, somatic variations ?

2) In the absence of a specific effect, is there a general effect upon the germinal material leading to degeneracy of the progeny ?

3) What are the effects in general upon the soma of the subject, and do they give any clue to the probable origin and mechanism of the germinal changes ?

I. — The general plan and method, the material and subjects of the experiment are described. The animals used were hybrids from Black Hamburgs (males) and Barred Plymouth Rocks (females). Besides other advantages, the use of hybrids renders possible wider and more precise observations on the eventual variations of the inherited characters as a result of artificial poisoning and the determination of the extent to which these variations deviate from the Mendelian laws. The subjects were divided into 3 groups according to the poison administered—ethyl alcohol, methyl alcohol and ether. These substances were administered by the use of well-closed galvanised iron tanks, in which the animals were placed each day for at least one hour. The floor was made partly of heavy galvanised wire gauze which connected the tank with a cylinder below which was filled with absorbent cotton soaked in the toxic substance. Similar experiments made previously by STOCKARD have shown that the birds absolutely refuse to drink water in which the substance is placed, so that this method is impracticable.

II. — The organic and physiological effects of the inhalation of the toxic substances were studied with the following results :—

1) The *mortality* among the treated birds was much lower than among the control birds from the same parents. After 15 months' treatment the difference was 41 % in favour of the treated birds. This is opposed to the accepted idea that alcoholism shortens life. Too much importance is not attached to this fact and it is believed that as the experiments continue and include more animals this difference will gradually decrease. The photographs show that there is very little difference in the appearance of the treated and untreated birds.

2) The *body weight* of the treated birds began to increase immediately after the beginning of the treatment in autumn. This increase, which probably was not due to the treatment, was greatest in January and February and was followed by a sharp and prolonged fall till May or June, when there was another steady increase till the following February (1916). At this date the treated birds were on the average 9.9 % heavier than the untreated birds.

3) *Egg production* showed no marked difference between the treated birds or control birds ; both groups of birds laid normally in each season.

Throughout the 15 months of the experiment the average production per bird was 184.74 eggs for the controls, and 183.97 for the treated subjects ; the difference — 0.77 — is negligible.

III. — The effects on the progeny of the administration of toxic substances to the parents are given, and the characters which may be expressed quantitatively are examined. Treating one or both of the parents with toxins reduced the *number of fertile eggs*, i. e. those in which a zygote was formed by the union of sperm and ovum. Pre-natal as well as post-natal *mortality* at all ages was lower in this case than in the control birds. The *sex ratio* of the progeny was not affected by the treatment of the parents. Treating the male only did not affect the *weight of the offspring at hatching*, but when both the parents were treated the hatching weight was superior to that of chickens from the control birds. This also holds good for the *adult body weight* of the progeny of both sexes. There was little difference in the *rate of growth* of the male offspring till after 100 days, after which the treatment of the parents resulted in a steady increase in weight. The effect on the female offspring was similar, but occurred only after 200 days.

The treatment did not affect the *proportion of abnormal chickens*, which was similar in both cases. The *Mendelian laws* were not affected, at least as regards dominance, recessiveness and sex linkage. Nothing in the experiments showed the administration of toxic substances to have any injurious effects on those germ cells which formed zygotes. The results obtained support the theory that alcohol and similar substances act as *selective agents on the germ cells* of the treated subjects. It may be assumed that the relative vigour or resisting power of germ cells varies continuously from a low to a high degree. Treatment with alcohol thus has several results :— certain germ cells will be incapacitated from forming zygotes ; these are clearly the least resistant ; others will produce defective zygotes ; these are those which have been unable to resist the poison completely ; finally, those which are not perceptibly affected will produce normal zygotes. This would explain why the progeny of parents which have been treated with toxic substances are, on the whole, superior to those of parents not so treated as regards physical resistance, vigour, development and mortality. In experiments of this kind the ratio between strong and defective zygotes depends on two variable conditions—the amount of toxic substance administered and the average resistance of the germ cells ; this second factor depends on the breed.

These results corroborate those of NICE with mice, as well as the statistical data obtained among the working classes by ELDERTON and PEARSON.

1019 — **The Use of Weevily Wheat for Feeding Poultry.** — *Agricultural Gazette of New South Wales*, Vol. XXIX, Part. 4, p. 292. Sydney, April, 1918.

• Methods for utilising wheat-meal made from weevily wheat for feeding poultry have been tried in the Chemist's Laboratory of the Department of Agriculture, New South Wales. A mixture of 1 of bran to 2 of wheat-meal gave a coarse mixture, but it made a good mash. One part of

bran to 3 of wheat gave a good mash of better appearance, while 1 of bran to 4 of wheat gave a mash of good appearance, that seemed too adhesive for poultry. The bran should be first scalded and then the other ingredients worked into it.

1020 — **The Use of Seaweed in Poultry Feeding** (1). — DECHAMBRE, P., in *L'Agriculture pratique*, Year LXXXII, Vol. XXXI, No. 12, pp. 230-231. Paris, June 13, 1918.

The author describes the experiments made by M. MORTE, at Tré-gastel, Côtes-du-Nord, on the feeding of poultry with seaweed. Ten hens and ten ducklings were fed first on *Laminaria* then on all kinds of algae. The algae were freed from salt by being washed several times in fresh water (this washing is not indispensable). They were then chopped into small pieces from 3 to 5 mm. long; this is easier if they have previously been partially dried. They are then mixed with boiled crushed potatoes and put in a baker's oven for three hours or cooked over a low fire. When the whole is well jellied it is kneaded and distributed to the poultry. The ration given the poultry experimented with varied from 6.6 to 8.8 lb. of algae mixed with 2.2 lb. of potatoes. No grain was fed.

Later the potatoes were deducted from the rations for the ducks, which ate the algae alone and fattened as rapidly as those fed normally. This was also attempted with the hens which, however, refused the algae alone, so that the potatoes had to be added and, later, swedes. The hens developed well, laid normally and their flesh had no peculiar flavour. The results were satisfactory in every way.

## FARM ENGINEERING.

AGRICULTURAL  
MACHINERY  
AND  
IMPLEMENTS

1021 — **Agricultural Machinery in the United Kingdom** (2). — COURTNEY, F. S. (Consulting Engineer to the Royal Agricultural Society of England), in the *Journal of the Royal Society of Arts*, Vol. LXVI, No. 3416, pp. 403-415. London, May 10, 1918.

In describing the history of the development of agricultural machinery in the United Kingdom, the author draws attention to the fact that the double-furrow plough was developed by LORD SOMMERVILLE (1802) and improved by T. PIRRIE (1867). It was used for a number of years, but it fell into disuse until the last 20 or 25 years.

As early as 1866-67 the Royal Agricultural Society made an inquiry on the subject of steam cultivation, and a most interesting report gives details of the work done, which was about 6 acres *per diem*. Direct haulage of the plough by the engine was tried as early as 1865, but it was abandoned owing to the soil-packing caused by the engine. Of all the cable haulage systems, the one that has maintained its position is the double-engine system, which is still pre-eminent for efficiency. Out of 540 sets of double-engine sets at work in England, 267 are over 40 years old, 99 between 30 and 40 years old, 13 between 20 and 30 years old, 28 between 10 and 20 years old, and 133 under 10 years old. The author next considers

(1) For the utilisation of algae for feeding purposes see R. March, 1918, No. 320. (Ed.)

(2) Paper read before the Royal Society of Arts at London.

the internal-combustion tractor and refers to the interesting paper by Mr. LEGROS, entitled "Traction on Bad Roads or Land" (1); he then deals with cultivators, scarifiers disc-harrows, and rotary diggers (a machine of this type was patented in 1857). After dealing with harrows, rollers, seed drills, potato planters and diggers and manure distributors, the author passes to mowing and reaping machines, harvesters, threshing machines, straw elevators, straw trussers and presses, the history of which he gives as well as the improvements they have undergone and the driving power they require. In 1849 the Royal Agricultural Society held its first trial of portable engines, built somewhat on present lines, *i. e.*, with locomotive-type boiler and horizontal engine. In 1850, as the result of further trials it was found that the engines were much improved owing to better design and the use of increased steam pressure. In 1872 still greater improvements were found.

After describing the development of road traction for carrying agricultural produce, the utility is shown of applying water and electric power to agricultural purposes. In comparison with other countries there is relatively little water power available in Great Britain, but the author advises farmers to utilise as fully as possible any such water power that is available in their district.

**1022 - Hints on the Use of an Agricultural Tractor.** — Extracted from *La Journée*, in the *Bulletin Mensuel de la Chambre Syndicale des Constructeurs de Machines Agricoles de France*, No. 3, pp. 143-144. Paris, May, 1918.

It is important, in the first place, that the field of action of the tractor should not be too wide. If it is true that the majority of tractors are well sprung nowadays, it is none the less true that their chief use is not that of running about on the road. First, these journeys waste time, petrol and oil, and end by over-working if not damaging the machine. This results in time wasted, expensive repairs, the machine being held up, and the delay of urgently-needed work, without considering that all these journeys and delays considerably decrease the daily yield of the machine and that the extra cost due to running on the road, increases the bill of the tractor. This means a higher cost for ploughing an acre, the price in reality falsified by the bad use of the tractor. For example, a 20 H.P. tractor working on an 20-acre field at the rate of 5 acres per day, will, by long, frequent journeys, decrease its yield to 2.5 and 3.7 acres, a yield which does not justify the use of a tractor.

The tractor should also be used intensively, *i. e.*, night and day, weather permitting, so as to increase its yield. In bad weather, animals should be used to do the work. It is true that with the use of chain-track tractors and the tractors used in electroculture, the slipping of the wheels in wet soil is avoided.

Another point worth considering is that tractors do not give their full yield unless they are used with such implements as are suitable to them, which is not always the case.

(1) Summarised in *R.*, July, 1918, No. 803. (*Ed.*)

For agricultural work other than ploughing, the full power of the tractor should be used so as to obtain the best yield. Thus, a 20 H. P. tractor hauling a single binder will not give a good yield; two or more binders should be hauled at once.

Similarly, light work is best done by draught animals. The tractor is not meant to do away with draught animals, but to do better than them, more quickly and cheaply, and where animal traction is obviously insufficient to attain the desired end.

These hints will be specially useful to agricultural groupings formed for mechanical cultivation.

1023 - **The Dirube and Sabaria System of Cable Traction Applied to Agriculture.** — GIAGNONI, C., in the *Revista de la Liga Agraria, Asociación Nacional*, Year XXI, Vol. XX, Nos. 9 to 12, pp. 183-193. Buenos Ayres, September to December, 1917.

With previous systems of cable traction (FOWLER and DEBAIN, HOWARD and FISCHER), nearly 25 % of the power is lost in overcoming a series of passive resistances, which, however, are said to be eliminated in the DIRUBE and SABARIA system of traction. In this the machine moves to the end of the furrow carrying with it the traction platform to which the anchored cable is attached. Meanwhile the steel cable rolls on a drum coupled to the engine in such a way that the remaining part of the cable lies on the furrow. After this the operation recommences for the next furrow up to the anchorage already prepared on the opposite headland. In this way the resistance due to pulleys and cables is avoided, thus giving an efficiency of 88 to 92 %. The inventors have patented both the machine and the fuel, which is a gas. The machine has a pull of 45 H. P.; it weighs 8 800 lb.; works a breadth of 131 in. and a depth of 6 in.; the coefficient of circular friction is 0.15; the tractive effort per sq. dm. is 60 kg., the work per hour (10 hour day with 8½ hrs. actual work) is 2.35 acres; actual work per 10-hr. day is nearly 20 acres. A driver and one assistant are required. The machine with all accessories (platform and engine, balance plough, about 5 000 ft. of metal cable, anchor, etc.) is 12 250 paper pesos (about £ 1 078). The fuel (a patent gas) is consumed at the rate of 500 gm. per H.P.-hour; it costs 25 pesos (£ 2.2s.) per metric ton. Allowing 236 working days per year, the author finds that the cost of ploughing 1 hectare is 4.02 pesos. (about 2 s. 10 d. per acre).

The inventors have also built a 60 H.P. model. They intend to exploit their invention not by selling the machines but by hiring them out.

1024 - **Trials of Disc-Harrows with Tractors, in France.** — RINGELMANN, M., in the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year XCVII, Vol. CXXIX, n° 2, pp. 313-319 + 8 Figs. Paris, March-April, 1918.

With tractors turning the last furrows it is often necessary to use teams for scarifying and harrowing; these teams can be replaced by double disc-harrows working over a large width and thus doing much work. They are also very suitable for preparing the soil for autumn or spring sowing by replacing the scarifying and harrowing. A seed drill

or a broadcaster may even be mounted on the disc-harrow, thus sowing during the same operation, should the state of the soil permit it.

The author deals with trials with 2 ordinary Osborne disc-harrows; on light soil that had been fallowed, with a 16 HP Mogul tractor and a 14 disc harrow, about 53 820 sq. ft. are worked per hour with a consumption of 9.9 lb. of petrol per acre; on recently ploughed land with the same machines, about the same area is cultivated (53 389 sq. ft.) with a consumption of 12.4 lb. of petrol per acre. The speed was 3 662 yards per hour on fallow and 3 692 yards on recently ploughed land.

After describing the double disc-harrows (I) with smooth and toothed discs built by M. PILTIER of Paris, the author gives the results of the 1917 trials, using a double disc-harrow and a seed-drill: —

	I.	II.
Average depth cultivated in inches. . . . .	2.95	4.4
Average traction in lb. . . . . total	1026.08	1288.32
"    "    lb. per sq. dm (= 0.1 sq. ft.) . . . . .	47.74	41.8
"    "    lb. per disc. . . . .	31.9	40.26
Quality of the work. . . . .	Very good. Excellent	

The angle of each disc with the direction of traction was 77° in the first trial and 74° in the second.

Under ordinary conditions the smooth discs work quite well. The toothed discs might be reserved for soil liable to cake strongly; as regards this point the author has not sufficient information to allow him to give any definite information.

1025 — **The Marti Earth-Grab.** — GACHET, A., in *La Torre Vaudoise*, Year IX, No. 35 pp. 323-324 + 2 Figs. Lausanne, Sept. 2, 1918.

The Landed-Estate Improvement Society of Bioley-Orjulaz (Canton of Vaud, Switzerland) uses an earth-grab made by M. F. MARTI, of Berne, for constructing drainage canals. The earth-grab is worked by a movable steam crane. The grab is let down into the ground, into which it is driven by its own weight; the completeness of the filling depends on the nature of the ground. The steam engine then draws up the grab by means of the crane cable until the pawls on the grab engage in an automatic opening device. The grab is then let down; it opens but remains suspended by the pawls engaged in the release. When opened and emptied it is lifted slightly; the pawls release automatically and the grab can be let down again. The earth is emptied on the side of the canal for, while the crane is lifting the grab up, the machine is turned to the right or left. The grab runs along rails, which are moved forward as the work continues. The height of fall depends on the height at which the opening device can be attached to the arm of the crane.

A machine similar to that described is being used for making embankments at Eau-Froide (Canton of Vaud); the contract price is 1 franc per cubic metre; the earth-grab can dig and load 150 cubic metres a day. At

(1) See *R.*, May, 1918 No. 561. (Ed.)

Bioley-Orjulaz, the contractor receives the same price for work done with the machine or by hand.

1026 - **Machines Used for Harvesting Cereals in the Argentine.** — FERRÉ, J. A., in *Ministerio de Agricultura de la Nación, Dirección General de Enseñanza e Investigaciones Agrícolas, Sección Escuelas Prácticas y Viveros*, pp. 1-103 + 100 Figs. Buenos Aires, 1917.

An illustrated description of the working parts of mowers, reapers, binders, simple headers ("espigadoras"), binders-headers, etc.

In the Argentine the most commonly used makes are: the McCORMICK, DEERING, JOHNSTON, OSBORNE and CHAMPION reapers, usually cutting a 65 or 71 in. swathe; the McCORMICK, DEERING, JOHNSTON, OSBORNE and "Acme" binders, cutting 59 to 95 in.; the McCORMICK, DEERING, JOHNSTON, W. WOOD, CHAMPION headers, usually cutting 142 in.; the "La Golondrina", McCORMICK, OSBORNE, "Acme", DEERING and JOHNSTON binder-headers, cutting 142 in.; the DEERING, CRESCENT, "La Golondrina", "La Australiana" combined headers and threshers, those most used cutting 71 in., 82 in., 95 in., and requiring a team of 8 horses. By changing horses the full width of the machines can be used, thus doing 12.35 and 18.5 acres per day of 10 hours' actual work.

1027 - **The Chiesa Drier with Multiple Recipients.** — TARCHETTI, A., in *Il Giornale di Riscoltura* (Organo Mensile della R. Stazione Sperimentale di Riscoltura e delle Colture Irrigue, Vercelli), Year VIII, No. 4, pp. 54-58 + 2 Figs. Vercelli, April 30, 1918.

The author describes a new type of drier for rice and maize, made by C. CHIESA, of Milan, and sold under the name of "Automatic drier with multiple recipients". It includes 2 or more recipients, generally all of one size; the yield of the machine depends on the number of recipients. In the movable type described in the present article, there are 2 recipients; in the fixed type there are 3 or more. These machines can be worked by hand or by power.

The build of the new drier is the same as the old CHIESA type or like the ordinary type with vertical chambers or cells. In the new type, however, 2 or more machines of the old type are placed one above the other and provided with shorter vertical chambers.

In the movable type, there are 2 rows of chambers, or two superimposed recipients supported by a strong wooden frame. Under each recipient there is a horizontal, oscillating tray that carries the rice from one recipient to another placed underneath; under the last there is an inclined plane over which the grain passes into a hopper and fills the sacks.

The recipients are rectangular (13 ft. long by 3 ft. 3 in. wide and 8 in. deep) and divided into 24 cells.

The warm air from the stove passes into the recipients, whence a fan distributes it in the cells filled with grain, through which it passes into the open air. As the grain passes from the upper recipient into the lower one it is mixed, thus exposing it uniformly to the warm air. In the new drier the warm air passes vertically through the grain to escape at the

surface of the recipient ; on the contrary, in the old types, the air passes horizontally through the thickness of the cell.

According to the maker, the machine produces 59 cwt. of dry rice and 88.6 cwt. of dry maize per 24 hours, with a consumption of 1 H.P. per recipient ; thus the movable 2 recipient type inspected by the author produces 118.1 and 177.1 cwt., with a consumption of 2 H.P.

1028 - **The Use of Potato-Drying Plant in Rhodesia.** — NOBBS, E. A. (Director of Agriculture), in *The Rhodesia Agricultural Journal*, Vol. XV, No. 2, pp. 126-135 + 2 Tables. Salisbury, Rhodesia, April, 1918.

Considering the possibilities of exporting Rhodesian potatoes to England and owing to the impossibility of sending fresh potatoes such long distances, the author advises that they should be dried and to that end describes two British systems together with the plant necessary. The first system, that of JAMES MILNE & Son. Ltd., Milton House Works, Edinburgh, who have supplied a number of potato-drying plants to the Food Production Department in England, consists in steam-cooking the washed potatoes and passing them, by a rough crushing process, over a special type of drying machine. They are washed in a canal, about 2 ft. wide, 2 ft. deep and about 100 ft. long, with a fall of less than 1 %. A good flow of water enters with the potatoes and removes most of the sand and dirt. At the end of the canal is a grating through which the dirty water and sand escape, and the potatoes shoot down into a rotary washer with a horizontal shaft. This vat has 4 partitions with holes in each through which the potatoes pass, and revolving arms agitate them constantly in their transit from end to end of the machine. The washing is perfect and the potatoes leaving this machine are taken up a slope elevator and conveyor which distributes to hoppers over the cookers and drying machines. The cookers are arranged in duplicate over each drying machine. As the cooked potatoes emerge from the steaming vessels they are roughly crushed between small rollers, and then pass between 2 much larger steam-heated cylinders, which run practically in contact one with another ; the film adhering to each cylinder dries in the course of about  $\frac{1}{2}$  revolution, and is removed by sharp knives. The drying cylinders are worked at a pressure of about 80 to 90 lb. per sq. in., and require a very special mixture of iron to be sufficiently hard and yet strong enough to resist the pressure. The flake from the drying machines is milled and sifted to remove the peel, which commands a good price as a cattle feed. The cost of the plant when installed depends on the number of machines : — £1 500, £1 800, £2 200, £2 500 for 1, 2, 3, 4 machines respectively.

The yields depend on the content of dry matter ; with 15 % of dry matter in a season of 25 weeks of 60 hours each the yields for 1, 2, 3, 4 machines are 135, 270, 405, 540 tons of flour respectively and 34, 68, 102, 136 tons of peel respectively ; with 25 % of dry matter for the same season the yields of 1, 2, 3, 4, machines are 225, 450, 675, 900 tons of flour respectively and 56, 113, 170, 226 tons of peel respectively.

Figures are also given showing the cost of working 1, 2, 3 or 4 machines, which varies according to the cost of fuel, etc.

The second system, that of Messrs. L. LUMLY & Co., Ltd., the Minories, London, consists in evaporating the water of the potatoes in their "Invicta" fruit and vegetable dryer and evaporator, which is made in 5 sizes. It consists of a furnace for heating air which passes through an inclined chest or frame filled with trays on which are laid the potatoes, fruit or vegetables to be treated. The greatest heat is concentrated upon a tray when it first enters the machine, and each tray subsequently introduced pushes the previous one into a lower temperature. The circulation of the hot, dry air ensures rapid desiccation of the outside, so that colour and flavour are unimpaired. By this process thin-sliced potatoes can be rapidly changed into a hard, light, dry form which will keep and bear freight to distant points for further manufacture or consumption.

Beside these systems the author says there are many others, duly protected by patents, such as those of H. G. BENJAMIN, New York, and the ALLIANCE VEGETABLE Co., Ltd., London.

1029 - **New Applications of Artificial Cold.**—FICHET, A., in *Le Génie Civil*, Year XXXVIII, Vol. LXXXII, No. 22, pp. 396-399 + 9 Figs. Paris, June 1, 1918.

Owing to present-day needs the application of cold to industrial purposes has much increased, especially in the way of constructing cold-storage motor-vans and small cold-storage vehicles for the use of the armies in the field, for preserving vaccines, serums, meat, perishable food-stuffs, and, recently, the construction of new types of cold-storage trucks that are an improvement over those previously used. These different applications of cold have been made possible by the use of the AUDRIFFEN-SINGRÜN refrigerator which is absolutely automatic, not requiring a mechanic to attend to it, as the machinery is enclosed in a hermetically sealed case.

This refrigerator consists of two hollow metal balls joined by a shaft whose end bears a pulley serving to give a rotatory movement. One ball acts as a freezer, the other as a condenser. These are placed on two tanks, one containing water and the other a non-freezing brine. When the apparatus is rotated the brine tank cools down while the water is warmed in the other tank owing to the compression. A stream of cold water is therefore necessary, as with all freezing machines, to maintain a suitable temperature in the condensing tank.

The ordinary freezing agents — ammonia, sulphurous anhydride, methyl chloride, etc. — can be used. A detailed description of how the machine works is given, the principle being that of most refrigerators: — liquefaction of a gas by compression and cooling and evaporation of the liquid thus obtained by decompression. Owing to its extreme simplicity the machine has been used by various of the French Ministries, especially for the production of pure ice near front-line hospitals, for troops in the field in the colonies, for preserving serums and vaccines, and for cold-storage transportation. The author describes all these applications in detail. The A-S refrigerator has been adopted by the American Army Transport Commission in France for the refrigerator waggons which are to be built, on account of its simple construction, which allows it to be

left alone indefinitely without any fear of it going wrong or deteriorating. In the refrigerator waggons a small room is cut off from the length of the waggon by means of an interior wall. In this room a refrigerator of 3 000 "frigories-heure" (1) is installed with a pump and a small fan. The driving power is provided from the waggon axle. A governor prevents the speed exceeding a certain point which can be adjusted as required.

Six large brine pipes are fixed on the roof of the waggon of sufficient capacity to provide for refrigerating the waggon in case of a 12-hour stop. The fan distributes the air to assure a uniform temperature in all parts of the waggon.

The floor, roof and walls are insulated against heat by a covering of wood fibre and compressed cork slabs. To avoid too great changes of temperature, a thermostat acts on the salt pump, limiting its action when the temperature descends below  $+3^{\circ}\text{C}$ . A 10-ton waggon can carry some 8 800 lb. of goods. These waggons will be used for carrying meat and fruit from the south of France.

## RURAL ECONOMICS.

1031 - Farm Management and Farm Profits on Irrigated Land in the Provo Area (Utah Lake Valley), U. S. A. — CONNOR, L. G., in the *U. S. Department of Agriculture Bulletin* No. 582 (Office of Farm Management), pp. 1-40. Washington, D. C.; January 7, 1918.

The farm-management survey discussed in this bulletin was made in 1914. The object of the survey was to determine, approximately, the profits that farmers receive in the irrigated area of the intermountain region.

The 104 farms studied were divided into the following classes: — 1) owners; 2) owners renting additional land; 3) tenants.

The 75 records from farm owners were divided into three groups, as shown in Table I. The first group represents fruit and sugar-beet or truck farms, no one of which is as large as 27 acres, and most of them much smaller. The chief cash crops are fruit, beets and truck, other crops being quite unimportant on these small units.

The second group comprises those farms of more than 27 acres in size, but on which practically the same crops are grown as on those in the first class. Productive live stock (usually stock other than work animals) is of but minor importance in either division. The farmers operating more than 27 acres derive a greater proportion of their crop receipts from grain, hay, and sugar beets than from fruit. Considerably more than half of the total receipts comes from the sale of crops in both of these groups.

The third group comprises the live-stock farms from which records were secured. Practically half of the total receipts on these farms comes from the sale of stock and animal products, while only a little more than half of the total receipts comes from the sale of crops. The most important cash crop is the sugar beet, and fruit is a minor consideration if present.

TABLE I. — *Average area, capital, receipts, expenses, farm income, and labour income on 75 farms operated by their owners (Utah Lake Valley).*

Item	Group I (26 small farms)	Group II (29 fruit and beet farms)	Group III (20 livestock farms)	All farms
Size of farms . . . . . Acres	16.48	77.20	106.65	63.99
Tillable area per farm . . . . . »	15.04	56.64	68.06	45.26
Crop area per farm . . . . . »	13.34	46.05	47.81	35.18
Capital . . . . . Dollars	6 142	13 337	16 507	11 688

Table II presents the results from 22 farms where the operator owns an area which he deems too small for profitable farm management and rents additional land. This method of operation is becoming more and more general in this region as elsewhere, with the rise in land values. It represents a step midway between tenant and owner, and is very effective in enabling men with limited capital to increase their labour income with but a small increase in their investment. The first group in Table II, with but three-fifths as much capital as the small owners in Table I (\$3 597 as against \$6 142), made considerably more labour income (\$398 as against \$ 350). They raised but little fruit, devoting a large part of their crop area to sugar beets. The size of farm and the crop area is a little larger than in group I, Table I.

TABLE II. — *Average area, capital, receipts, expenses, farm income, and labour income on 22 farms operated by owners renting additional land (Utah Lake Valley).*

Item	Group I (8 small farms)	Group II (14 general farms)	All farms
Size of farm . . . . . acres	20.03	113.25	79.35
Farm area owned . . . . . »	8.03	89.18	59.67
Additional area rented . . . . . »	12.00	24.07	19.68
Tillable area per farm . . . . . »	18.59	47.62	37.07
Crop area per farm . . . . . »	17.00	43.70	33.99
Capital . . . . . \$	3 597	8 041	6 425
Receipts . . . . . \$	1 026	2 197	1 770
Expenses . . . . . \$	448	1 095	859
Farm income . . . . . \$	578	1 102	911
Labour income . . . . . \$	398	700	590

The second division in Table II comprises 14 farms comparable to those of the same group in Table I. With less than two-thirds as much

capital, they make practically one-fifth more labour income than the larger owners operating fruit and general farms.

The last group in Table II shows the results for all the farmers renting land in addition to the area owned.

These farms are compared with the last group in Table I which presents the average for all farms operated by their owners. The average tillable and crop area in the two classes under discussion is a proper measure of size.

On somewhat smaller farms, and with a little over half as much capital as the average owner, the farmers renting additional land made an average labour income of \$ 590, or nearly six-sevenths as much as that of the straight owners (\$ 728). The greater proportion of live-stock on farms run by owners accentuates the difference in labour income in their favour.

The average labour income of all the owners and owners with additional land rented is \$ 697. The average capital is \$ 10 096. This compares favourably with returns from a similar size of business in other parts of the country.

Table III presents the average of all the dairy farms included in the survey. Not all are operated by owners, there being two tenant farms included and two which are operated by owners with additional land rented. These are handled statistically as though run by straight owners, the operators being charged with the landlord's expenses, credited with

the corresponding receipts and interest on the landlord's investment deducted from the farm income to secure the labour income.

Table IV presents the results secured from 7 farms operated by tenants. The tenants made a labour income of \$ 1 012, and the landlords 5.79 % on their investment.

*Renting compared with buying.* — From the preceding tables it seems very clear that the farmer with limited capital should rent rather than buy land in this area. The prevailing rate of interest on farm mortgages is 8 % (1914). The average owner of the 22 renting additional land had the use of \$4 447 in real estate belonging to the landlords, and paid only 4.5 % for it (\$ 182). The tenants paid less than 6 % on the average, but with only \$ 1 100 owned capital they made labour incomes much larger than the farmers in Table II or in the first two groups in Table I.

*Distribution of receipts.* — Table V shows the percentage distribution of farm receipts under the different headings (crops, stock, stock products, miscellaneous including outside labour, and increase of inventory less decrease) as well as the percentage distribution of crop receipts and of expenses.

*Work horses.* — The data concerning the number of work horses per farm and the crop acres per horse are presented in Table VI. The small farms have 1.94 work horses and only 7.32 acres of crops per horse. This shows a relatively low efficiency of the farm draft. With the total cost of keeping a horse a year ranging from \$ 70 to \$100, the inefficient use of farm draft on small farms represents an appreciable reduction of the labour income unless the horses can be used in idle periods at outside work. The average charge per crop acre for horse labour would therefore range between approximately \$ 6.40 and \$ 9.

TABLE VI. — *Number of work horses and crop area per horse (Utah Lake Valley).*

Farm group	Number of farms	Number of work horses	Crop area per horse acres
Small farms. . . . .	34	1.94	7.32
General and fruit farms . . . .	49	3.71	12.14
Live stock farms . . . . .	21	4.60	11.30
Total or average . . . . .	104	3.31	10.98

*The farmer's labour and the influence of outside labour on labour income.* — An estimate was obtained from each farmer on the values of the work done by him for that year. The average of all these estimates was \$ 429, which is considerably higher than the average labour income earned by the small owner, or small owner with additional land rented. The actual wages paid to dependable men by the year were frequently

higher than the estimates of the farmers as to the value of their own year's work. These wages usually range (1914) from \$ 420 to \$ 480 per year.

The importance of outside labour in increasing the labour income of the small operators is shown in Table VII. The size of business on these small Utah farms is comparable with farms very much larger in area in non-irrigated sections. The intensive type of farming followed on irrigated land calls for a labour supply commensurate with the size of business, but the operator and his family are often confronted with slack periods of considerable duration during the crop growing season, because the farms are not large enough to permit a widespread adoption of enterprises which would call for labour in the idle periods. The small farmers in the Provo area took advantage of these periods of farms inactivity to earn large additions to their farm receipts. An interurban trolley line built into Provo created a much greater demand for man and team labour than ordinarily exists in this section. These receipts from outside labour increased the labour incomes by more than 50 % in the case of the small owners and small owners with additional land rented.

TABLE VII. — *Importance of outside labour in increasing income on small farms (Utah Lake Valley).*

Item	Group I (15 small farms with 20 % or more of receipts coming from outside labour)	Group II (26 small farms (owners) showing amount of receipts from outside labour)	Group III (8 small farms (owners) with additional land rented showing receipts from outside labour)	Group IV (29 large fruit farms and beet farms (owners) showing receipts from outside labour)

*Results by type of farming as well as by size.* — In the preceding tables the various data and the returns for work done have been presented by size of farm. In Table VIII they are presented by type of farming followed. All the farms were tabulated which could be used in the six classifications of (1) small fruit, (2) small general, (3) large fruit, (4) large general, (5) dairy and (6) poultry farms. In arriving at the amount of labour used the value of extra labour hired was all reduced to a man-time basis at \$ 2 per day, the regular daily wage. When members of the farm family worked the value of their labour (above their board) was reduced to man time at the prevailing rate of wages for hands hired by the month.

These results show that the type of farming followed, as well as the size of business, is an important determining factor in the net return to the large orchardist, while in the case of the general farmers size of business is the chief factor in their net returns. The size of business in an important factor in the large net return on the dairy farms, but the type of farming appears of equal importance. Most of the labour used on these farms works longer hours than on the other types and the labour is performed on enterprises all of which give good returns.

In connection with the study of the type of farming as presented in

Table VIII, it is particularly interesting to analyse the data presented in Table IX in which the labour requirements of the important crops grown on these farms are presented in detail, with special reference to extra days of man labour which are given in the footnotes. By consulting these two tables a good idea can be secured not only of the farm business as a whole but also of the demands on the time of the operator in producing the different crops.

The figures in the above table include extra labour, mainly at harvest times, which in all cases, even when done by children, is reduced to the equivalent of man time. This extra labour is as follows:—

(1) Extra day man labour, 22.68 in third column; 0.2 in other columns.

(2) " " " " 34.50 in column 4; 0.50 " " "

(3) " " " " 20 in column 5; 1.34 " " "

- (4) Extra days horse labour, 3 (hauling).
- (5) Extra days man labour 17 in column 5; 2.28 in other columns.
- (6) " " " " 8 in column 4 and 5; 2 in other columns.
- (7) " " " " 8 in column 5; 1.50 in other columns.
- (8) " " " " 0.75 evenly distributed at each cutting.
- (9) Total extra days man labour 0.77.
- (10) Total extra days horse labour 0.2 (planting).
- (11) Total extra days man labour 0.80 (at harvesting and thrashing).
- (12) Extra days man labour 22.50 (picking by boys and girls).
- (13) Extra days horse labour 18 in columns 4 and 5 (picking mainly women and children); in other columns 1.25.
- (14) Extra days man labour 2 (digging) in column 5; 0.9 in other columns.
- (15) Extra days man labour 13.60 (digging) in column 5 (harvest mainly children); 5.33 in other columns, of which 4 are used in weeding before Sept 1 (done by boys).
- (16) Extra days horse labour 2.67 (hauling).
- (17) Extra days man labour, 5 in column 5 (harvesting), 1.07 in other columns includes thinning about June 1 (done by boys).
- (18) Extra days horse labour, 3.75 (hauling beets).

The factors which apparently control the income of the farmers in the area surveyed, according to the data presented in the previous tables seem to warrant the conclusion that the greatest need of the small farmers in this district is more land to work, and that diversification, also when needed, is not nearly as important as an increase in size of farm. A market crop which is more certain than fruit, particularly sugar beet, should be the proper diversification for the increased farm.

A further increase in the number of very small farms in this region seems to be unwise. About 30 acres seems to be the smallest size for efficient management without much reliance on live stock. Forty to fifty, preferably fifty acres, seems to be the smallest unit for efficient management where live stock enterprises are given a prominent place by the typical farmer. This is specially true for dairying.

The general farms which grow truck and fruit as secondary enterprises approximate the ideal cropping combination for this region.

1032 - **The Economic Results of the Overhead Irrigation of Strawberries in Illinois, U. S. A.** — ADRIAN, J., in *System on the Farm*, Vol. II, No. 4, pp. 134-135 + 1 Plate. Chicago, April, 1918.

In 1916, after having grown strawberries for 12 years without irrigation, the author installed an overhead irrigation system (1). The cost of installation was \$ 1 200 for 6 acres, or \$ 200 per acre. The water is derived from the municipal supply, and is charged for per cubic foot, the yearly cost of irrigation amounting to \$ 60 for the 6 acres. The average amount of water required for the whole area is 1400 000 gallons a year. The irrigation pipes are placed in parallel lines 50 feet apart. This distance allows the water from two parallel pipes to meet in the middle.

All the field, with the exception of 1 acre of autumn fruit, is planted

(1) See B. 1912, Nos. 486 and 627; B. 1914, No. 1090; B. 1915, Nos. 95 and 1330; R. 1917, Nos. 408 and 708. (Ed.)

with spring fruit, but, in time, the author intends to grow the autumn variety exclusively because of the greater profit obtained from it.

During 12 years the average receipts from strawberry growing without irrigation were \$ 188.56 per acre, and the average profits \$ 125.54. With overhead irrigation the average receipts per acre were \$ 542.86, and the average profits \$ 362.00.

## AGRICULTURAL INDUSTRIES.

### INDUSTRIES DEPENDING ON PLANT PRODUCTS

1033 - **A New Method for Determining the Watering of Wine** (1). — PRATOLONGO, U., in *Le Stazioni sperimentali agrarie italiane*, Vol. LI, Pt. 1-2, pp. 56-60. Modena, 1918.

The problem of diagnosing the watering of wine has not yet been satisfactorily solved, but, according to the author, it is not only possible to show watering, but, under certain conditions, easy.

The method reported in 1912 by Prof. PAGNOTTA is based on the fact that natural wine forms a saturated solution of mono-potassic tartrate and calcium tartrate. If the wine to be tested is saturated with mono-potassic tartrate and the difference between the tartrate dissolved and the added tartrate and residue determined, it should be possible to calculate the amount of water added. The author made a series of investigations into the solubility of mono-potassic tartrate and calcium tartrate in hydro-alcoholic solutions, with respect to the temperature, and content in alcohol and tartaric acid, considered as variables. He also investigated the influence on the solubility of these two salts of the chemical treatments and changes to which wine may be subjected.

The results of his study led him to believe that it is possible to show with certainty the watering of wine even with quantities as small as 5 to 10 %. It is, moreover, possible to show the presence of other prohibited matter, such as, for example, sulphuric acid, even if the amount is too small to be detected by other analytical methods. The method is not only qualitative, but also quantitative when the water added varies from 5 to 20 %. The author proposes to study the influence of changes which wine undergoes during ageing and through diseases. The method does not permit the detection of water added to the must.

The method may be outlined as follows:— The wine to be tested is saturated with mono-potassic tartrate and calcium tartrate separately, the contact of the two salts in excess being kept at a temperature of from 50-60° C. for half an hour. The excess of mono-potassic tartrate and calcium tartrate dissolved is allowed to settle by cooling, and, in the wine thus saturated, the following points are determined:— 1) the difference in the amount of mono-potassic tartrate dissolved and the two comparative acidometric determinations made with non-saturated wine and wine saturated with mono-potassic tartrate; 2) the amount of calcium tartrate dissolved, with the determination by weight of the total calcium in the wine before and after saturation.

1034 — **The Influence of the Vegetable Function of Yeast on the Yield of Alcohol; a New Interpretation of Fermenting Power.** — LINDET, L., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 22, pp. 910-913. Paris, June 3, 1918.

In a previous paper (1) the author had shown that, during alcoholic fermentation, yeast splits up the sugar it destroys into two parts: — 1) that part corresponding to the formation of the cells, to the production of glycerine, succinic acid, and carbonic acid corresponding to the respiration of these cells, etc.; this part he called "fermentation residue" but now calls "vegetable function part"; 2) that part which gives rise to the alcohol and carbonic acid corresponding to the breaking-up of the sugar (GAY-LUSSAC's formula), which is the "zymatic function part".

The results are given of new experiments in which yeast was subjected to anaerobic conditions. The influence of the food value of broth, that of the sugar concentration, of the more or less plasmolysed globules, and of the temperature of fermentation were studied.

The less yeast there is, the longer does fermentation last; the higher the proportion of sugar consumed by the vegetable function, the lower the yield in alcohol. In the experiments lowering the temperature had more influence on the duration of fermentation than on the reduction in weight of the yeast. This also holds good when the amount of yeast is increased. When a certain limit (1 in 1000 of dry yeast) is exceeded, fermentation is very rapid, but the maintenance and respiration of an excessive number of cells causes too great a consumption of sugar for the vegetable function. The origin of the yeast does not appear to influence the yield.

The fermenting power must be considered to lie in the two functions of the yeast; the amount of sugar consumed by a yeast unit for its vegetable life should be called *vegetable power*, that consumed to accomplish its zymatic function should be called *zymase power*; the total of these two represents PASTEUR'S fermenting power. In the experiments these two powers proved higher in proportion as the yeast gathered was less and fermentation continued longer. This prolongation of vegetable life, accumulating more residue, formed a larger quantity of zymase.

If these two powers, especially the vegetable power, are compared with a unit of time (24 hours), it is seen that, except when lowering the temperature hinders respiration, the weight of sugar yeast utilises to form a given weight of yeast in a given time, is practically the same under the various conditions of the experiment.

1035 — **Decortication of Wheat Previous to Milling.** — LINDET, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 19, pp. 569-573. Paris, May 29, 1918.

The attention of the Ministry of Agriculture and Food Supply has been drawn to a method by which wheat may be decorticated previous to milling so that only the kernel remains to be ground. The wheat is moistened with a small quantity of water in an Archimedian screw which conducts it to the decorticator, composed of two plates with radiating grooves.

(1) See R. Dec., 1917, No. 1218. (Ed.)

One of these plates is fixed ; the other revolves in front of the first at the rate of 300 revolutions.

A commission was appointed to examine this method and the author (professor at the " Institut National Agronomique "), who was a member of it, gives the results of the experiment.

All the results were negative. The apparatus removed only the pericarp, leaving the other three coats (seminal tegument, hyaline layer and protein cells) which are the most important. The wheat thus decorticated gave less flour, and even less bran, than the control wheat, the loss being about 2.49 % instead of 1.10 %, the normal figure. The bran of the wheat treated by the new process contained more adhering flour, the flour less gluten, and the bread made from it was brown and tasted of bran, *i. e.*, had the taste of all bread made with wet wheat. The skins which come from the apparatus as paste are not saleable.

The author concludes that this method and all others based on the same principle can give no satisfactory result.

1036 - **Oil of *Pistacia Lentiscus*** — *The Cyprus Agricultural Journal*, Vol. XIII, Pt. 2, pp. 28-29. Nicosia, April, 1918.

In Cyprus an edible oil (shinia oil) is extracted from the fruit of *Pistacia Lentiscus*, a plant which grows wild throughout the island. Although the consumption of this oil has increased greatly of late years its preparation only constitutes a small industry of the poor classes, who manufacture it for domestic use, and but little for commerce. The yield is about 18 %. Owing to the primitive methods of preparation it rarely keeps more than three months without turning rancid.

1037 - **Experiments on the Biological Saponification of Various Fats from the French Colonies.** — HENR, F., in the *Bulletin de l'Office colonial*, Year XI, No. 124, pp. 227-231. Melun, April, 1918.

The biological saponification of fats causes them to break up into fatty acids and glycerine under the influence of a special soluble ferment. The soluble saponifying ferments must occur in all oily seeds at the time of their germination; their action alone allows the embryo to utilise, after saponification, the oil reserves of the seed. Indeed, at the moment of germination of various fatty seeds it has been possible to determine a more or less considerable increase in the amount of free fatty acids. This breaking-up (hydrolysis) of the fat normally occurs *in vivo*; for some unknown reason it is difficult to reproduce it *in vitro*.

The soluble ferment of the castor oil seed is the only one it has been possible to isolate and make act on a certain number of fats to cause saponification. Very pure products (fatty acids and glycerine) were obtained, and the method has been adopted commercially.

The Department for the study of colonial products has studied the fats capable of being split-up and treated with castor oil ferment without having to be subjected to the different operations required for aqueous acid or alkaline saponification. The only fats on which castor oil ferment had any notable action under the experimental conditions adopted, were

oil of cotton, tea, the pericarp of aouara, the kernel of aouara, *Funtumia elastica*, *Carapa microcarpa*, *Sorindeia olessa*, and *Chrysophyllum congoense*. The fermentation action was negligible for the other fats examined, and before and after the action the proportions of acidity were either very similar or identical.

As a rule the proportion of acids formed is fairly low, and, with the exception of *Carapa microcarpa*, is rarely above the 80 or 90 % which has sometimes been found in saponification with castor oil. This may be due to the relatively high temperature at which the fermentation tests were carried out — 37 to 38°C., when the optimum temperature is about 30°. This higher temperature was indispensable to maintain the fat in the liquid condition essential to the normal progress of fermentation.

The initial acidity of the oils of the pericarp of aouara and *Chrysophyllum congoense* seems to show them to contain a saponifying ferment. The subsequent commercial utilisation of the ferments contained in the various oily seeds calls for a long series of successive studies.

1038 — **The Utilisation of Paddy in Italy at the Present Day** (1). — NOVELLI, N., in *Il Giornale di Riscicoltura*, Year VIII, No. 4, pp. 49-52. Vercelli, April 30, 1918.

Before the war paddy supplied in Italy numerous commercial varieties of rice representing as many different stages of the preparation of rice often in connection with the variety of paddy. There were varieties "mercantile" (commercial), "raffinato" (bleached), "camolino" (polished), "oleato" (polished with oil), "brillato" or "francesino" or "diamante" (coated) etc. (2). The forms representing the last stages of preparation were originally intended for exportation (which exceeded  $\frac{2}{5}$  of the production) for which rice which would keep during voyages and in hot countries was indispensable. Later they were used for local consumption, either because Italians preferred them to other varieties, or because dealers, by polishing, could better hide certain natural defects.

As is known, complete polishing reduces the yield of rice by as much as 50 % in some cases, and deprives the seed of the outer layers which are the richest in fats, albuminoids and phosphorus. In order to obtain the highest possible yield and the best food value from rice the "Commissariato generale dei Consumi" (General Food Commissariat) therefore ordered the standardisation of the different types of prepared rice, so that at the present time only one type is produced. This is neither polished with oil nor scoured and represents the commercial type, which follows on rice which is merely husked ("sbramato"). A slight percentage of small or pointed seed ("mezzagrana") is also left in this rice. The proposal to reduce the preparation of rice to the husked type has been given up because it always contains numerous silicious fragments derived from the husk and is more difficult to keep. About  $\frac{4}{5}$  of the total number of the different varieties of rice grown in Italy are of Asiatic origin, very resistant to disease, and very productive. For this very reason they have a longer vegetative period and consequently are not always entirely physiologically ripe, with the result

(1) See also *R.*, August 1918, No. 906. — (2) For these terms see *R.* October, 1917, No. 933. (*Ed.*)

that their seeds are richer in moisture. Such rice when simply husked will not, therefore, keep long.

From a point of view of their keeping qualities husked Italian rices are not equal to husked Hindoo rices, which are perfectly ripe physiologically and naturally dry. On the other hand they contain about 20% of seed with glumes which lessen fermentation but make it necessary to re-treat the imported rices to remove these glumes.

About  $\frac{4}{5}$  of the rice requisitioned in Italy at the present time gives a yield of 67 to 70 %. The small or pointed seeds ("mezzegrane"), broken rice mixed with weed seeds ("risetto") and broken rice ("pistino") are ground into flour for bread; the coarse flour ("farinaccio") is used for bread-making and the residue, sometimes mixed with that of various products, is used for preparing dressing for fabrics. The residue containing fragments too adulterated with seeds of weeds is sold to breweries, and the residue of decorticated rice ("pula") is used as a food for cattle. Investigations into the best methods of utilising the residue of decortication for the making of bread and other foodstuffs are now in progress.

1039 - **Drying Vegetables.** — VERMOREL, in *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. IV, No. 20, p. 613. Paris, June 5, 1918.

The author emphasises the importance of the problem of drying vegetables; and points out that the temperature in nearly all the methods adopted is from 70 to 80°C. To avoid coagulation of the albuminoids the temperature should not exceed 40 to 42°C., or the dried vegetables become so hard that they are unfit for consumption.

1040 - **"Gelso-lino" (Mulberry Flax), in Italy.** — SANSONE, A., in the *Bollettino dell'Associazione dell'Industria laniera italiana*, Year XXXII, No. 5, pp. 52-54. Biella, May 31, 1918.

Some 50 years ago a small manufactory was founded in Bergamo for making strong, resistant paper, imitating the Chinese and Japanese varieties, and using mulberry fibre; the factory, however, did not last long. Besides this the author recalls work done in his manufactory at Vittorio Veneto (Province of Treviso) by PASQUALIS, who found a method for isolating mulberry fibre, which he called "gelso-lino", for use in spinning and weaving. The author describes his full scale experiments carried out in 1906 at the works of the "Unione Concimi e Prodotti Chimici" at Bovisà, near Milan. These experiments showed that the most practical method for separating the fibre in the mulberry branches (loppings) was as follows:—Soak the branches in pools or ditches (not necessary if wood is green); crush the retted or green branches with a heavy roller on a cement, wood or tiled floor; collect the bark thus separated; crush the wet bark mechanically to separate the epidermis, which is easily powdered; sieve in a metal mesh cylinder, the fibre remaining inside, the impurities passing through the meshes; bleach with alkalies and acids, and then with a hypochlorite solution. The author carried out these experiments with the idea of finding whether mulberry fibre could be used as a cheaper substitute for jute for making sacking. Owing to the low price of jute at that time, the results were negative. However, mulberry fibre, freed

from its gummy matter and bleached, can give products of much greater value than jute. At Vittorio Veneto, PASQUALIS made pure "gelso-lino" textiles. The author advises that it should be treated to obtain more even fibres, although they are shorter, then carded; the longest fibres should be mixed with cotton, spinning wool, or hat felt while the shortest should be used as a water-absorbent. "Gelso-lino" alone or mixed with wool or cotton dyes perfectly. Two-shade effects can be obtained in the mixed tissues by means of the acid-dyes used for wool. The short fibre can be used in paper-making to strengthen paper made with inferior material. The yield of bleached fibre is from 10 to 20 % of the dry bark, *i.e.*, 2 to 5 % of the weight of branches treated.

The author points out that there are from 100 to 150 million mulberry trees in Italy. If each tree gives loppings with 100 to 150 gm. of fibre, an annual production of 15 million kg. of "gelso-lino" would be possible. The system of growing mulberry trees high, common in Italy, is not the best for fibre production. To obtain the long, uniform branches best suited for the industry, the mulberry should be grown with a low trunk as in the method usual in Japan but rare in Italy.

1041 - **The Manufacture of Paper Pulp from Dead Leaves.** — BRAMSON, K., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLVI, No. 21, pp. 853-854. Paris, May 27, 1918.

Each year in France there are from 35 to 40 million metric tons of dead leaves. To meet the country's paper requirement only 4 million tons would be necessary, which would, moreover, yield 2 million tons of useful by-products. It is easy to collect the leaves, and as they may be utilised throughout the year it is not necessary to store them. They could be transported in compressed form, but it would be better to instal works on the outskirts of the large forests where the raw material could be collected as required.

The process for making paper pulp from leaves is simple, rapid, and inexpensive. The leaves are crushed and then divided into two parts — the *veins* and *powder* (the blade falls into powder after crushing). The veins form the raw material for the pulp; they are steeped in lye for a short time, then washed and bleached, and the pulp is made.

The powder may be used as a fuel. It may be compressed into bricks with or without coal dust. Dry distillation is, however, preferable. By this method is obtained a relatively pure (porous) fuel, rich in calories (6 500 to 7 000), and easily agglomerated. At the same time are obtained a tar (which has all the properties of Norwegian tar), acetone, and pyroligneous acid. The powder may also be used as a food for cattle for, as the fibrous parts of the leaf have been removed, the assimilable, nutritive parts remain. The food value of this powder is almost equal to that of hay. Mixed with compressed molasses it given a cake as good as that of hay.

The yield of 1 000 lb. of leaves is: — 1) 250 lb. of paper pulp; 2) 200 lb. of pure fuel (or 500 lb. of food powder); 3) 30 lb. of tar, 1 lb. of pyroligneous acid, 0.6 lb. of acetone.

1042 - **The Cotton Mill Industry of the World.** — *The Indian Textile Journal*, Vol. XXVII, No. 319, p. 221. Bombay, April, 1917.

The consumption of cotton in the various countries of the world and the number of spindles in active use during the years 1901 and 1916 are given in the following table: —

	Cotton consumption Bales of 500 pounds gross Season of 1915-1916	Cotton spindles	
		1901	1916
United Kingdom . . . . .	4 120 000	46 400 000	56 400 000
United States . . . . .	7 325 000	20 800 000	33 000 000
Germany . . . . .	800 000	8 140 000	11 750 000
Russia . . . . .	2 070 000	7 900 000	9 100 000
France . . . . .	1 025 000	5 700 000	7 300 000
India . . . . .	2 040 000	5 000 000	6 850 000
Italy . . . . .	900 000	2 000 000	5 000 000
Austria-Hungary . . . . .	390 000	3 500 000	4 050 000
Spain . . . . .	400 000	1 800 000	3 200 000
Japan . . . . .	1 670 000	1 250 000	2 900 000
Brazil . . . . .	325 000	400 000	1 500 000
Switzerland . . . . .	90 000	1 300 000	1 500 000
China . . . . .	2 525 000	200 000	1 250 000
Belgium . . . . .	20 000	920 000	1 100 000
Canada . . . . .	225 000	600 000	975 000
Scandinavia . . . . .	169 000	400 000	850 000
Mexico . . . . .	85 000	300 000	550 000
Holland . . . . .	100 000	335 000	545 000
Portugal . . . . .	60 000	230 000	480 000
Other countries . . . . .	161 000	220 000	585 000
Total . . . . .	24 500 000	107 395 000	149 785 000

1043 - **The Carbonisation and Distillation of Peat, Wood-shavings, Household Waste and Other Light Organic Products.** — GALAINE, C. and HOULBERT, C., in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLVI, No. 21, pp. 854-856. Paris, May 27, 1918.

Even when after the war coal-mining again becomes normal in all countries, the peat industry will have a great future before it because this product is less important as fuel than for the distillation of the peat itself or of the "tourbon" (1) as a substitute for wood in the manufacture of acetic acid, methyl alcohol, ammonia and tar, which forms the basis of so many colouring matters.

With very dense matter, such as coal, small, rectangular, elliptical, relatively narrow retorts can be used, but for peat, or light products, it is

(1) "Mr. Eckenberg of London has shown that peat heated under pressure at a temperature above 150°C. loses its gelatinous consistency and can be easily dried by compression. For purely technical reasons it has not hitherto been possible to apply ECKENBERG's method industrially. Nevertheless the product obtained therefrom has very interesting properties; it is no longer peat, but a new substance to which we give the name "tourbon". (GALAINE-LE NORMAND and HOULBERT, Sur l'exploitation économique des tourbes de Châteauneuf-sur-Rance (Ille-et-Vilaine), in *Comptes rendus des Séances de l'Académie des Sciences*, Vol. CLXV, No. 10, p. 337. Paris, Sept. 3, 1917). (Ed.)

necessary to use a large retort which will allow a more easy transmission of the heat from the periphery towards the centre. From their experiments the authors concluded that the best results were obtained with a revolving retort. They describe their apparatus which is constructed on the principle of roasters for organic matter (coffee, cacao, chicory, etc.), and is fitted with a recipient for collecting the distillation gases. The apparatus has three characteristic peculiarities:— 1) revolving retorts which successively bring the substances to be carbonised into contact with the heated wall; 2) perfectly continuous working; 3) easy emptying and charging with fractional separation of the distillation products.

The apparatus may also be used for the carbonisation and distillation of wood, lignite, saw-mill waste, household waste, and all more or less completely dry organic residues.

1044 — **The Four Essential Factors in the Production of Milk of Low Bacterial Content.** — AYERS, S. H., COOK, L. B. and CLEMMER, P. W. (Dairy Division of the U. S. Department of Agriculture), in the *U. S. Department of Agriculture, Bulletin* No. 642, pp. 61 + 28 Tables + 23 Figures + 6 Plates + Bibliography of 47 Publications. Washington, April, 1918.

INDUSTRIES  
DEPENDENT  
ON ANIMAL  
PRODUCTS

This paper is a new contribution to the hygienic factors influencing the bacterial content of milk. The authors wished to confirm once more the necessity of observing the well-known sanitary rules (1) by supporting them by indisputable scientific data. They made several bacterial counts of milk taken under the following conditions: — 1) sterilised utensils; 2) clean cows with clean udders and teats; 3) small-top pail.

The following data taken from the numerous tables given in the bulletin show the degree to which the cleanliness of milk is to be attributed to the observation of these principles.

1) **STERILISED UTENSILS.** — This is the factor with the greatest influence on the bacterial content of milk. Counts made from 60 samples of milk showed an average of 6 306 bacteria per cc. when the utensils were sterilised and 73 308 when they were not sterilised; the difference (67 002 bacteria) can, thus, only be attributed to the sterilisation of the utensils.

2) **WASHING THE UDDER AND TEATS.** — When the animals and barn were kept clean the bacterial counts per cc. of 65 milk samples gave the following figures:— 1) *udder and teats washed*, minimum 620 bacteria, maximum 5 400, average 2 154; 2) *udder and teats unwashed*, minimum 10 050, maximum 20 400, average 4 524.

3) **SMALL-TOP PAIL.** — The small top pail is of the ordinary type with a fixed top leaving only a small semi-circular opening near the edge. Throughout the experiment milk taken in this pail always had a much lower bacterial content than that taken in an ordinary open milking-pail whatever the other conditions were. The maximum number of bacteria per cc. in the first case was 750 000, in the second, 1 200 000.

In order the better to control their results the authors combined the various factors in different ways. Data on the contamination of milk by faeces are also given.

(1) See *R.*, May, 1917, Nos. 483 and 485. — *R.* January, 1918, No. 71. (*Ed.*)

Finally, the *effect of temperature* on the bacterial content of milk was observed. Counts were made of fresh milk kept at 4.4°, 10°, and 15.5° C. and 21.1° C. for 24 hours and 4 days. At the end of 96 hours the figures for the bacterial growth in all the samples tended to resemble each other. The optimum temperature is 10° C. or less.

The authors believe the three factors considered and the keeping of the milk at a temperature near 10° C to be the most essential conditions for the production of fresh milk with a low bacterial content, and that too much attention has often been given to other, less important factors. Moreover, these conditions may easily be observed, even in medium-sized dairies.

1045 - **The Enzymes of Milk and Butter.** — THATCHER, R. W. (Minnesota Agricultural Experiment Station) and DAHLBERG, A. C. (Wisconsin Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. XI, No 9, pp. 437-450 + Bibliography of 27 Publications. Washington, November, 1917.

The deterioration of butter during storage is often attributed to the enzymes in the buttermilk which it contains. Most investigations into the matter give little information as they chiefly deal with the chemical changes in the butter itself during storage and not its enzyme content. The following types of enzymes have been reported to be normally present in cow's milk: — an amylase, a lipase, proteases, a peroxidase, salolase, catalase, reductase, a lactose-fermenting enzyme. These results are not always in agreement.

During the summer of 1915, DAHLBERG prepared several lots of butter under carefully controlled conditions of manufacture and placed them in storage, in order to study the effect of varying methods of manufacture. He also studied the bacterial development in these butters (1). Thus excellent material was ready for a study of the enzyme content of the butter after storage, and such a study was undertaken by the authors, the results being given below.

**RESULTS.** — Proteolysis in skim milk was completely inhibited by 1 % of chloroform and by 15 % of sodium chloride. Galactase (the normal proteolytic enzyme of milk, which aids in the slow decomposition of milk proteins into peptones, amino acids and ammonia) cannot act in normal butter because of the high salt content.

In the separation of milk the factors which increased the percentage of casein in the total nitrogen also increased the galactase content. The ripening of cream did not increase the rate of proteolysis. No oxidase was found in milk or butter. Only one sample of butter out of 8 gave any evidence of lipase at the end of 4 days at 40° C. The enzyme content of butter is very small, because of the high dilution in fat. Expressed on the basis of total nitrogen the butter examined contained as much galactase as fresh whole milk, twice as much catalase, but only one hundred and sixtieth as much peroxidase. The cold storage of butter weakens the per-

(1) See WASHBURN, R. M. and DAHLBERG, A. C., The Influence of Salt on the Changes taking place in Storage Butter, *Journal of Dairy Science*, Vol. II, No. 2, pp. 114-126, 1917 (Ed.).

oxidases, but has little effect on the catalase and galactase. Enzymes are present in butter in such small amounts and under such unfavourable conditions for enzyme activity during cold storage that they need not be considered as a factor in the deterioration of butter during storage.

1046 — **The Deterioration of Condensed Milk; Estimation of its Acidity.** — DUGARDIN, M., in *Annales de Chimie Analytique*, Vol. XXIII, No. 4, pp. 83-84 + 1 Table. Paris, April, 1918.

The present large demand for condensed milk has resulted in its being manufactured with increasing rapidity. If, however, sterilisation is imperfect the milk easily undergoes a fermentation which makes it unfit for consumption. To determine this deterioration it is sufficient to estimate the acidity.

The author estimated the acidity in several samples of condensed milk of different brands. The method used was as follows: — 10 gm. of the sample are diluted in 25 cc. of tepid, distilled water (from which the  $\text{CO}_2$  has been previously removed by boiling); titration with a decinormal solution of caustic soda, using phenolphthalein as an indicator; the acidity is expressed as lactic acid per 100 gm. of matter. The results showed that the normal acidity for sweetened unskimmed milks and for sweetened skimmed milks does not exceed 0.5 gm. An acidity between 0.5 and 0.75 gm. shows a deteriorated milk. Milk with an acidity above 0.75 gm. is unfit for consumption. In this last case the boxes bulge out very much, and the contents are violently expelled when they are opened. Unsweetened milks become clotted and are difficult to dissolve in water. Sweetened milks are solid and give off a disagreeable smell.

1047 — **Bacterial Precipitins and the Detection of *Bact. botulinus* in Preserved Foods by the Thermo-Precipitation Method.** — BORNAND, M. (University of Lausanne and the Cantonal Laboratory of the Sanitary Service), in *Travaux de chimie alimentaire et d'hygiène publiés par le Service suisse de l'hygiène publique*, Vol. IX, Pt. 2 and 3, pp. 87-98. Berne, 1918.

The author reviews the work on *precipitins*, first observed in 1897 by KRAUS, who found that a typhus or cholera anti-serum in the presence of the filtrate of a homologous culture causes a precipitate. As the precipitation reaction was nearly always specific, work on the precipitins has given rise to their being put to various uses: — 1) particularly in the analysis of foodstuffs anti-serums have been prepared for identifying eggs and milk in products said to contain them; 2) in the control of meats and the determination of their nature, e. g., CLARKE (*Bull. Pasteur*, p. 731, 1914) was able to prove that meat sold in an hotel as bear's meat was in reality meat of a deer, the hunting of which was prohibited; 3) in medical diagnosis: — parasitical diseases (echinococcosis, Leishmaniosis, dourine, etc.); bacterial diseases (glanders, cerebro-spinal meningitis, human and bovine tuberculosis, etc.).

ASCOLI METHOD. — ASCOLI and VALENTI discovered that bacterial precipitogens are very resistant to heat and adapted this knowledge to a new method for the diagnosis of bacterial infections called by them the *thermo-precipitin* method; e. g., in the diagnosis of anthrax a few grams of the ma-

terial believed to be infected are placed with the physiological solution in a test tube which is left from 3 to 5 minutes in a boiling water bath. After cooling and filtering the clear liquid is placed in contact with the precipitating serum, and if the material examined is infected, a white ring is formed at the point of contact of the two liquids. Putrefaction, which impedes the search for the bacterium in direct examination, has no action in this case; thus the precipitation reaction was still positive for an infected cow, the dead body of which had been buried at a depth of about 6  $\frac{1}{2}$  feet for 45 days and had been sprayed with paraffin, and also for organs kept in alcohol for 4 months.

Control experiments showed the reaction to be specific. The ASCOLI method the value of which is recognised, has been used for the diagnosis of swine plague, tuberculosis, Malta fever, paratyphous infections, etc.

DETECTION OF *B. botulinus* IN PRESERVED FOODS. — The author wished to determine if the immunisation of a rabbit with extracts of *Bact. botulinus* would make it possible to obtain a precipitating anti-serum for this organism, and if it could be detected in preserved food by thermoprecipitation. He immunised a rabbit by sub-cutaneous inoculations in both thighs made at intervals of 3 or 4 days with extracts of a culture of the bacterium. Eight days after the last injection the animal was bled, part of the serum filtered and the other preserved with toluene. A precipitating anti-serum specific for this bacterium at ordinary temperature was thus obtained.

Taking advantage of the thermo-stability of the precipitogen the author attempted to identify the presence of the organism in question in artificially infected preserved foods: — 3 boxes of braised beef, 1 box of herrings and 1 box of peas. At the end of 5 months the lids of all the boxes except that of peas bulged considerably. When opened gases with a butyric smell were given off. A microscopical examination and cultures made from the contents of the boxes showed the presence of *Bact. botulinus*. Five grams of the contents were then treated in physiological solution by the ASCOLI method. (The filtered anti-serum has a weaker precipitating action than that kept in toluene). The results of the reactions thus produced at room temperature may be summarised as follows:— anti-serum + extract of *Bact. botulinus* culture gave a precipitate after 30 minutes; anti-serum + extract of normal preserved braised beef, no precipitation; anti-serum + extract of infected preserved braised beef and infected preserved herrings, precipitation after 60 minutes; anti-serum + extract of preserved peas, no precipitation.

It is seen that the reaction is negative with preserved vegetables (peas).

CONCLUSIONS. — 1) By injecting rabbits subcutaneously with extracts of a culture of *Bact. botulinus*, a precipitating anti-serum of this bacterium may be obtained.

2) The presence of *Bact. botulinus* may be detected in preserved meat by the ASCOLI method as a result of the thermo-stability of the precipitogen of this bacterium.

## PLANT DISEASES

### DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

1048 - **Researches on Apple-Spot Diseases.** — BROOKS, C. and FISHER, D. F. (Bureau of Plant Industry, U. S. Department of Agriculture), in *The Journal of Agricultural Research*, Vol. XII, No. 3, pp. 109-137 + 10 Figs. + 4 Plates + Bibliography of 22 Publications. Washington, January 21, 1918.

GENERAL

The present paper deals with the effects of soil-water supply upon bitter-pit, Jonathan-spot and certain other non-parasitic spot diseases of the apple (*Malus sylvestris*). It also includes notes upon the relation of the time of picking to the development of apple-spots in storage. The authors' summary of the results is given below.

1) Bitter-pit and Jonathan-spot are to be distinguished from rosy-aphis stigmonose, drouthspot, cork, blister. Bitter-pit usually appears first as spots of dead, brown tissue in the sub-epidermal portion of the apple. These spots are associated with the terminal branches of the vascular bundles and in later stages of the disease the browning often follows the vasculars deep into the flesh of the apple. Rosy-aphis stigmonose is characterised by similar brown spots in the sub-epidermal region but the affected tissue is firmer than in the case of bitter-pit and there is no association with the vascular bundles. The early stages of Jonathan-spot are confined to the colour-bearing cells of the skin of the apple. Drouthspot is characterised by the checking of the growth at certain points on the apple without the production of any large quantity of corky tissue; fairly large areas of dead brown tissue usually occur near the surface of the apple, but sometimes are to be found deeper in the flesh; the spots are usually located in the blossom half of the fruit, which appears to be more susceptible after it is some one-third grown. Cork differs from the drouthspot in the presence of comparatively large spots of brown corky tissue, and in the fact that these are usually rather deeply seated in the flesh of the apple. Blister is a superficial lesion associated with cork and characterised by its blister-like appearance.

2) Drouthspot was produced by sudden and extreme drouth. It occurred on trees that were favourably located as well as on those that were growing under rather unfavourable soil conditions. Cork is apparently also a drouth effect, but it differs from drouthspot in the fact that its occurrence is usually associated with certain peculiar soil types.

3) Experiments have shown that there is a close relationship between

the soil-water supply of the orchard and the development of bitter-pit in storage. Heavy irrigation greatly increased the disease, but not so much as medium irrigation followed by heavy irrigation. Light irrigation greatly reduced it, but heavy irrigation followed by light resulted in the lowest percentage of the disease. Sudden changes in the amount of soil-water apparently did not increase the disease.

4) Heavy irrigation may have been slightly favourable to the development of Jonathan-spot, but the contrasts were too slight to justify definite conclusions.

5) Large apples showed greater susceptibility to bitter-pit than small ones, but with Jonathan apples heavy irrigation increased the disease on the medium-sized fruit as well as on the large, and with Grimes the percentage of increase from heavy irrigation was even greater on small apples than on large ones. Apparently, large apples are not susceptible to bitter-pit merely because they are large, but rather because of certain conditions under which they become large.

6) In 1915 there was more Jonathan-spot on the large apples than on the small ones, but in 1916 there seemed to be no correlation between size of fruit and severity of disease.

7) During the first weeks of cellar storage more Jonathan-spot developed on apples that were picked early than on apples that were picked late, but with longer periods of storage these contrasts seemed to largely disappear. The results indicate, however, a greater susceptibility in the early-picked fruit.

8) Bitter-pit was worse on the Jonathan apples that were picked early than on those that were picked late.

1049 — *The Injurious Action of Magnesium Carbonate on Plants.* — Sec No. 969 of this Review.

## DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

### GENERAL

1050 — *The Morphology and Biology of **Blepharospora cambivora**, an Agent of the "Ink Disease" of the Chestnut* (1). — PETRI, L., in the *Annali del R. Istituto superiore forestale nazionale*, Vol. III, pp. 3-34 of the Reprint + 8 Figs + 1 Plate. Florence, 1918.

The mycelium that kills the cambium and which constitutes the specific agent (*Blepharospora cambivora* Petri) of the disease should be classed with the order *Saprolegniineae* of Schröter. It is characterised by an abundant development of multicellular hyphae on dead organic matter as well as by the formation of lemonshaped, isolated, terminal sporangia that produce zoospores or non-motile spores. The formation of spheroidal oospores with smooth walls takes place in the terminal oogonia fertilised by the filamentous antheridia.

The spores germinate in the water of the soil humus of the chestnut

(1) See R., March, 1918, No. 361 (*Ed.*)

[1048-1050]

wood or in that of streams into which the mycelium may be washed. In artificial culture the spores were germinated in drinking water or in very dilute solutions of nutritive mineral salts. Up to the present the formation of oospores has only been observed in the infected tissues of young, germinating plants. The presence of soluble carbohydrates and nitrogenous compounds hinders the formation of sporangia, while it favours the purely vegetative growth of the mycelium. The presence of calcium oxide not only inhibits the formation of spores, but also hinders the growth of the mycelium.

The dissemination of the parasite in the same chestnut wood or over a relatively limited area is chiefly due to rain water running over the ground and into the brooks.

The mycelium and the motile and non-motile spores cannot resist drying.

Dissemination by the wind only takes place in the case of the oospores. Chestnut woods should, therefore, be very closely watched, as it is chiefly from them that the durable germs of the parasite spread in large numbers and to a great distance. Infection does not take place through the direct attack of the germination tube of the spore, but always after the mycelium produced by a spore has developed saprophytically in contact with the receptive organ.

Artificial infection tests have shown that the parasite may attack germinating young plants as well as subjects of all ages, but only in the subterranean organs or in the basal portion of the stem. The great ease with which the disease was reproduced artificially shows that the effect of eventual conditions favouring receptivity can rightly be considered as negligible in the etiological study of the disease.

A damp and mild winter and spring constitute the principal conditions favouring the appearance of the disease, given that they are essential factors for the development of the parasite.

The parasitication of *Bleph. cambivora* can be considered as specific, as the fungus has been found to be unable to attack other Cupuliferae.

1051 — The Resistance of Manitoba Wheat to Fungous Diseases (1). — SCHRIEBAUX, in the *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. IV, No. 17, pp. 530-532. Paris, 1918.

In the spring of 1917, "Manitoba" and "Aurore" wheats were sown at the Grignon School of Agriculture by the side of "Japhet", "Bon Fermier" and "Saumur de printemps" for the purpose of studying their comparative resistance to fungous diseases.

The results are interesting, showing the superiority as regards their resistance to smut of the alternative wheats (Japhet and Bon Fermier) over the spring wheats (Saumur de printemps and Aurore) which, before Manitoba was introduced, were usually grown at the School. Thus, for 3 smutted ears of Bon Fermier and 16 of Japhet, sown on March 16, 1917, there were no less than 74 for Saumur de printemps.

(1) See R., January 1918, No 34. (Ed.)

For the same wheat the number of smutted ears increases as the sowing date gets later. Thus Saumur de printemps, sown on March 16, gave 74 smutted ears and when sown in the same soil a month later, on April 14 gave 157 or more than double.

Manitoba is remarkably resistant to smut and to fungous diseases in general. In the experiments in question, not a single smutted ear was seen either in the plots sown early (March 16) or in those sown late (April 26).

The author concludes that Manitoba wheat will probably be of great value to plant breeders for the creation of new wheats resistant to fungous diseases.

MEANS  
OF PREVENTION  
AND CONTROL  
DISEASES  
OF VARIOUS  
CROPS

1052 — **Patents for the Control of Diseases and Pests of Plants.** — See No. 1030 of this Review.

1053 — **Cereal Mildew (*Sclerospora macrospora*) observed on Maize, in Piedmont (1), Italy.** — GABOTTO, L., in *Il Coltivatore*, Year LXIV, No. 16, pp. 331-333 + 3 Figs. Casale Monferrato, 1918.

In 1917, in a plot containing about 300 plants of maize, the author found about 60 plants attacked by *Sclerospora macrospora* Sacc. The diseased plants — with a weakly general appearance — had virescent male flowers and no ears.

The author advises that infected plants should be burnt to prevent the spread of the disease, and a watch kept for freshly diseased plants.

1054 — **Smuts Injurious to Sorghum in the Presidency of Bombay.** — KULKARNI, G. S. in the *Agricultural Research Institute, Pusa*, Bulletin No. 78, pp. 1-16 + 6 Plates, Calcutta 1918.

The word "Jowar", as used in the Bombay Presidency, indicates all the cultivated varieties of *Andropogon Sorghum* Brot. (= *Sorghum vulgare* Pers.), which takes the first place among cultivated crops in the Presidency. Jowar is so largely grown on account of its two-fold use as food and fodder.

The number of fungous diseases affecting this crop is large, but by far the most important of them from the economic point of view are those that cause the well-known smut disease. In the Bombay Presidency 4 smuts have been found attacking sorghum; these are:—

1) *Sphaelotheca Sorghi* (Link) Clinton, occurring throughout the Presidency; known as "grain smut";

2) *Sph. cruenta* (Külm) Pot., in the Sholapur district; known as "loose smut";

3) *Tolyposporium filiferum* Busse, in Sind; known as "long smut".

4) *Sorosporium Reilianum* (Külm) Mc Alpine, sporadically, throughout the Presidency; known as "whole-head smut".

The virulence and distribution of the disease seems to depend largely upon the freedom or otherwise from contamination of seed with spores previous to sowing. In general, localities with high rainfall have more smut

(1) See R., April 1917, No. 381; R., Sept. 1917, No. 872; R., April 1918, No. 477. (Ed.)

than those with low rainfall. It has also been found that the varieties of sorghum called Kharif (the monsoon crop, sown in June-July and harvested in October-November) are more attacked than those called Rabi (the winter crop, sown in September-October and harvested in February-March). However, loose smut (*Sph. cruenta*) is more common on the Rabi varieties in the Sholapur district.

The intensity of the damage caused by these smuts varies from year to year and even from field to field in the same locality. Thus the loss may be from 2 to 3 % for mild attacks up to 40 or 50 % for severe ones.

The deformation of the inflorescence resulting from the attack of each of the smuts is described as well as the characteristics and germination of the spores.

The author's observations confirm those of previous authors, which have shown that infection in the grain and loose smuts takes place at the seedling stage through the seed-borne spores.

As regards whole-head smut (*Sor. Reilianum*), the plant appears to be chiefly infected through the soil. In the long smut (*Tolyp. filiferum*) whose life-history is not known, it still remains to be ascertained whether infection takes place through the flower or through the spores in the soil from the previous crop.

The best preventive measure against *Sph. Sorghi* and *Sph. cruenta* is to treat the seed with copper sulphate solution, thus providing an easy, quick and cheap method. It was found that the seed can be dipped into a copper sulphate solution for 10 minutes, even at 3 % strength without in any way injuring their germinating power, and that even a  $\frac{1}{2}$  % solution acting for 10 minutes is successful in preventing the appearance of the two smuts in question.

No preventive measure against *Tolyp. filiferum* can be advised, as its complete life-history is not known.

The copper sulphate treatment is now widely advocated by the Bombay Agricultural Department and is practised by the cultivators. In order to meet the demands of the cultivators for copper sulphate, small packets of copper sulphate, worth an anna, have been prepared for some years. Each packet contains sufficient material for treating seed for 4 acres and includes instructions for use printed in all the vernaculars of the Presidency.

1055 - *Bacillus Solanacearum* Injurious to *Ricinus*, in U. S. A. (1). — SMITH, E. F. and GODFREY, G. H., in *Science*, New Series, Vol. XLVIII, No. 1228, pp. 42-43. Lancaster, Pa., July 12, 1918.

To the already considerable list of natural host plants of *Bacterium Solanacearum* (brown-rot of Solanaceæ) must now be added the castor oil plant (*Ricinus communis*), which has been seriously attacked by the fungus in various localities of Georgia and Florida.

The *Ricinus* plants wilt in various stages of growth, and often at an

(1) See R., August, 1912, No. 1238 and R., July, 1917, No. 680. (Ed.)

early one. Dwarfing is usually the first sign of the disease in the seedling plants.

By using a culture of the bacterium isolated from the castor oil plant the author was able to produce the disease in several plants known to be subject to *B. Solanacearum*.

Land on which any of the common Solanaceous plants have wilted should not be planted to *Ricinus*, unless it is known positively that the wilt was not of bacterial origin.

1056—**The Danger of Burying Felled Coconut Trees Between Rows of Rubber Trees in the Federated Malay States.**—SOOTH, F. W., in *The Agricultural Bulletin of the Federated Malay States*, Vol. VI, No. 6, p. 269. Kuala Lumpur, 1918.

Observations recently made on a large rubber estate have shown that the practice of burying felled coconut trees between rows of rubber trees, is very dangerous. The coconut trees, instead of being buried, must be split, dried and burned.

A part of the estate in question had originally been planted with coconuts. At a later date the coconuts were interplanted with rubber. About 3 or 4 years ago, the coconut trees were cut out and their trunks cut into lengths and buried in the middle of the spaces between the rows of rubber trees. In 1917 it was found that a large number of the rubber trees were dying or sickly. They were found to be suffering from root diseases, principally brown root disease, *Hymenochaete noxia*, and wet rot, *Poria hypolateritia*, either together or separately. In nearly every case it was found that a badly diseased and decaying root of each of the attacked trees ran back into one of the pits in which the coconuts had been buried. In some instances only the roots connecting with the pit had become diseased, and the disease had not reached the main root and collar. In such cases the infected roots were cut off and burnt, thus saving the trees. In other cases, however, the main root and collar were badly affected and the trees had to be taken out and burnt.

After this discovery all the pits were opened, and the decaying trunks were taken out, split up, dried and burnt. At the same time rubber roots in the pits were followed up and when diseased were removed and burnt. Indications of the presence of *Poria hypolateritia* were found on most of the decaying coconut trunks.

Heaps of dug-out coconut wood that had been drying for a few weeks also showed numerous fructifications of the fungus *Fomes lucidus*, a common saprophyte in the tropics that has been recorded as killing trees, which it attacks at the roots and collar.

It was evident that two of these fungi that were rotting the coconut trunks were *Hym. noxia* and *P. hypolateritia* and that these trunks were full of these fungi in an actively growing condition just about the time that the roots of the rubber trees had grown long enough to penetrate well into the mass of decaying material. It should be remembered that such decaying material contains moisture and that tree roots are definitely attracted by moisture.

1057 - **Diseases of Sugar-Cane in Tropical and Subtropical America, especially the West Indies.** — JOHNSTON, J. R. (in collaboration with ASHBY, S. F., BANCROFT, C. K., NOWELL, W., and STEVENSON, J. A.), in the *West Indian Bulletin*, Vol. XVI, No. 4, pp. 273-308 + 7 Plats. Bridgetown, 1918.

It has seemed desirable to publish, in brief form, and for the use of both investigators and planters, descriptions of common cane diseases and their causative fungi occurring in tropical and subtropical America.

The bulk of the data given in the paper was compiled by Mr. JOHNSTON when working on the subject during a residence of four years in Porto Rico, several years in Cuba and during studies in Santo Domingo and in the Southern United States, besides various visits to many parts of tropical America.

As it was considered specially desirable to make the records as complete, the cooperation of the following phytopathologists in the American Tropics was asked:— ASHBY (Jamaica), BANCROFT (British Guiana), NOWELL (West Indies), and STEVENSON (Porto Rico).

The description of the diseases is followed by notes on their prevention and cure (a whole chapter is devoted to the control of fungous diseases) and a long bibliography on the subject.

The following diseases are specially considered:—

- 1) *Bacterium vascularum* (gumming disease of sugar cane);
- 2) Humid gangrene or "Polvillo" a disease probably due to the above-mentioned bacterium;
- 3) *Trichosphaeria Sacchari*;
- 4) *Gnomonia Iliou* (stem rot or Iliou);
- 5) *Sphaerella Sacchari*;
- 6) *Eriosphaeria Sacchari* (red leaf spot);
- 7) *Leptosphaeria Sacchari*;
- 8) *Thyridaria tarda*;
- 9) *Nectria Laurentiana*;
- 10) *Ustilago Sacchari* (smut);
- 11) *Hypochnus Sacchari* (thread blight);
- 12) *Odontra saccharicola*;
- 13) *O. Sacchari*;
- 14) *Marasmius Sacchari* (root disease);
- 15) *M. stenophyllus* (root disease);
- 16) *Schizophyllum alneum*;
- 17) *Laternea columnata*;
- 18) *Cytospora Sacchari*;
- 19) *Coniothyrium melasporium* and *Darluka melaspora* = *Melanconium Sacchari* (rind fungus);
- 20) *Diplodia cacaoicola*;
- 21) *Colletotrichum falcatum*;
- 22) *Melanconium saccharinum*;
- 23) *Cephalosporium Sacchari* (wilt);
- 24) *Thielaviopsis paradoxa* (pine-apple disease);
- 25) *Cercospora longipes* (brown leaf-spot);

- 26) *C. vaginæ* (red spot of leaf sheath);
- 27) *C. Kopkei* (yellow leaf-spot);
- 28) *Helminthosporium Sacchari* (eye leaf-spot);
- 29) *Sclerotium Rolfsii* (red rot of leaf-sheath);
- 30) *Himantia stellifera*;
- 31) Yellow stripe disease;
- 32) Top rot;
- 33) Sereh;
- 34) Mottling disease;
- 35) Wither-tip;
- 36) Chlorosis.

1058 — *Cercospora solanicola* and *Cercospora* sp., Fungi respectively injurious to Tobacco and Sesame in the State of Pernambuco, Brazil. — AVERNA, S. R., in *Secretaria da Agricultura, Commercio e Obras Publicas do Estado de Sao Paulo, Boletim de Agricultura*, Series XIX, No. 1, pp. 70-71. Sao-Paulo, 1918.

Tobacco leaves from the School of Agriculture of Soccorro (Pernambuco) were found to be attacked by *Cercospora solanicola* Atk., a parasite already recorded in the State of Sao-Paulo, in 1913 and 1914 on some plants of *Nicotiana Tabacum*.

The disease is very serious as the numerous spots on the leaves render them almost worthless. The parasite usually attacks plants growing in damp, shady places. The various species and varieties of tobacco show varying degrees of resistance to the disease.

As anticyptogamic remedies, though efficacious, would sensibly affect the commercial value of the leaves, the author advises growers to limit themselves to the following measures:—

- 1) the choice of resistant species and varieties;
- 2) if the ground is too damp, it should be drained or used to grow other crops;
- 3) avoid planting too close so as to allow the free passage of air round the plants;
- 4) at the first sign of infection, all diseased leaves should be cut and burnt.

On the leaves of "gergelim" or sesame (*Sesamum indicum*), also from Soccorro, were found spots, which, from the microscopical examination were attributed to a *Cercospora*. The plants should be carefully watched and it is advisable, on the first signs of the disease, to uproot and burn the infected plants at once.

## INJURIOUS INSECTS AND OTHER LOWER ANIMALS.

### MEANS OF PREVENTION AND CONTROL

1059 — *Aphelinus boveili* n. sp. and *Metalaptus torquatus*, Hymenoptera Parasitic on other Insects. — MALENOTTI, E., in "*Redia*", Pt. 1 and 2, pp. 77-92 + 17 Figs. Florence, 1918.

With the discovery of *Aphelinus boveili* n. sp., 8 Chalcidids are now known as parasites of the scale insect *Chrysomphalus dictyospermi* Morg (1).

(1) See R., January, 1918, No. 118; R., July, 1918, No. 828. (Ed.)

The author examined 5 females from Bridgetown (Barbadoes), sent by Prof. J. R. BOVELL, to whom the present species is dedicated.

A description is also given of another chalcid, *Metalaptus torquatus*, Malen., which had already been mentioned in a previous note (1917). The description is based on: — 10 specimens hatched out on orange leaves placed under a bell-jar for the purpose of studying the parasites of *Chrys. dictyospermi*; 3 females and 1 male in material from Mandarano (province of Catania); and 2 females in material from Palermo. The author thinks, however, that this species is not a parasite of *Chrysomphalus*, as certain Psocidae and some very minute lepidopterous larvae were present of which, as with other species of *Mymaridae*, *Metaloptus torquatus* might prove to be a true parasite.

1906 — *Casca luzonica* n. sp., a Hymenopteron Endophagous on the Scale-Insect *Schizaspis lobata*, in the Philippines. — MALENOTTI, E., in "Redia", Vol. XIII, Pt. 1 and 2, pp. 73-76 + 6 Figs. Florence, 1918.

A description of the chalcidid fly *Casca luzonica* n. sp., an endophagous parasite of *Schizaspis lobata* Cockerell and Robinson, based on 2 females found by the author in specimens of that scale-insect on leaves of *Ficus nota*, sent to the Royal Station of Agricultural Entomology at Florence by Prof. C. F. BAKER, of Los Baños (Luçon Isle, Philippines). The male of the new hymenopteron is as yet unknown.

Although the hymenopteron had not pierced a great number of scales, yet appreciable damage was done.

1901 — The Use of Bats in the Control of Insects especially Tortricidae, Injurious to Pine Woods (1). — JOLYET, A., in the *Revue des Eaux et Forêts*, Year XVI, Vol. LVI, No. 6, pp. 121-216. Paris, June 1, 1918.

On account of the damage suffered by French forests on account of the war, the author considers the possibility of invasions of injurious insects. Among those attacking pine woods, he fears *Evotria* (*Retinia*) *resinella*, *E. bouliana* Schiff. (pine-shoot tortrix moth) and *E. turionana* Hb. (pine-bud tortrix) the most. As bats destroy great numbers of these insects, the author proposes to breed these most useful Chiroptera or, rather, to encourage them to come to live near pine woods requiring protection. To do this it is sufficient to erect cots in the midst of the pine wood to serve as refuge during the day and where the bats can winter without suffering from the severe cold.

The author has devised a cot consisting of a wooden box with double walls (leaving an air space of about 1 in.) of cubical form with sides 3 ft. 3 in. long. The box is protected from the rain by a double roof of planks covered with tarred paper and projecting beyond the sides.

The space thus left between the box and the roof should be filled with hay to keep out the cold. On the side of the box facing east an opening 12 in. high and 8 in. broad should be cut. A slide moving up and down grooves will serve to shut or open the door, through which the bats will enter

(1) For the use of bats for the destruction of mosquitoes, see R., August 1913, No. 903. (Ed.).

or leave the shelter. The slide should be so arranged that it can be opened and closed by pulling a string, as the box should be placed about 10 ft high on a wooden scaffold or on a small tower built of stones without mortar. Inside the box rods will serve as perches for the bats.

The author advises the choice of bats belonging to the family Vespertilionidae (gen. *Vesperugo*) which hibernate in barns, towers, hollow trees, rather than bats belonging to the genera *Rhinolophus*, *Synotis*, *Plecotus*, *Vespertilio*, which are sensitive to cold and hibernate and caves and underground places. The first mentioned stand the cold better, are hardier, and live more peaceably with other bats than the latter, and also take to the cots more easily. In the genus *Vesperugo*, the large *V. noctula* and *V. serotinus* are of special interest. These attain a length (without the tail) of 3.1 and 2.7 in. respectively, the spread of the wings being 14.1 and even 16.5 in. for the first and 12.9 in. for the second. *V. noctula*, so common, is particularly suitable on account of its size, its rapid, high flight and because it leaves its hiding place at night fall. The author also remarks upon *V. pipistrellus* (1.1 in. long; spread of wings 3.1 in.), a small species, but the commonest and easiest to adapt to a state of semi-domestication.

INSECTS, ETC.,  
INJURIOUS  
TO VARIOUS  
CROPS

1062 - The Alfalfa Looper (*Autographa californica*), Injurious to Various Cultivated Plants in Canada. — GIBSON, A., in *The Agricultural Gazette of Canada*, Vol. V, No. 2, pp. 132-136 + 2 Figs. Ottawa, February, 1918.

*Autographa californica* (the alfalfa looper) is widely distributed in western North America. In Canada it occurs in the provinces of British Columbia, Yukon, Alberta and Manitoba. Although there are no actual records of its presence in Saskatchewan, it undoubtedly occurs, also, in that province. In the United States it occurs in the states of California, Nevada, Colorado, Oregon, Wyoming, Washington, Idaho, Utah and Montana. It has also been collected in Alaska and it appears to be present in New York state. It has been known in the United States as a pest of economic importance since 1895. In Canada, however, it only become sufficiently numerous to cause serious injury to crops in 1914. During that year, the damage caused was confined to the province of British Columbia. A large number of crops — alfalfa, lettuce, clover, beans, apple trees (leaves and fruits), clover, turnips, cabbage, garden, peas, potatoes, rhododendrons, laurel, rose, holly, etc. — were attacked.

In the United States the insect has been found feeding on malva, barley, elder, dock, sweet clover, wild lettuce, flax, sugar-beet, maize, carrots, cucumbers, muskmelons, watermelons, squash, currants, gooseberries, raspberries, lamb's-quarters and sunflower.

In 1903, at Ottawa, the author reared an adult moth found feeding on lupin at Mt. Arrowsmith, Vancouver Island, B. C.

In 1914, natural enemies of the alfalfa looper were present in British Columbia to a marked extent. These natural checks were very widespread and efficient. From material received at Ottawa from various localities the following natural enemies were reared: — *Plagia americana* Van der

Wulp, a tachinid fly already known as a parasite of *A. californica*; *Exorista futilis* O. S., a new tachinid fly parasite of the moth; *Microplitis alaskensis* Ashm., a hymenopteron known as a parasite of the moth in the United States; the tachinid fly *Phorocera saundersii*; and the hymenoptera *Sargagitis wehsteri* Vier., *Rhogas autographae* Vier., *Microplitis* sp., *Amelotenus* sp., *Apanteles hyslopi* Vier.

In addition to these natural enemies, birds were observed to feed readily upon the larvae, which, in some localities, were also attacked by a bacterial disease.

Since 1914, there are no records, thanks to its natural enemies, of the insect occurring in destructive numbers.

Paris green or arsenate of lead will destroy the caterpillars if used strong enough, but when they are present in such enormous numbers, spraying with an arsenical mixture is a rather hopeless task. A mechanical means of protection would probably be advantageous, such as digging trenches across the line of march of the caterpillars.

The insect and its life-history are fully described

1063 — **The West Indian Mole Cricket (*Scapteriscus vicinus*), Injurious to Crops in Porto Rico.** — VAN ZWALUWENBURG, R. H., in the *Porto Rico Agricultural Experiment Station, Mayaguez, P. R., Bulletin*, No. 23, pp. 3-28 + 3 Plates + Bibliography. Washington, 1918.

The most serious insect pest of general agriculture in Porto Rico is the West Indian mole cricket (*Scapteriscus vicinus* Scudder) known locally as the "changa".

In economic literature this insect has always been treated under the specific name of *didactylus* (1) a name now given to a closely related species. *S. vicinus* is a native of South America and the West-Indies, but it does most damage in Porto Rico.

The changa feeds primarily on vegetables, animal food seeming to form only a small part of its diet. Almost any young plant growth is attacked. The insect remains underground and feeds from below, commonly selecting the crown of the plant as the point of attack. *S. vicinus* attacks tobacco, tomato, egg-plant, potato, pepper, sugar cane, grama grass (*Paspalum* sp.), yerba dulce (*Eleusine indica*), Bermuda grass (*Cynodon dactylon*), rice, cabbage, collard, rape, turnip, cantaloup, sweet potato, lettuce, *Coleus* spp. and *Livingstonea* spp. The insect also causes much damage by trimming roots that lie along its path.

The author describes the adult and deals with its life history. The life cycle covers about one year. About three weeks are required for the egg stage; about nine months for development from hatching to the adult stage; and over two months for the pre-oviposition period.

Although the changa has many natural enemies particularly among the native birds, it is not held in check by them. With the exception of a nematode, no parasitic enemies of the insect are known to occur in Porto Rico.

(1) See R., January 1916, No. 129 (Ed.)

During the autumn months the changa flies in large numbers on damp, overcast evenings. The greater proportion of changas attracted to lighted areas are females. Flooding is of value when water is easily available.

Napthaline and sulphur are the only repellants found to be of any value, and even they are only partially effective.

Sugar cane is protected from the changa by planting it in a perpendicular or slanting position. Hilling up plants greatly reduces changa injury in gardens.

The use of poison baits, together with clean cultivation of the area to be planted, is recommended. A dry mixture of 3 % Paris green with cheap flour is particularly acceptable to the changa.

1064 - *Trioza alacris*, a Hemipteron Injurious to Laurel in New Jersey, U. S. A.

— WEISS, H. B. and DICKERSON, R. T., in *Psyche*, Vol. XXV, N. 3, pp. 59-63. Boston, June, 1918.

*Trioza alacris* Flor (syn. *T. lauri* Targ.), which was introduced into New Jersey from Belgium and which is well known and destructive in Europe, had already been recorded by WEISS in 1917 as occurring in New Jersey.

This Psyllid occurs in New Jersey on bay trees which are kept either under glass all the year or out of doors during the summer. Its presence on the bay (*Laurus nobilis*) can be readily detected by the curled, discoloured, swollen, blistered leaves, usually at the tips of the branches, containing what appear to be whitish masses. Observations on the biology of the parasite were made on trees kept outside during the summer months. The author describes the eggs and then the five stages of the nymph, using alcoholic material. The description of the adult is quoted from CRAWFORD.

While contact insecticides are useful, it is impossible to reach the nymphs in the curled leaves. In New Jersey almost complete killing was secured in one case by fumigating with tobacco smoke as for aphids while the trees were in storage and heavily infested by over-wintering adults. Hydrocyanic acid gas has been used with success.

It is the practice of some firms to pick off all curled infested leaves, but this is a slow process in a large establishment.

1065 - *Papilio thoantiades*, a Macrolepidopteron Injurious to Citrus and the Hymenopteron *Pteromalus caridei*, its Natural Enemy, in the Argentine. —

CARIDE MASSINI, P. and BRÈTHES, J., in the *Anales de la Sociedad Rural Argentina*, Year, LIII, Vol. LII, No. 2, pp. 73-76 + 2 Coloured Plates. Buenos Ayres, 1918.

In Florida the macrolepidopteron *Papilio thoantiades* Burm. ("isoca de los naranjos") is one of the most dangerous pests of citrus plants (orange, lemon, etc.) whose leaves the pest attacks when in the larval state. Fortunately, the chalcidid *Pteromalus caridei* Brèthes, first described in 1913, attacks the pest, laying its eggs in the chrysalis of the lepidopteron. The chalcid also sometimes attacks the macrolepidopteron, which is its only host, in the larval stage.

From each chrysalis of *Papilio* emerge 80 to 100 individuals of *Pteromalus*. In one case 98 % of the chrysalids were attacked.

The hymenopterous can be easily transported and used in the control of *P. thoantiades*; in consequence the chalcid should be bred and protected in citrus-growing regions.

A detailed description of *P. thoantiades* and *P. caridei* is given.

1066 - A Tortricid Moth Injurious to the Chestnut Tree, in Italy.— DEL GUERCIO, G., in *L'Agricoltura Coloniale*, Year XII, First Half Year, No. 1, pp. 21-30 + 3 Figs, Florence, 1918.

In the chestnut woods on the Apennines between Emilia and Tuscany, after August has begun, one may see the soil covered to varying degrees, according to the year and the position, with very young chestnuts, still green or partly yellowed. On these chestnuts, hidden by a mass of excreta, is a round hole which is the opening of a tunnel leading into the cavity occupied by the growing achenes (chestnuts).

Inside these husks or in the chestnuts themselves, there are nearly always one or two larvae of different ages, which, according to the author, are the larval stage of a tortricid moth, probably *Carpocapsa splendana*.

According to the inhabitants of the region, the nuts begin to fall in September without, however, affecting the injurious action of the larvae. The presence of the larvae causes the nuts to open prematurely in the second half of September or even at the fall of the first chestnuts.

In October and the beginning of November, the chestnuts are more and more attacked by the larvae and when the drying of the chestnuts by fire is begun in the first half of November (in the high Modenese and Bolognese Apennine), a great number of larvae leave the chestnuts after 24-36 hours exposure to the heat.

Once the chestnuts are dried and freed from the pericarp, the worm-eaten nuts should be separated from the sound ones before grinding them to obtain the flour used for making "pattona" or "castagnaccio". These foods have often, however, a bitter, unpleasant taste. This is due to the fact that the farmer or proprietor does not separate the sound from the worm-eaten chestnuts in order to have a greater quantity of flour to sell. As a result of this the excreta and larval skins impart the bad qualities of the flour from diseased chestnuts to that from sound chestnuts. Such flour, unfit for human consumption, might be given to live stock, but sparingly, as it might cause various disorders if given in quantity. Moreover, chestnuts eaten by the larvae are not relished by live stock.

To restrain the ravages, the nuts that fall to the ground in August should either be collected and burnt, or buried deeply; they may also be thrown in the pits full of stagnant water which, in the Apennine districts, serve as a manure heap. The first chestnuts to fall must on no account be left lying on the ground and those that fall normally should be collected as soon as possible. When the chestnuts are dried, precautions should be taken that the larvae do not escape and seek shelter when, under the action of heat, they leave the chestnuts.

1067 - *Stictolobus trilineatus* n. sp., a Hemipteron (Homoptera) living on Cypress, in Louisiana, U. S. A. — FUNKHOUSER, W. D., in *Entomological News*, Vol. XXIX, No. 5, pp. 185-187 + 1 Plate. Philadelphia, 1918

The author gives the description of the Membracid *Stictolobus trilineatus* n. sp., found in comparative abundance on cypress at Bogaloussa' on June 15, 1917 and on the next day at Colyell, also on cypress.

This insect is the first membracid found on cypress and the second representative of the genus *Stictolobus* founded by METCALF in 1916 to accomodate *Membracis subulata* Say (= *Stict. subulatus* Say).

### Mechanical Ploughing.

#### Methods for Ploughing in Ridges.

by  
A. TARCHETTI

*Engineer in Charge of the Mechanical Department of the "R. Stazione Sperimentale  
di Riscoltura" of Vercelli, Italy.*

#### PLOUGHING IN RIDGES.

This is the most usual method of ploughing in Italian soils, especially for irrigated crops, and it is also that most suited to the great majority of motor- or tractor-ploughs imported from the United States, that is, ploughs turning the soil to one side only (with a single mould-board, right- or left-handed).

This system may be used with balance, turn-wrest and double-brabant ploughs when the open furrows separating the ridges are narrow and shallow. In this case, provided care is taken that the plough wheels do not fall into the open furrow, the ordinary method of ploughing without ridges (1) may be carried out, neglecting the open furrows (especially if a gang plough or, better still, cable traction is used), which will only be partially filled up, thus leaving a depression which will serve as a guide when the open furrow is reopened or put right with an ordinary plough.

(1) See Fig. 1, of the second article, *Methods of ploughing without ridges*, in *R.*, Sept., 1918, p. 1018.

But when the open furrows are large and deep and when the ground must be maintained perfectly level — as is the rule for the rice fields of upper Italy — ploughing without ridges does not allow of good work and, to preserve the ridges, it is necessary to resort to gathering up and casting.

• It should first be noted that, in ploughing without ridges, the drainage-furrows are left at the same place each year whilst with the second method (gathering-up and casting) the open furrows are displaced each time the

Fig. 1. — Displacement of the open furrows each time the ground is ploughed.

ground is ploughed : the furrows  $a, a_1, a_2, \dots$  (Fig. 1) are filled up on gathering-up and, on casting, an equal number of new open furrows corresponding to the median axes  $x, x_1, x_2, \dots$  of the ridges are opened, at the place where the summit of the ridges was previously. This fact, as will be seen later, has considerable influence on the method to be followed in ploughing.

Fig. 2. — The strip left unploughed by various machines.

Ploughing in ridges can also be carried out with balance, turn-wrest and double-brabant ploughs. In this case the half-ridge  $ax$  is ploughed, after which, leaving the half-ridge  $ax_1$ , the half-ridge  $a, x_1$  is ploughed, and so on, so as to plough all the half-ridges to the left of the open furrows. When the last but one half-ridge —  $a_{n-1}, x_{n-1}$  — is ploughed, the ploughs are *turned*, so that those that turned the soil to the right in going now turn to the left on the return, or viceversa, *i. e.*, the last half-ridge  $a_{n-1}, x_{n-1}$  is ploughed, then  $a_{n-2}, x_{n-2}$ , etc., up to the second,  $ax_2$ , which completes the work. But this method leads to loss of time and awkward turns (with cable anchorages, it is practically impossible), so that ploughing in ridges is reserved for machines with ploughs having but a single mould-board.

Before examining the method of procedure in each case it will be advisable to recall certain considerations.

In our (Italian) soils it is almost impossible to complete the mechanical ploughing of the ridges. Above all, the machines, especially with gang

ploughs, are unsuitable for opening the first furrows along the open furrow and, to make sure of the regularity of the following ploughing, it is always advisable to carry out the work first gathering-up the open furrows to the left and right with an ordinary plough. Again, the ordinary machines cannot finish the ploughing, or as the farmer says, cannot close it. In fact, if the three commonest types of machines in Italy (Fig. 2) are considered, it will be seen that each of them has to leave unploughed a more or less wide strip (12 to 39 in. and more) in every ridge, unless the wheels pass over the ground already ploughed, which would be detrimental. On the other hand it is very difficult to finish such a narrow strip, for the resistance of the soil is not equal for all the ploughs, so that they would slip sideways. On the contrary, with the stilt plough it is easier to correct the unavoidable irregularities of the strip and to open, exactly in the middle of the ridge, a straight furrow of uniform width.

In order that this strip may be ploughed as well, it is necessary that the machine should haul a gang of such a width that the total width ploughed is equal to or even greater than the distance between the driving wheels, which would give the mechanical advantage of displacing the centre of resistance towards the centre of power; but in our (Italian) soils, and in the case of direct haulage, the difficulties of gripping the soil are in opposition to this.

Thus, it should be reckoned that, for each ridge (Fig. 3), independently of its width  $L$ , a total width of from 39 to 63 in. cannot be ploughed mechanically in practice, so that with ridges only 10 to 13 ft. wide for example, about half the field would have to be ploughed with teams. As a result the width of  $L$  should be kept as large as possible, which gives the driver the extra advantage of avoiding too narrow turns and of enabling him to obtain, with the more continuous and uniform handling, more regular ploughing. It is hardly necessary to add that the width of the ridges should be such that the width  $A$  is a multiple of the width of the gang.

On the other hand, however, there are two considerations in opposition to the excessive increase of the width of the ridges; these are as follows:—

1) *The total journey with the ploughs lifted on the headlands at the head of the ridges is not proportional to the width of these latter, but, as Prof. RINGELMANN has justly remarked (1), increase in an arithmetical progression. In fact, let us take a machine ploughing a strip 47 in wide, and let us suppose for the sake of simplicity that the axis of the machine (generally the centre of power) coincides with the centre of that strip (that is, with the centre of resistance of the gang) and that the machine can*

Fig. 3. — Plan of ground to be ploughed with a team.

(1) See the *Journal d'Agriculture pratique*, 1917, p. 436.

"close" the ploughing completely. Let us consider what takes place on one-half of the headland at the head of the ridge: — as that is repeated on the other half of the same headland and on the two halves of the opposite headland, there will be 4 equal operations for each headland. If the ridge is, for example, 23 ft. 6 in. wide, or 11 ft. 9 in. for each half (Fig. 4), the machine will plough the half-ridge in 3 journeys, that is, in order to arrive at the first furrow (gathering-up) it would have to move a distance of

Fig. 4. — Ploughing a half-ridge, 11 ft. 9 in. wide, in 3 turns.

Fig. 5. — Ploughing a half-ridge, 23 ft. 6 in. wide, in 6 turns.

10 ft. on the chief headland, and then turn at right angles so as to begin the first furrow at *a*. When it returns on the same headland to begin the second furrow, it will have to move 5 ft. 11 in., and, finally, for the third furrow 2 ft. In the 3 journeys it has thus moved a distance of 17 ft. 8 in. on the edge of the field.

If the ridge is double-width ( $L = 47$  ft. 3 in.;  $L/2 = 23$  ft. 7 in.) the machine will plough the half-ridge in 6 journeys, but the various journeys (Fig. 5) will be respectively 20 ft. 10 in., 18 ft. 2 in., 13 ft. 9 in. . . . and the total distance travelled will be 70 ft. 10 in., that is to say not double, but *four* times the previous one.

The total distance travelled with the ploughs lifted along a half-headland is thus equal to the product of the average journey ( $L/4$ ) and the number of journeys, or, speaking algebraically, to the sum of the terms of an arithmetical progression whose first term is half the width of the strip ploughed (or of the gang), whilst the ratio or difference is that of the width itself (1).

(1) Prof. RINGELMANN considers the width of the gang or strip ploughed as the first term of the progression, and thus obtains, in his calculations, figures that are rather too high; on the contrary, however, we, on the assumption that the axis of the machine coincides with that of the gang, have obtained figures that are rather too low, but which we consider are nearer to practical conditions.

The result is that the time lost and fuel consumed on the journeys with the ploughs lifted are the greater as the ridge is wider, and it is with reason that Prof. RINGELMANN proposes a width of 98 feet (in practice not more than 66 ft.) as a maximum, also with the idea of avoiding excessive injury to the headlands by repeated passage of the machine.

2) The width of the ridges nearly always depends on the nature of the ground or crop, as well as on the form of the field (1).

On account of this necessity for width of the ridges, the ploughing has nearly always to be carried out in a special way, which is also necessary and *quite distinct for each case*.

If one uses a machine with a central gripping drum (GALARDI-PATUZZO type motorploughs) which can pivot on the drum itself, the width of the ridge has no influence, and the work can be carried out as with the ordinary stilt plough. In fact, in the case of a ridge limited by the open furrows

Fig. 6. Gathering-up a ridge.

Fig. 7. — Casting a ridge.

*aa bb* (Fig. 6) the work is begun at *A* in the direction of the arrow by gathering up the last furrow to the right, then passing to the other side of the last furrow, always gathering up to the right (if the plough throws to the right) and continuing in this way until, having arrived near the middle

(1) In the rice fields of the Vercelli region, ridges not more than 22 to 26 ft. wide are usually adopted so as to facilitate levelling and drying the ground and also as to *a*) be able to broadcast the seed in one journey; *b*) lose no time at the moment of scarifying in order to move the bunches of weeds gradually up to the longitudinal open-furrows; *c*) help in loading and carting the sheaves by allowing one of the cart wheels to run on the firmer bottom of the open furrows. In the rice fields of the Lomellina district, the ridges are still narrower, sometimes being less than 13 ft.; in such cases no attempt should be made to plough in ridges with machines with 2 driving wheels.

**XX** (where the strip to be finished with a team is shown wider), the machine passes at *B* to the last furrow *bb*, where the operation is repeated (1).

The ploughing may also be carried out as shown in Fig. 7, *i. e.*, casting instead of gathering up.

But if the machine, as often happens, is a tractor plough or a gang motorplough, which has to turn in a semi-circle with a well defined minimum radius (generally of 20 to 26 ft.), in this case and *according to the width of the ridges, the method to be followed must be decided upon clearly beforehand*, so that the work may be finished without requiring useless double turns and journeys with the ploughs lifted.

We add a few solutions of the commonest cases where, for the sake of simplicity, a series of only 3 gangs or furrow-slices are represented for each zone where the manœuvre is repeated.

Admitting that a strip equal to a half or whole ridge should be left in the field at the edge of the first and last furrows to enable the machine to pass to finish the headlands (2), the internal limit of that strip may be assumed to be the edge of the field; this is why the beginning and end of the ploughing, as has been already said previously, coincides in the following figures, now with an open furrow (solution A), now with the centre of the ridge (solution B).

In all the examples the ploughs are understood to turn the soil to the right, which is usually the case.

Case I. — *Ridges wider than 82 feet* (at least 2 are necessary). — It will be convenient to consider the ridge as divided into 4 zones or parts, each of which corresponds to a fresh manœuvre.

*Solution A* (Fig. 8). — Ploughing is begun at *A* by gathering up the open furrow *AB*; at *B*, the end of the furrow, the gang is lifted, and the machine turns to the left, and, at *D*, begins gathering up the second open furrow, up to *C*. There the gang is again lifted, the machine turns, always to the left, and the ploughs are earthed to the right of the first open furrow, and so on, going in the direction of the arrows, passing in turn from zone I to zone II, from zone II to zone III, from III to IV, etc., until, having turned the furrow of zone VIII nearest to the axis *xy* of the first ridge, the machine passes to the third ridge and begins ploughing the third and fourth ridges at *E*, as has been done for the first two turns. On the sides of the median axes *xy*, *x*, *y*, . . . the usual strip some 31 to 59 in. wide will remain to be ploughed with a team.

The narrowest turn (from 16 to 23 ft.) is only made in the first passage from zone VI to zone VII and corresponds to about  $\frac{1}{4}$  the width of the ridge.

(1) In this and the following figures, the journeys normal to the furrow slices are spaced for the sake of clearness, but it is obvious that in the field they are superimposed, the machine always travelling on the same line on the chief headland.

(2) See Fig. 1 of the second article, *Methods of ploughing without ridges*, in *R.*, September, 1918, p. 1018.

*Solution B* (Fig. 9). — Beginning at *B*, end near the axis  $X_2 Y_2$ . Two minimum turns — in the first passage from zone II to zone III and from zone VI to zone VII.

When the ridges are wider than 82 ft., the ploughing can be carried out in different ways; thus, for example, Figs. 10 and 11 show two variants,

*CASE I: Ridges wider than 82 feet.*

Fig. 8. — Solution A.

Fig. 9. — Solution B.

Fig. 10.

Variants of Solution A.

Fig. 11.

limited, for brevity, to solution A and showing only one furrow per zone. In both cases, the total journey with the ploughs lifted on the headlands is slighter more than in the case of Fig. 8; however, in the variant shown in Fig. 11, the minimum turns include half a ridge, that is, they can be carried out in the space of about 40 ft.

*Case II. — Ridges from 49 to 82 feet wide* (at least 3 are necessary). — In this and the following cases, the work is divided into two sections per ridge, that is, at the middle of the last furrow and vice-versa.

*Solution A* (Fig. 12). — There are 2 minimum turns (of 11 to 23 ft.) corresponding to about half the width of the ridge in the first passage from zone II to zone III and from zone IV to zone V.

Figure 13 represents a variant, drawn schematically like the previous ones and limited to solution A.

*Solution B* (Fig. 14). — Here also there are 2 minimum turns in the passage from zones II to III and IV to V.

As is shown in Fig. 14 the zones follow in the same order as in solution

*CASE II: Ridges from 40 to 82 feet wide.*

Fig. 12. — Solution A.

Fig. 14. — Solution B.

Fig. 13. — Variant of Solution A.

*A* (Fig. 12). This is why, in the following cases we have suppressed the graphic representation of solution B for the sake of brevity and we only indicate, by the dotted arrow, the beginning of ploughing.

*CASE III; Ridges from 20 to 49 feet wide.*

Fig. 15. — Solution A.

Fig. 16. — Variant of Solution A.

*Case III. — Ridges from 20 to 49 ft. wide (at least 4 are necessary). — Solution A* (Fig. 15). The minimum turns correspond to the width of a ridge; consequently, instead of first ploughing zones I and II completely,

then zones III and IV, etc., as is shown in Fig. 15, the machine can pass immediately, when each furrow is finished, from one ridge to another and finish the *cycle* of the 4 ridges furrow by furrow instead of zone by zone. Thus, after the first furrow to the right of *AB* and the second to the left of *FE* are opened, when the machine is at *E*, instead of returning to zone I, it moves to zone III, to the right of *GH*, then from *H* to zone IV, to the left of *DC*, and so on until the cycle to the right of *HG* is finished. When at *G*, the machine returns to zone I (as shown by the dotted line *mon*) and begins the second cycle at *n* and so on until the work is finished at *p* and the machine passes to the 4 following ridges. In Fig. 16 a variant of the usual procedure is shown.

CASE IV: *Ridges less than 19 ft. 6 in. wide.*

Fig. 17. — Solution A.

Fig. 18. — Variant of Solution A.

Case IV. — *Ridges less than 19 ft. 6 in. wide* (at least 6 are necessary). The same lettering is employed as in the previous case, but here the minimum turn includes the width of about 2 ridges.

*Solution A.* (Fig. 17) with a variant (Fig. 18).

With all the preceding solutions the field can be *completely* ploughed, provided (independently, of course, of the side and top headlands) that the field is divided into such a number of ridges as to form a multiple of the minimum number possible to complete each *cycle* of operations. Thus, in Case I, the ridges should be even numbers; in Case II, 3, 6, or 9, etc.; in Case III, 4, 8 or 12, etc.; in Case IV, 6, 12, or 18, etc.

But although the latitude allowed for the width of the ridge usually

allows the field to be subdivided as required, it is not always either possible or desirable to do so. On the other hand it must be admitted that all these solutions are rather complicated and require much attention from the driver, if not even numbers placed on the ridges to avoid doubt or errors in turning. This is why, in the United States, where the fields are extreme-

*Simplified method of continuous ploughing in ridges advised  
in the United States.*

Fig. 19. — Solution B  
of Case I.

Fig. 20. — Solution A  
of Case I, obtained  
by applying that  
method.

ly large and where the uniformity of the ridges is only of secondary importance, more simple methods are advised which might be called the system of *continuous* ploughing as the *cycle* is shortened and instead of closing, continues indefinitely.

One of these procedures, given in "*Farm Power*"; (published by the INTERNATIONAL HARVESTER COMPANY, Chicago, 1915) and reproduced in various French periodicals (such as *Le Génie Rural*, 1917, No. 66), can be applied to our Case I (ridges more than 82 ft. wide). It is shown in Fig. 19 which corresponds to our Solution B of Case I, while Fig. 20 shows the Solution A obtained by applying it.

As is shown in these figures, the first two ridges are narrower than the following ones; which might prove disadvantageous for certain crops. In

any case we submit the variants shown in Figs. 21 and 22, in which the unequal ridges are reduced to one only.

*Variants of the continuous method proposed by the author.*

Fig. 21. — Solution B of Case I (see Fig. 19).

Fig. 22. — Solution A of Case I (see Fig. 20).

But, if it was desired to employ the system of continuous ploughing, the method might be simplified still further and applied to all the cases

*Simplified continuous method proposed by the author.*

Fig. 23. — Case II: Ridges from 49 to 82 ft. wide.

Fig. 24. — Case III: Ridges from 20 to 49 ft. wide.

previously considered. In Figs. 23, 24, 25 a few examples of the application to various cases are shown.

*Simplified continuous method proposed by the author.*

Fig. 25. — Case IV: Ridges less than 29 ft. wide.

The last methods do away with the complicated manoeuvres required with the previous procedures when starting ploughing, but the idea must be abandoned of ploughing one, or, at a maximum, two zones, both at the beginning and end of ploughing. These zones would then be ploughed separately, either with the machine before commencing continuous ploughing or with a team afterwards. Again they might serve to allow the ploughs to pass to finish the work, thus replacing the side headlands.

SECOND PART  
ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION.

1068 - The Organisation of Colonial Agriculture in Indo-China and France.—CHEVALIER, A., Report presented to the *Congrès d'Agriculture coloniale organisé par l'Union coloniale française*, Government of Indo-China, Saigon Series, *Bulletin* No. 13, 64 pp. Saigon, 1918.

DEVELOPMENT  
OF  
AGRICULTURE  
IN VARIOUS  
COUNTRIES

When, in 1917, it was decided to organise a congress of colonial agriculture at Paris, the president of the congress, M. J. CHAILLEY and the organising committee asked the author (Chief of the Permanent Agricultural Mission at the Colonial Ministry) to draw up a report for the section for the study of the organisation of the colonial agriculture departments in France and the colonies. This report was to contain the observations made by the author in the course of his missions, so that the section should be informed of the organisations necessary both at home and in the colonies.

The author left for Indo-China where he was commissioned by the Governor General, M. ALBERT SARRAULT, to inspect the agricultural and forestry services with a view to giving advice for the rapid intensification of production during and after the war. It was on this instructive inspection that the author based his report to the congress. The organisation of agriculture in Indo-China and the progress made in the country since the French occupation are discussed, thus bringing to light the great efforts made by the natives and the French colonising organisation. He shows the mistakes made in the past, the early attempts of the colonists and the instability of the agricultural experiment stations. It is necessary that an end should be made of the old habits, *i. e.*, lack of coordination and perseverance. The programme drawn up by M. SARRAULT for his collaborators includes first and foremost the combination in every branch of all energies and labour for the development of the colony. Reforms are now being introduced throughout the agricultural service of Indo-China. They are given by the author in the first part of his work, entitled "*The organisation of Agriculture in Indo-China*".

[Abstract No. 1068]

If the latent wealth of a country is measured by the variety of raw materials it produces, then Indo-China must be placed among the most important of the French colonies, by reason of its mineral resources, its sea produce, forest wealth, numerous crops grown or capable of being grown. Inhabited by hard-working, intelligent and civilised races, Indo-China was already well developed economically when the French settled there. Nevertheless it is necessary to improve the agricultural methods in order to increase the yields of the crops and obtain the maximum yield from the land.

Cochin-China was fortunate in having for a long time at the head of its Botanical Service the botanist LOUIS PIERRE, who lived there for 12 years and contributed largely to the study of its crops and introduced numerous useful plants. He founded the Zoological and Botanical Garden of Saïgon in 1865, soon after the annexation of Cochin-China, and continued to direct it till 1878.

The experimental work was chiefly concerned with sugar cane, maize, rice (of which about 200 varieties were collected), Leguminosae, forage plants (teosinte and Para grass, now acclimatised), textiles (ramie, cotton, jute), tobacco, pepper, vanilla, and fruit trees. Already at that time the necessity of manuring all crops had been shown. Over 400 000 coffee plants were distributed in a few years, the first experiments in the growing of coffee on a large scale made, and several varieties introduced from Bourbon and Java. PIERRE also studied plant diseases as well as the introduction of rubber and gutta-percha plants (he discovered *Dichopsis Krantziana* in the forests of Cochin-China and Cambodia).

A list is given of the institutions in Cochin-China devoted to the development of agriculture.

In 1886 PAUL BERT founded the "*Comité d'études agricoles industrielles et commerciales du Tonkin*" (Committee for agricultural, industrial, and commercial studies of Tonkin). A school of agriculture was founded at Hanoi and made into a Botanical Garden in 1889. In 1897 an *Agricultural Board* was formed at Tonkin. M. P. DOUMER created in 1898 a *Board of Agriculture and Commerce* which, in 1901, was changed into the *Board of Agriculture, Forestry and Commerce*. Local agricultural services were installed in Annam, Cochin-China and Cambodia. In the meantime a *Forestry Service* and a *Veterinary, Zootechnical and Epizootic Service* had been organised. Mention should also be made of the establishment at Saïgon and Hanoi in 1889 of laboratories for agricultural and commercial analysis and, lately, of a Service for the repression of fraud, of the founding of the *agricultural, commercial and industrial museum* at Hanoi in 1902 and of a similar one at Hué in 1915; two others will shortly be formed at Saïgon and Cambodia. Other scientific services and institutions which are not directly concerned with agriculture but of great use to it are:— 1) *the Irrigation and Dredging Service*; 2) *Geological Service*; 3) *Meteorological Service*; 4) *library of the Far-East French School* at Hanoi; 5) *Board of higher education* (University of Indo-China); 6) *Far-East scientific mission*, which, unfortunately, was very short-lived; 7) *Pasteur Institute of Nhai-rang* and its Saïgon branch;

8) *Naval arsenal* at Saïgon, which may be used for testing materials.

To these institutions must be added, on the one hand, three societies, mostly composed of European colonists engaged in agriculture, on the other, the private societies of planters or exporters of agricultural products. The first group includes: — 1) the *Cochin-China Chamber of Agriculture*; 2) the *Chamber of Agriculture of Tonkin and North Annam*; 3) the *Mixed Consultative Chamber of Commerce and Agriculture of Cambodia*. Among the private societies may be mentioned: — 1) the *Association of Rubber Planters of Indo-China* which publishes *Les Annales des planteurs de caoutchouc*; its headquarters are at Saïgon; 2) the *Syndicate of Rice Exporters of Indo-China*.

In 1903 it was decided to establish a certain number of experiment stations in Indo-China and they were opened between 1904 and 1908. Unfortunately the *Board of Agriculture, Forestry and Commerce*, as well as the technical services depending on it, was suppressed in 1909. At the present time it is replaced by a *Service of Economic Affairs* (order of December 21, 1911). By the order of June 6, 1917, the Governor General formed a *Mission for the Inspection of Agriculture and Forests in Indo-China*.

From the first moment of his arrival in Indo-China, the Governor-General, M. SARRAULT, acting on the suggestion of the Director of the Economic Services, M. H. BRENIER, decided to form new specialised experiment stations devoted to the principal products of the country. The first, established in Cochin-China should have dealt with the selection and cultivation of rice. The war has made it impossible to realise this programme completely; nevertheless a *Rice-Selection Service* is now working the Laboratory of Saïgon and the Rice Station of Cantho. It has done useful work on the agricultural characters and commercial value of different varieties, and has introduced to the markets of the mother country "terê-ky" rice, which has been much appreciated there and the cultivation of which is spreading greatly in Western Cochin-China. According to experts, this rice may take the place of Spanish rices, which in Europe have a much greater value than those imported from Indo-China. As soon as normal conditions prevail the Cantho Station will make experiments in mechanical cultivation and other tests, in order to improve the agricultural implements and machinery at present used by the natives.

An experiment station for maize selection was established in 1914 at Tuyenquang. It has recently been transformed into a modern farm so as to experiment not only with maize, but with all the native crops of the Tonkin Delta and central district, especially those plants which might be grown in rotation with maize. An experiment station for cotton selection is now being organised in Cambodia. The formation of stations for coffee and tea growing in Tonkin and Annam is under consideration and will probably be carried out when conditions make it possible to obtain a competent staff to direct them.

The organisation described is only the first step toward the establishment of specialised stations for each kind of local crop. Finally, silkworm egg stations and model silkworm breeding centres, experimental mulberry

plantations and factories for native silk-spinning should be formed in all parts of Indo-China where they do not yet exist.

The work of the European colonists is described and stress laid on their efforts to develop the crops in the Colony. It may be said without exaggeration that the cultivation of coffee in Tonkin, Cochin-China and North Annam and that of rubber in Cochin-China and South Annam has been perfected to the same extent as in the Dutch Indies and the Malay Peninsula, where it has been practised much longer. These crops are still grown only over limited areas — 49 400 acres for rubber and 6 200 for coffee. Tea-growing also shows great promise, especially if the companies, which have already studied the question and considered making large plantations on the slopes of the Lang-biang, or in the Tourane district, turn their attention to the improving of the cultural methods and the preparation of the product.

Certain other crops are now attracting the attention of the European colonists, especially cotton, in Cambodia, coconut, oil palm (*Elaeis*), and sugar-cane in Cochin-China and Annam, and tobacco, jute, and starch plants in Annam and Tonkin.

As soon as circumstances permit, the Governor General has decided to establish an Institute for scientific research devoted to native agriculture, European enterprises, and local agricultural and forestry services, for the improvement of the industrial value of the country. This Institute will doubtless be placed in the plain of Giarai, at the foot of the volcanic mountain Nui-chua-chou (over 2 620 ft. high; and with a temperature at the summit frequently at 8° C. lower than at Saigon), three hours' distance from Saigon. This Institute will have two departments — 1) the Institute properly speaking, including laboratories, and library, on the mountain; 2) the botanical garden and experimental fields, at the foot of the mountain.

The organisation of the future Institute of Giarai which is to become the "Buitenzorg of Indo-China", is then discussed in detail, and special stress is laid on the decisions of M. SARRAULT with respect to the organisation of agricultural and forestry instruction in Indo-China. By the order of July 8, 1917, an Indo-Chinese University was founded for the higher education of colonists and natives. The instruction is to include a School of Medicine and Pharmacy, a Veterinary School, School of Agriculture and Forestry, School of Pedagogy, School of Administration and Law, a Central School with special departments for Public Works, Electricity, Commercial Chemistry, Architecture and Building, a Higher School of Navigation and Fisheries. At the same time as it was decided to establish these schools, there was organised a School of Science, affiliated to the School of Medicine of Hanoi, to prepare for the first three grades of the above mentioned schools. Practical schools of agriculture will also be formed.

The author then passes to the improvement of the social condition of the natives, the outlet for the agricultural and forestry products provided by the *Agence économique de l'Indochine* (an organ recently formed by M. SARRAULT to bring the producers of the colony into touch with the manufacturers and merchants of the home country), statistics (which are to be

drawn up by a special department of the Economic Service of the Government), the sending of supplies to France, and transport.

The second part of the report is devoted to the reforms which appear essential, in France as well, for the organisation of the Service of Colonial Agriculture. Taking as an example the work that has been done in Indo-China, it should be possible to improve the agricultural services in all the other French colonies. Most of the institutions being established in Indo-China should be established successively in all the other French possessions, leaving, of course, free scope to each to adapt these institutions to its own requirements. Since Indo-China has set the example and, thanks to its new organisation, is much more advanced than the others, it would be well if specialists leaving the Universities and large schools of France with a view to entering the colonial service were to stay a few months in the Far East colony.

At the present time there are many institutions in France cooperating in the scientific study of agriculture in the French colonies, but they are in no way connected, and have but a very limited action. In Paris and neighbourhood alone there are the following institutions supported or subsidised by the Colonial Ministry or local grants:—

- 1) The *Mission permanente d'Agriculture coloniale*, considered as the general inspection department of colonial agriculture, but possessing only a very limited staff and restricted power of action ;
- 2) the *Jardin colonial de Nogent-sur-Marne* with the *École supérieure d'Agriculture coloniale* affiliated to it ;
- 3) the *Laboratoire d'Agronomie coloniale de l'École des Hautes-Etudes*, in the Museum of Natural History, which is a branch of the permanent Mission ;
- 4) the *Laboratoire de Biologie coloniale au Muséum d'Histoire naturelle* ;
- 5) the *Laboratoire de Matière médicale de l'École supérieure de Pharmacie* ;
- 6) the *Research Service of the Colonial Office* ;
- 7) the *Maîtrise de conférences de Botanique coloniale* at the Sorbonne, etc.

In many of the large towns, Marseilles, Bordeaux, Lyons, Nancy, there are also colonial Institutes or courses which, especially at Marseilles, contribute valuable work to colonisation. It would be well to unite into one at least the most important of these institutions.

The organisation of the agricultural services of the colonies calls for the formation of a new Central Service or Service of Inspection in each of the governments, or in each of the principal independent colonies, each federated colony having its local service. The work of each service, the research of each station and laboratory should, however, be coordinated. For this reason there should be in each colonial government a head of such service, dependant on the governor, whom he should advise as to the scientific help necessary to the colony.

The functions of a scientific agricultural service in the colonies must be restricted to technical work and consist of investigations and experiments, taking into consideration the requirements of the colonists and natives, and should bring pressure to bear on them to introduce improvements.

It is necessary to organise an Agricultural Service at the Colonial Ministry to coordinate and control the research carried out in the colonies by the colonial agriculture services. This Central Service would have the general direction of the others and control their activities.

RURAL  
HYGIENE

1070 - **On the Bactericidal Action of Sunlight (Total White Light and Partial or Coloured Lights).** — DE LAROQUETTE, M., in *Annales de l'Institut Pasteur*, Year XXXII, No. 4, pp. 170-192 + 3 Figs. Paris, April, 1918.

The action of sunlight on bacteria has been considered above all as a destructive action in which chemical rays, especially ultra-violet rays, play an almost exclusive part. Numerous facts, however, especially in warm countries, where bacteria are not lacking in spite of the amount of sun, seem to show that the bactericidal action of sunlight is neither as efficient nor as constant as is generally believed, and that special conditions are required for its action.

The author sought to solve experimentally the following questions:—

- 1) To what extent has sunlight a bactericidal action in the air, in liquids and solids?
- 2) To what depth does its action penetrate under these conditions?
- 3) What intensity and duration of insolation does this action demand?
- 4) How does it act?
- 5) Is the action chemical, calorific, or desiccative?
- 6) What are the differences in this respect between the various rays of the solar spectrum?

The experiments were made at Algiers in two principal series:— from May to July, 1914, and from November to December, 1916. In the first, made in summer, the bacteria were acted on with the maximum intensity of sunlight. In the second, made in autumn, moderate intensities could be used similar to those in the north of France. In some of them white or coloured (blue, green, yellow, red) greenhouses built north-south were used. In these plants, bacteria, moulds, and various animal species were grown continually, from 1911 to 1914.

The results obtained from the various experiments were as follows:—

Prolonged, vigorous insolation greatly reduces the bacterial content of air but does not sterilise it completely. At a depth of 10 mm. under water *Bacterium coli* resisted very strong insolation for 5 hours; at a depth of 2.5 mm. it was killed, even through the glass of a closed Petri dish, by 3 or 4 hours' insolation. The *B. coli* killed in 4 hours in 20 cc. of water at a depth of 2.5 mm. had resisted for 7 hours in 40 cc. at a depth of 5 mm. Filtration of the rays through 1 cm. of water which absorbs part of the infra-red and ultra-violet did not modify the results previously obtained with the full light. Continuous cooling of the dish by ice decreased evaporation and prevented the sterilisation of the water. This shows heat to play an important part in the bactericidal action of sunlight which appears, partly, to act by evaporation. Filtration of light through glass of any colour greatly reduces its evaporation power and, at the same time, its bactericidal action. *B. coli* in broth in a 15 mm. test tube resisted strong insolation during 6 hours, but was killed in 8 hours; spread out in thin layers of 2.5 mm. it was destroyed by 4 to 5 hours' insolation; in tubes it lived in diffused

white and coloured light for 43 days. *B. Coli* on potato resisted 7 hours' strong insolation. On gelatine *B. coli* in open dishes was killed by 2 hours' insolation; under coloured glass as in the open air, it was killed by 7 hours' insolation. Under uncoloured thick glass and under a cover full of water which absorbed the greater part of the infra-red and ultra-violet rays, it was killed by 4 hours' insolation, whereas it resisted under all the coloured glasses, even the blue. When thin layers (1 mm.) of skin, fat or muscle protected the gelatine cultures of *B. coli* exposed to the sun for 5 hours they were not killed. When ice surrounded the dish, thus preventing desiccation of the gelatine and the cultures the bacteria resisted 4 hours' strong insolation, even when completely exposed. Gelatine cultures of Eberth's bacillus are killed by 2 hours' insolation; a very thin layer (about 0.5 mm.) of vaseline delays destruction for about 1 hour. Streptococci and *Staphylococcus citreus* in tubes on potato and in broth withstood 7 hours' insolation. On paper *S. citreus* lived in all the greenhouses, except that with colourless glass, for 22 days; it died in all of them, except the green and the black, in 38 days; on gelatine in tubes it resisted moderate insolation everywhere during 16 days. In gelatine tubes the cholera vibrio grew well in all lights except white, and withstood 38 hours' insolation everywhere. *Micrococcus mabittensis* on gelatine in tubes developed everywhere, except under green glass; under white it was destroyed more rapidly than under black; on broth it grew moderately in white and blue light and died soon; in red and black light it did not grow though it lived 20 days. Cultures of Hérelle's coccobacillus on gelatine and on paper grew well in all the houses, drying up and becoming sterilised in white, blue and yellow light. They resisted 38 hours' insolation in the green, red and black; on paper they were sterilised in 21 days in white, blue, green and yellow light. *Sarcina rosea* on gelatine did well in all the houses, but there was a little delay under black. Grape yeasts on gelatine in plates gave good cultures which developed quickly everywhere; they were stopped twice out of 6 times and modified 4 out of 6 times in white light (desiccation of colonies and medium); continuously in the other lights the cultures are a little flattened after the 10th day, especially in white and blue light; the yeasts were alive everywhere at the end of 38 days except in 2 out of 6 in the white light. In tubes of must fermentation was intense everywhere, but slightly hastened by light, especially white; the yeasts were alive in all the tubes after 38 days. The paper was sterilised in 21 days in white, blue and yellow light; and in 38 days in all the glass houses. Yeasts appear to be especially subject to desiccation.

CONCLUSIONS. — Sunlight is only bactericidal with prolonged or direct isolation; it acts particularly on the surface of dry media and in air where bacteria are more exposed to sun rays and desiccation. In liquid media the bacteria are only destroyed when the light is very intense and at shallow depths. Total white light is much more active than any partially coloured light. Diffused light is insufficient. Blue light is slightly more bactericidal than other coloured lights, but much less so than white light; yellow comes next, then red and, lastly, green which, for bacteria as for plants is most closely related to black.

The most active part of the solar spectrum is the luminous part; ultra-violet has a slight action in the bactericidal effect of sunlight; filtration through a thick glass which absorbs most of the solar ultra-violet did not perceptibly diminish these effects. The same applies to infra-red; filtration of sunlight through water did not inhibit its bactericidal action. Nevertheless heat plays a certain part; cooling with ice during insolation delayed the death of the bacteria and the desiccation of the medium.

The bactericidal power of the rays appears to be connected both with their chemical action and their dehydrating action (on the protoplasm and culture medium) and, the author believes, more particularly to the latter, which, however, is not exclusive, since it cannot act efficiently in liquid or strongly hydrated media. In this case it would be due to a kind of kinetic shock or poisoning by excessive energy.

Finally the death of bacteria exposed to the sun seems to be caused by too great an absorption of energy, of which the first effect is usually dehydration and coagulation of the protoplasm. As it is only the energy absorbed which acts, the so-called chemical rays with the shortest waves are most active on the surface, probably because they are most largely absorbed by the bacteria and media. At a depth, however, the more penetrating calorific rays are more efficient, but can produce no bactericidal effects because of their progressive filtration and slight density. Moreover, all rays, like all forms of energy, are destructive or beneficial for living protoplasm, and consequently for bacteria, according to the quantity absorbed, and there is no specific action properly speaking. In the bactericidal effect exposure to the air which usually accompanies exposure to the sun must also be taken into consideration as it contributes very largely to the desiccation of the bacteria and media.

In practice, both in hygiene and therapeutics, it would be useless to rely largely on the bactericidal action of sunlight, especially in temperate districts, as it has no effect at a depth exceeding a few millimetres and is inhibited by thin layers of fat or muscle.

**1071 - Researches, from the Standpoint of Food Hygiene, on the Ganglionic and Muscular Virulence of Macroscopically Healthy Organs in Generalised Bovine and Swine Tuberculosis.**—CHAUSSE, P., in the *Annales de l'Institut Pasteur*, Year XXXI, No. 1, pp. 1-18 + 4 Tables + Bibliography of 29 Publications. Paris, 1917.

When discussing the historical aspect of the question the author remarks that no value whatever should be attributed to those researches carried out by ingestion; he has found that even the guinea-pig readily resists the ingestion of several million, very virulent bacteria and a still stronger quantity of virus if this consists of coarsely ground bovine tubercle material. He also finds that researches by inoculation are insufficiently searching for several reasons and faults of technique. Three "historical" tables show, with the results obtained, all tests of the virulence of muscle and ganglions, whether by inoculation or by ingestion.

The author attempted to throw light on the question of ganglionic and muscular virulence as regards food hygiene by acting as follows:—60 samples (18 pigs and 42 cattle slaughtered for food and seized for gene-

ralised tuberculosis) were inoculated subcutaneously into guinea-pigs (3.5 subjects for each inoculation) *in the form of muscle juice* and also *in the form of tissue fragments*. The guinea-pigs were killed 45 days after inoculation and in no post mortem examination was tuberculosis found.

The ganglia of the seized animals are rarely attacked in a visible manner; many are of quite normal aspect and the author tried to find whether the macroscopically healthy ganglia are virulent. The extra-visceral ganglia removed were arranged in symmetrical pairs (*e. g.*, 2 popliteal, 2 crural, etc.); the juice and pulp were inoculated subcutaneously into guinea-pigs. Virulence was found: —

a) for the 9 pairs of ganglia from the pig, *twice*, in each positive case, with 3 tuberculous guinea-pigs out of 3 survivors;

b) for the 44 pairs of ganglia from the cow, *11 times*, with, in these cases, 100 % of tuberculous guinea-pigs and, in other cases, the half or two-thirds.

CONCLUSIONS. — 1) From the 60 negative results obtained in the muscle tests, this tissue is not virulent practically; in consequence the consumption of muscle, even when raw, of subjects affected with generalised lesions, has no appreciable danger.

2) The consumption of macroscopically healthy lymphatic ganglia is not without danger when they are insufficiently cooked.

The law is therefore right, in allowing the consumption of meat from tuberculous animals after sterilisation and removal of the ganglia. But, notwithstanding scientific evidence the sale of such meat at low prices after sterilisation is against popular opinion and, in normal times, the greater part of such meat is lost. The author therefore suggests as a remedy that the State should buy such meat at a low price and preserve it, for use in penitentiary establishments.

1072 — **Rice and the Chemistry of Food.** — GUARESCHI, I., in *Annali della R. Accademia d'Agricoltura di Torino*, Vol. LX, 1917, pp. 41-77. Turin, 1918.

Rice is a more nourishing cereal than supposed and richer in albuminoids than indicated by the old analyses. The substances hitherto found in "riso svestito" (hulled rice, *i.e.* freed from its glumelles but not decorticated) are: —

*Water*; *nitrogenous matter* (albuminoids), globulin, edestine, or phytovitelline, glutenin or gluten-casein, gluten-fibrin; *vitamines*, in the external layers; *ferments*, lipases, cytases, diastases; *carbohydrates*, starch, fibre, hemicellulose, arabinoxylane, xylane ( $C_5H_8O_4$ ), sugar, gum; *fat*, (riceoil), free oleic acid, glycerides of arachic, behenic or lignoceric acids; *phosphatides*, phytin or salt (Ca, Mg) of anhydro-oxi-methylene-di-phosphoric acid; *minerals*, especially potassium phosphate with magnesium phosphate, etc.

The average composition per cent. of good hulled rice is: —

Moisture 13.17, nitrogen 8.13, fats 1.29, nitrogen-free extract 75.5, crude fibre 0.88, ash 1.03.

All the chemical elements contained in rice are suitable as food. The nitrogen content may reach, or even exceed, 9 %; Piedmontese rice is

superior to rice from India, Japan and Java in this. The albuminoids of rice, are included in the so-called whole albuminoids because the products of their hydrolysis include phenylalanine, tyrosine and tryptophane.

The most important substances and those which have a beneficial influence on the nutrition of the nervous system are found especially, and in some cases exclusively, in the pericarp or external coat of the grain. They are vitamins, phosphates of potash and magnesium, phosphatides, and ferments.

From 100 lb. of "riso vestito" or "risone" (paddy) are obtained: — 75-80 lb. of "riso svestito", "sbramato" or "bruno" (hulled rice), 65 lb. of "riso bianco mercantile" (white commercial rice), 62 lb. of "riso camolino" or "levigato" (polished rice), 59 lb. of "riso brillato" (coated rice), 55 lb. of "riso brillato stella" or "perla" (fancy head). From 20 to 25 lb. are, therefore, lost and can be used only as a food for live stock.

The by-products from the decortication of rice (pula) contain no phosphates, but there is much phosphoric acid in the by-products from the decortication and polishing of rice. They contain, moreover, all the vitamins. Polished rice contains no vitamins, the organic compounds of an alkaloid nature necessary to animal life. Polished rice, even when eaten with other nutritious foods more or less rich in vitamins, will always be inferior to rice which has been prepared little.

The people of the districts of Novara, Vercelli, Cremona, etc., who live largely on unpolished rice, thrive well on it, but this would certainly not be so with polished rice because excessive polishing (an almost modern operation) lowers the food value of rice. Asiatic peoples, who have used unpolished rice as their principal food since remote times do not suffer from the special diseases caused by under-nutrition. It is in those places where polished rice has been introduced that special diseases, particularly beri-beri which previously occurred rarely, have developed. Investigations made from 1896 to 1914 have shown that polished rice eaten with or without other foods, can produce serious diseases due to under-nutrition, especially in the nervous system, and that even with really nutritious foods, it will always be inferior to rice in the most natural state.

The author refers to the investigations made by English and American chemists and physiologists into diseases caused by the continual use of decorticated cereals, especially beri-beri (polyneuritis) caused by decorticated rice and particularly by polished rice, *i. e.* rice completely deprived of its outer layers. Photographs are given of hens fed on white or polished rice. In a short time the birds contract polyneuritis and die, whereas others fed on undecorticated rice, do very well. Attention is drawn to the work of C. Funk who, in 1912, isolated from rice bran a vitamin which rapidly cures, and even prevents beri-beri (1).

From all points of view, chemical, physiological, economical, the use of rice prepared excessively, and especially polished, should be absolutely abolished. It is said that polishing is necessary for keeping rice and making it fit for transport, etc. The rice kept for over a century and analysed

(1) As regards vitamins, polyneuritis, etc., see R. Aug., 1918, Nos. 833, 824 and 835; R. July, 1918, No. 719 with the note. (Ed.)

by BALLAND was, however, not polished rice, nor is that which comes to Europe from very distant countries. The rice imported into Europe is paddy and partially prepared rice, such as exported by Italy, polished rice ("rafinato" or "camolino") cannot stand journeys.

In healthy and rational feeding unpolished rice and rice prepared to a slight extent only should be used as polishing is opposed to all the scientific and practical laws of feeding.

1073 - **Coffee Substitutes Made with Lupin (1) and their Disadvantages.** — ECKENROTH, H (National Institute of Hygiene, Lodz), in *Zeitschrift für Untersuchung der Nahrungs- und Genussmittel*, Vol. VI, No. 35, pp. 240-242. Münster, 1918.

At the present day coffee substitutes containing as much as 50 % of lupins are being used in Germany. The infusion made from these substitutes has an exceeding bitter flavour, difficult to improve by the addition of sugar or milk. This proves that the toxic substance contained in the lupins (lupinin) has not been removed. Roasting is not sufficient to eliminate this substance, although some workers maintain it is, and recent investigations (BRAUER and LOESNER) show that lupins if inefficiently treated and consumed as in these substitutes can cause illness and must be considered as unfit for human consumption. For this reason the measures already taken in Austria to prohibit the use of lupins as a food should be adopted everywhere unless there is sufficient guarantee that the requisite preliminary treatment has been carried out.

1074 - **The Antiseptic Value of Some Essential Oils.** — CAVEL, L., in *Comptes Rendus des Séances de l'Académie des Sciences*, Vol. CLXVI, No. 20, pp. 827-829. Paris, May 21, 1918.

The author classified a certain number of essential oils according to their antiseptic value, by determining for each the minimum quantity necessary to prevent all bacterial growth in ordinary neutralised meat broth plentifully sprinkled with water from a septic source. The inhibiting quantity of phenol under the same experimental conditions being 5.6 ‰ the author obtained the following classification for essential oils according to the quantity required to inhibit growth:—

Thyme 0.7 ‰; marjoram 1.0; orange-peel oil 1.2; verbena 1.6; cassia 1.7; rose 1.8; clove 2.0, eucalyptus 2.25; mint 2.5; geranium (Rose de France) 2.5; vetiver 2.7; bitter almond 2.8; gaultheria 3.0; geranium (Indian) 3.1; winter-green 3.2; meadowsweet 3.3; spike-lavender 3.5; aniseed tree 3.7; iris 3.8; common cinnamon 4.0; wild thyme 4.0; birch 4.8; anise 4.2; mustard 4.2; rosemary 4.3; cumin 4.5; neroli 4.75; lavender 5; balm 5.2; ylang-ylang 5.6; juniper 6.0; sweet fennel 6.5; reseda 6.5; garlic 6.5; lemon 7.0; cajeput 7.2; saffrafr 7.5; heliotrope 8.0; cedrate 8.4; turpentine 8.6; parsley 8.8; violet 9.0; camphor 10.0; angelica 10.0; patchouly 15.0.

Seven months after inoculation the culture plates were still sterile when the above quantities were used.

EXPERIMENTAL  
AND  
ANALYTICAL  
WORK

1075 - Recent Investigations at the Imperial Institute (1). — *Bulletin of the Imperial Institute*, Vol. XV, No. 3, pp. 297-334, 333-440. London, July-September, 1917.

AGRICULTURAL PRODUCTS OF CYPRUS (2). — Cyprus is essentially an agricultural country and most of its exports consist in products of the soil. In 1915 the quantities of the most important products were:— wheat 1 750 000 bushels, barley 1 900 000 bushels, oats 375 000 bushels, cotton 23 982 cwt., silk cocoons 651 207 lb., olives 59 756 cwt., grapes 479 719 cwt., carobs 245 914 cwt., pomegranates 115 396 cwt. The exports also include oranges, lemons, wool, hides, etc. The Agricultural Department was re-organised in 1913. There are an agricultural school, summer vacation courses for school masters, and travelling instructors. The Agricultural Department has undertaken experiments with new crops, especially fodders and foodstuffs (of these last rye and lucerne are now being grown by the farmers), the introduction of new varieties of tobacco and cotton, the improvement of vine and olive cultivation, silkworm breeding, bee-keeping, and methods of controlling insect pests and fungoid diseases, etc.

At the Agricultural Stations of Nicosia, Ashia and Akaki the Allen's Improved Long Staple, Mebane's Early Triumph, and Sakellarides varieties of cotton have been cultivated and, in addition, the New Orleans variety, grown to a fair extent in Cyprus, was also cultivated at Nicosia. At these stations, the highest yields were obtained with Triumph, which gave 271 lb. of lint per acre at Nicosia and 373 lb. at the two other stations; this variety was also the earliest. Samples of Allen's Improved and Mebane's Triumph were examined at the Imperial Institute and gave good results.
